Level V	Posterior triangle nodes. Bounded by the junction of the trapezius and SCM superiorly, the posterior border of the SCM anteriorly, the clavicle inferiorly, and the anterior border of the trapezius laterally. Subdivided into VA and VB by the plane of the inferior border of the cricoid cartilage.	Nasopharynx, oropharynx, thyroid, cutaneous structures of scalp and neck, breast.
Level VI	Also known as the central compartment. Pretracheal, precricoid (Delphian), paratracheal nodes, and parathyroidal nodes. Bounded by the hyoid bone superiorly, the carotid sheath laterally, and the sternum inferiorly.	Thyroid, glottic and subglottic larynx, piriform sinus, cervical esophagus.
Level VII (variably defined)	This level is variably defined and is the substernal extension of level VI to the level of the innominate artery.	Similar to level VI.

SCM, Sternocleidomastoid muscle.

FNA typically can be performed on an outpatient basis. Because multiple passes should be taken, the use of local anesthetic is suggested. If manual palpation guidance is used, the mass should be transfixed between the thumb and forefinger of the nondominant hand. If ultrasound scan is used, a 12.5-MHz probe is appropriate in most cases (Figure 4). The needle should be passed along the long axis of the probe at an oblique angle so that the entire needle course can be imaged in real time. Needle guides are available with some ultrasound equipment and may be used if desired. A 22-gauge to 25-gauge needle is affixed to a 10-mL syringe with several milliliters of air already in the syringe. The syringe may be placed in a special control handle, but this is not required. The mass should be entered with negative pressure on the syringe. Three to four aspirates should be made per pass, and multiple angled passes should be made to ensure adequate sampling. Suction on the syringe plunger should be relieved before exiting the mass to avoid aspiration of the sample into the body of the syringe. The syringe is then removed from the needle, filled with air, and placed back on the needle. The specimen is then expelled from the needle onto a glass slide. The slide containing the specimen is immediately smeared with another slide. The specimen is then promptly placed in formalin or ethanol to prevent desiccation. The presence of a cytologist for immediate review of the slides helps ensure that adequate specimen is achieved and increases diagnostic yield.

If initial FNA biopsy results are nondiagnostic, the surgeon should communicate with the pathologist to determine whether the specimen is inadequate or whether a different type of biopsy is needed. If inadequate biopsy is the problem, then repeat FNA with ultrasound guidance and immediate cytopathology review is indicated.

FNA biopsy provides the cytopathologist with the opportunity to comment on abnormalities at the cellular level but with minimal ability to comment on architectural characteristics. This may render specific diagnosis impossible, which is particularly a challenge for lymphoma and follicular thyroid cancer. In situations in which FNA biopsy is inadequate, core needle biopsy provides a small "plug" of tissue with some preservation of architectural features. A conversation with the pathologist familiar with the case is the best approach to ascertain if a core needle biopsy is expected to be helpful beyond an FNA and therefore worth the slightly increased risk of hematoma or other injury. Core biopsy also typically should be performed with real-time ultrasound guidance. If lymphoma is suspected, this should be communicated to the pathologist to ensure appropriate specimen handling, including sending the specimen unfixed.

Excisional biopsy may be necessary in a minority of cases, roughly 10% of those with malignant neck mass. Advantages include excellent tissue acquisition for pathologic analysis and the potential of therapeutic benefit in some cases. Disadvantages include cosmesis;

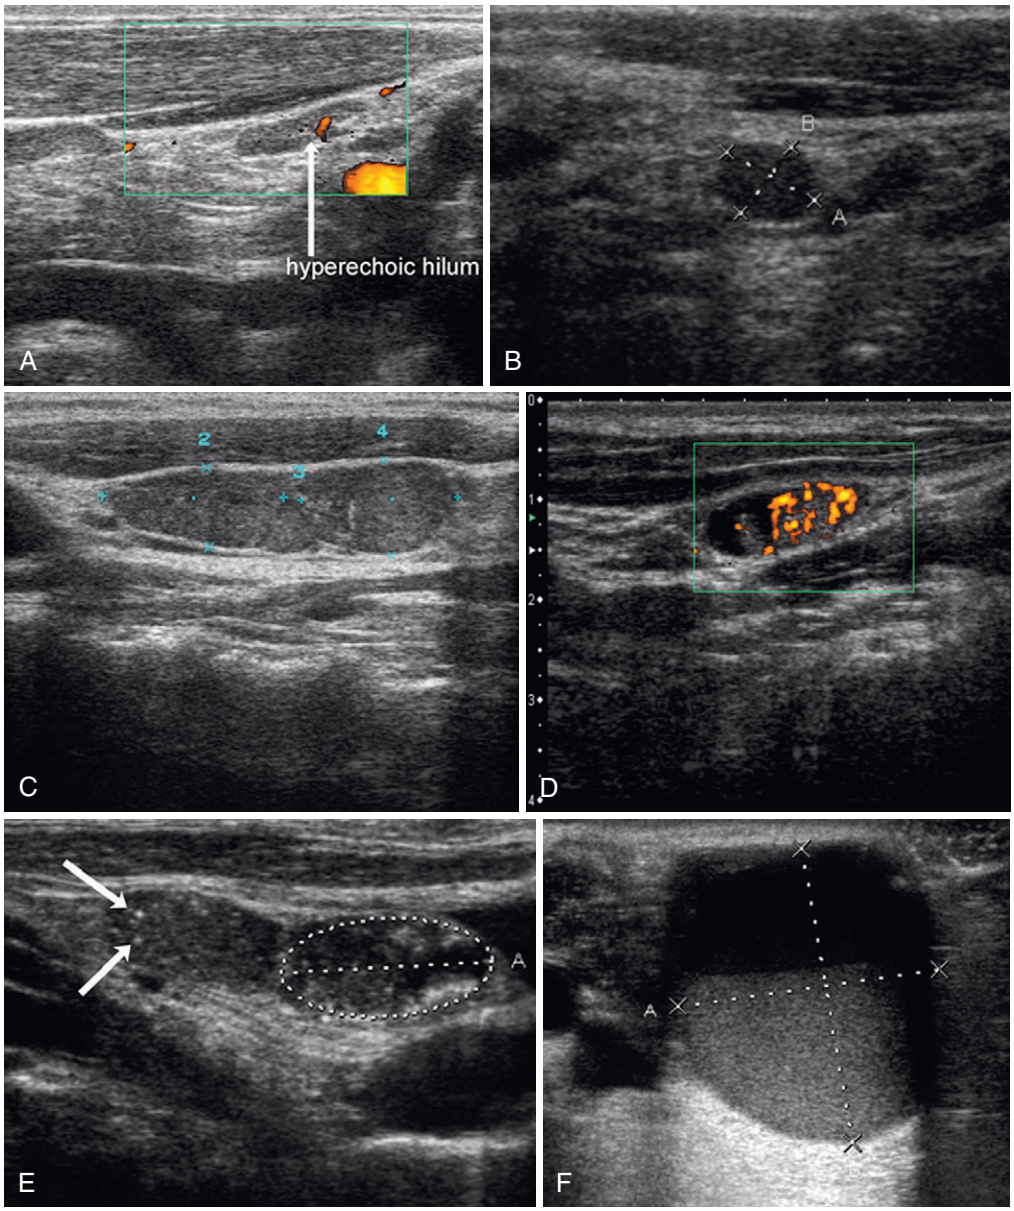

FIGURE 3 **A,** Benign lymph node shows hyperechoic hilum. **B,** Malignancy rounded and hyperechoic lymph node. **C,** Malignant lymph node with loss of hyperechoic fatty hilum. **D,** Malignant lymph node with peripheral and central vascularization. **E,** Malignant lymph node with hyperechoic punctuate calcifications. **F,** Malignant lymph node with cystic degeneration. *(From Leboulleux S, Girard E, Rose M, et al: Ultrasound criteria of malignancy for cervical lymph nodes in patients followed up for differentiated thyroid cancer,* J Clin Endocrinol Metab *92(9):3590-3594, 2007.)*

potential poor wound healing, particularly if therapeutic radiation may ensue; potential spread of disease; need for anesthetic; risk of surgical complication, such as nerve injury; and creation of a reoperative field if subsequent compartment-based dissection proves necessary. With the excellent success of FNA in diagnosis of squamous cell cancer, open biopsy should very rarely be necessary. Not only does it expose the patient to anesthetic and procedural risks, but it may worsen the prognosis and increase the local failure rate. If squamous cell cancers remain a possibility and an excisional biopsy is planned, the surgeon should discuss proceeding directly to formal compartment-oriented neck dissection with the same anesthetic if squamous cell carcinoma ultimately is identified. Obviously, a thorough examination for a primary malignancy should be completed before this approach; this should be a rare event given the utility of FNA.

Although most thyroid masses are benign, a thorough and thoughtful evaluation of thyroid nodules should be pursued. This workup is detailed elsewhere in this text, but FNA also plays a prominent role for thyroid lesions and is particularly effective in diagnosis of papillary thyroid cancer. On occasion, a biopsy of a lateral neck mass shows thyroid follicular cells in a patient without known thyroid disease. This finding should be considered an indication for a primary thyroid malignancy within the thyroid, most often a papillary thyroid cancer. The concept of benign embryologic rests of thyroid cells in the lateral neck, or lateral aberrant thyroid, has largely been disproved.

Carotid body paragangliomas typically can be diagnosed on the basis of classic imaging features on CT/CTA, MRI, or angiogram, including splaying of the internal and external carotid arteries. These lesions are highly vascular. Biopsy of carotid body tumors is not needed and should be discouraged.

Endoscopy and Biopsy

When FNA of a neck mass reveals squamous cell cancer, the surgeon must seek the primary lesion. As previously reviewed, the nodal level may direct the initial evaluation. A thorough history and physical examination, including mirror examination or flexible fiberoptic laryngoscopy, should be completed. Initial imaging consists of CT scan of the neck, which results in identification of a primary malignancy in 20% of cases. Chest imaging (plain x-ray or CT scan) aids

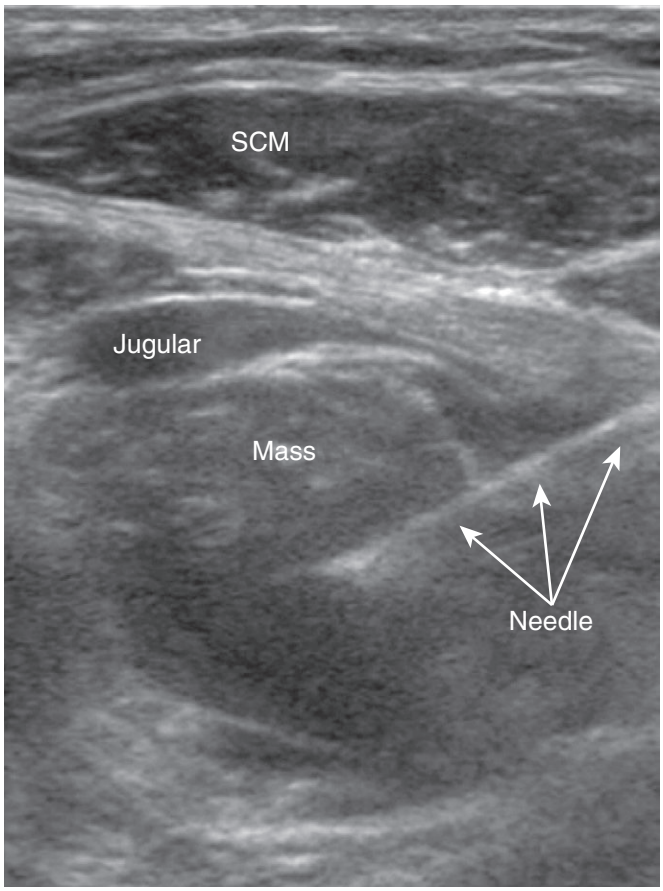

FIGURE 4 Ultrasound-guided fine-needle aspiration biopsy of a neck mass lying posterior to the jugular vein. This biopsy was performed with a 22-gauge needle and confirmed metastatic papillary thyroid cancer. *SCM,* Sternocleidomastoid muscle.

in the search and is particularly useful for lower neck nodal disease. PET may be a useful secondary imaging study. If PET is used as part of the diagnostic approach, it should be completed before endoscopy and biopsy both to aid in targeting the evaluation and to prevent false-positive PET findings from recently manipulated tissue.

When the primary tumor site remains occult after these studies, panendoscopy and biopsy should follow. Panendoscopy includes laryngoscopy, bronchoscopy, and esophagoscopy. If a primary tumor still is not identified, then at the same setting, biopsies should be performed. If the tonsils are still present, ipsilateral tonsillectomy should be performed; tonsils are found to be the primary source in 20% to 40% of these patients. Bilateral tonsillectomy also is a reasonable, but if this is not performed, then the contralateral tonsil should at least be biopsied. Directed biopsies also should be performed of the nasopharynx, hypopharynx, tongue base, and piriform sinus. Special attention should be paid to any area that was at all suspicious on the imaging evaluation.

SURGICAL CONSIDERATIONS

Anesthesia and Airway Considerations

Many neck masses feel superficial on examination but can be misleading. Neck masses usually lie deep to the platysma, and major neurovascular structures are in the operative field. Local anesthetic can impair motor response of nerves at risk. Therefore, most neck mass surgical biopsies or excisions are performed with general anesthetic, typically via orotracheal intubation. Although neck masses may commonly displace structures, including the airway, a standard intubation usually can be achieved; however, skilled anesthesiologists and the availability of adjuncts such as the difficult airway cart are important. In cases in which clinical or radiographic evaluation suggests significant airway compromise or distortion, communication with the anesthesiologist is imperative. Awake fiberoptic intubation or other strategies may be used. If the airway is markedly compromised, a planned tracheotomy may be appropriate and should be performed before extremis develops. Communication again is important regarding avoidance of long-acting paralytics to permit monitoring of motor nerve response.

Incisions

Transverse skin incisions that are preferentially placed in a preexisting skin crease are preferred for optimal cosmetic results. When possible, the incision should be placed along the same line as would be used if a subsequent more radical procedure, such as neck dissection, followed the initial procedure. If a small incision is initially used and a need for more exposure occurs, neck incisions can be widened with either transverse or oblique extensions (e.g., along the anterior border of SCM) for better visibility. Although cosmesis is important, it is more important to have adequate exposure to identify anatomic landmarks and protect vessels and nerves.

Potential Nerve Injuries

Neurologic injury may occur with both diagnostic and therapeutic interventions. An understanding of the anatomy is essential to minimize the rate of injury, as is discussion of all potential temporary dysfunction or permanent injury with the patient before intervention. Low-energy nerve-stimulating devices may aid in identification of motor nerves in the course of dissection but cannot substitute for knowledge of anatomy and meticulous technique. Among the most frequently at risk and commonly injured nerves in the neck are the spinal accessory nerve (CN XI) and the marginal mandibular branch of the facial nerve (CN VII). Both injuries cause significant morbidity.

The marginal branch of CN VII is at risk below the body of the mandible. It courses from the main trunk of the nerve in the parotid gland over the body of the mandible (at the area of the facial artery) onto the fascia of the submandibular gland, deep to the platysma. The nerve then courses superiorly to cross over the mandible and ultimately becomes more superficial to the level of the platysma and innervates the depressors of the lower lip. The nerve thus lies below the inferior aspect of the mandible for several centimeters. Avoiding the region of the body of the mandible can minimize chances of injury to this nerve. To avoid injury to this nerve, which may be diminutive in size, incisions should be made at least two fingerbreadths below the inferior edge of the body of the mandible. In dissection of the submandibular region, the fascia of the gland should be elevated with the skin flap and the facial vein should be isolated and divided low. Dissection should proceed bluntly, spreading in the expected direction of the nerve.

The vagus nerve (CN X) descends within the carotid sheath, typically posterior to the vascular structures. Unlike division of the vagus in the chest or abdomen, a vagal injury or sacrifice in the neck carries the added morbidity of creating an ipsilateral vocal fold paralysis and atrophy of the vocal fold. This occurs because the recurrent laryngeal nerve has not branched from the vagus nerve until after the latter has descended from the neck. If a vagus nerve injury occurs, neurorrhaphy is not expected to restore normal function but may help to prevent atrophy of the vocal cord, which improves the functional

result of subsequent vocal cord medialization procedures. In the right neck, the potential exists for a nonrecurrent laryngeal nerve that courses directly medially from the vagus. This aberrant nerve may course with the superior thyroid artery or more inferiorly. Nonrecurrent right laryngeal nerves occur in the setting of an aberrant right subclavian artery, arteria lusoria, and could be injured in the carotid sheath or central compartment if not recognized.

The spinal accessory nerve (CN XI) is at risk for surgical injury in cervical levels II and V. It exits the jugular foramen together with the vagus and glossopharyngeal nerves and courses inferior laterally deep to the posterior belly of the digastric. It passes either superficial or deep to the internal jugular vein. It gives off branches to the SCM and passes either through or deep to the SCM into the posterior triangle. It exits the posterior border of the SCM at approximately the junction of the upper and middle third of the posterior border of the SCM, typically 5 to 8 cm from the mastoid tip. This is approximately 1 cm cephalad to Erb's point, where cutaneous nerves including the greater auricular nerve can be found at the posterior border of the SCM. CN XI then runs superficially, overlying the levator scapula muscle in the posterior triangle to the trapezius and crosses, and may connect with branches of the cervical plexus in its course. It frequently has a meandering course in level V, and the absence of a defined platysma in the posterior triangle renders it even more susceptible to injury.

The hypoglossal nerve (CN XII) provides motor innervation to the tongue. It traverses levels I and II. It descends between the internal jugular vein and the carotid artery and then courses medially. It runs deep to the posterior belly of the digastric muscle, where is it surrounded by the ranine veins. Injuries to this nerve may occur during attempts to control bleeding from these veins.

Other Potential Complications

Although these procedures are usually clean, wound infection sometimes occurs and may be related to the smoking and nutritional status of the patient or irradiated tissue. Chyle leak also may occur and is most likely with procedures in the left level IV. The thoracic duct runs deep to the carotid artery low in the left neck and empties into the internal jugular vein deep to its junction with the subclavian vein. All tissue divided in this area lying between the phrenic and vagus nerves should be carefully ligated. When they occur, chyle leaks are initially managed conservatively with a low-fat diet and medium chain triglyceride diet. High-volume or persistent leaks occasionally require reoperation for definitive repair, which usually is accomplished with the placement of Weck clips once the leak is identified and isolated from other structures.

Hand Infections

Derek L. Masden, MD, and
Christopher L. Forthman, MD

INTRODUCTION

Hand infections are common and are often managed by a wide range of medical professionals. These infections can range from isolated and simple to complex with great potential for extensive damage, particularly in select patient populations such as diabetics and the immunocompromised. Early recognition of these infections with implementation of treatment is imperative to avoid more complex sequelae and tissue destruction. As with most infections, antibiotic therapy has a central role, but if there is more than just superficial cellulitis, these infections often require surgical therapy for complete eradication (Table 1).

Any patient presenting with a possible hand infection should undergo a thorough history and complete hand examination, including neurovascular status and evaluation of motion. In addition, specific attention should be paid to hand and finger posture, swelling, skin changes, and focal pain and tenderness, and an examination should be made both proximal and distal to the area of concern. Comparison should be made between both the adjacent nonaffected tissue (for example, the other fingers) and the contralateral hand.

Hand x-rays should be performed to evaluate for skeletal abnormalities such as bony destruction, to determine the presence of any gas formed by bacteria, and to rule out a foreign body. Routine lab studies including a complete blood count, erythrocyte sedimentation rate, and C-reactive protein may be performed. The physician should be reminded that often lab studies may be indeterminate, and clinical judgment will ultimately decide which patients require surgical intervention regardless of specific lab results. When possible, cultures should be taken to help tailor antibiotic coverage.

MICROBIOLOGY

By far the most common pathogen cultured in hand infections is *Staphylococcus aureus,* accounting for up to 80% of hand infections in some series. Anaerobes or mixed flora typically make up the remainder of the cultures and are more common in select patient groups such as diabetics and the immunocompromised (such as those with human immunodeficiency virus). Human bites often contain oral flora such as *Eikenella corrodens,* whereas dog and cat bites may contain *Pasturella multocida*. Cat scratches may be associated with *Bartonella henselae* and be associated with regional lymphadenopathy. Infections resulting from interactions with marine animals may contain *Vibrio* species or *Mycobacterium marinum*.

Methicillin-Resistant *Staphylococcus Aureus*

The rate of methicillin resistance in *Staphylococcus aureus* hand infections ranges from 34% to 78%. Community acquired methicillin-resistant *Staphylococcus aureus* (MRSA) infections are becoming more common, and these patients often experience a delay in appropriate antibiotic treatment. In many communities, empiric coverage for MRSA may be warranted in the patient presenting with a hand infection (Figure 1).

TABLE 1: General recommendations for hand infections

Infection	Likely organism(s)	Initial antibiotic therapy*	Surgical therapy
Cellulitis	*Staphylococcus* or *Streptococcus*	Cephalexin. Use clindamycin or trimethoprim/sulfamethoxazole (Bactrim) for suspected MRSA.	Only indicated for associated abscess
Abscess	*Staphylococcus*	Vancomycin. Add piperacillin/tazobactam (Zosyn) for diabetic/immunocompromised patients.	Immediate drainage (no closure), soaks and motion the day after surgery
Flexor tenosynovitis	*Staphylococcus,* anaerobes, polymicrobial	Ampicillin/sulbactam (Unasyn). Replace Unasyn with Zosyn for diabetic/immunocompromised patient and add vancomycin if possible MRSA.	Consider 12-24 hours observation for early signs; otherwise, drainage of flexor sheath (no closure), soaks, and motion the day after surgery
Septic arthritis	*Staphylococcus*	Vancomycin. Add ceftriaxone if *Neisseria gonorrhoeae* is suspected.	Immediate drainage (no closure), soaks, and motion the day after surgery
Animal bite	*Pasteurella multocida* is classic, but staph, strep, and anaerobes are common	Unasyn or PO equivalent. If penicillin allergic, then consider fluoroquinolone and clindamycin.	Clean thoroughly in ER and observe closely for signs of a deep infection. Cat teeth inoculate the deep tissues, so consider incising the puncture site to facilitate drainage. Dog teeth tear local tissues and will usually drain spontaneously.
Human bite	*Eikenella corrodens* is classic, but staph, strep, and anaerobes are common	Unasyn or PO equivalent. If penicillin allergic, then consider fluoroquinolone and clindamycin.	Clean thoroughly in ER and observe closely for signs of a deep infection (e.g., abscess, FTS, etc.). "Fight bites" require immediate drainage, even in the absence of overt infection.
Necrotizing fasciitis	*Streptococcus* or *polymicrobial*	Vancomycin *and* clindamycin *and* piperacillin/tazobactam (Zosyn)	Emergent radical débridement(s), hemodynamic monitoring, possible amputation
Gas gangrene	*Clostridium perfringines, Strep pyogenes, Staph aureus, Vibrio vulnificus*, polymicrobial	Vancomycin *and* clindamycin *and* piperacillin/tazobactam (Zosyn). Consider high-dose penicillin.	Emergent radical débridement(s), hemodynamic monitoring, possible amputation

*Antibiotic coverage should be adjusted once cultures are back to decrease the creation of antibiotic-resistant organisms and to minimize drug side effects to the patient.

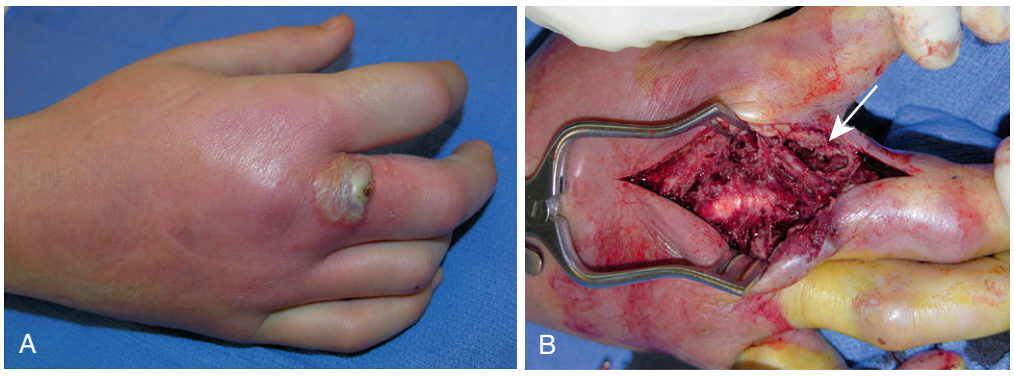

FIGURE 1 **A,** MRSA abscess. The red, swollen region with central necrosis or "spider-bite appearance" is typical. **B,** Infection has entered the webspace *(arrow)*, a "collar-button" abscess, and will require a palmar incision for adequate drainage.

The Diabetic and Immunocompromised Hand

The rising population of diabetic and immunocompromised patients mandates that physicians be aware of the rapid downward course they may encounter once these patients are infected. These patients may develop polymicrobial abscesses or abscesses with especially virulent bacteria such as pseudomonas or other Gram negatives. This fact should be considered when choosing antibiotic coverage. Additionally, infection spread can be rapid in this patient population, leading to challenges in treatment and greater morbidity and mortality. Even the simplest infections can lead to devastating complications and impairment in these individuals. These factors necessitate swift evaluation and require a low threshold for surgical exploration to prevent progressive tissue damage.

Bite Wounds

Bite wounds, most commonly from domesticated pets or other humans, are a significant contributor to hand infections. With the vast amount of bacteria found in the animal or human mouth, these wounds have the propensity to produce serious infections that, if left untreated, may have serious consequences. There are approximately 2 million cases of animal bite wounds every year, accounting for 1% of emergency room visits each year in the United States. Although the vast majority of these bites are from dogs, only a small amount of dog bites result in infection, in part due to the destructive nature of canine teeth, which usually leave open wounds. In contrast, cat bites more frequently become infected because feline teeth cause small puncture wounds that can inoculate the deeper structures of the upper extremity. These small puncture-type wounds can be the source of a flexor tenosynovitis, dorsal abscesses, or other deep hand infections.

Human "bites" are more often associated with an altercation that involves a direct blow to a person's mouth with a hand. The so-called "fight bite" can result in septic arthritis if the injury inoculates bacteria into an underlying joint. Septic arthritis presents as a swollen joint that is painful with limited motion. Similar to other hand infections, *Staph* is the most common organism, although other flora may be present, particularly if related to a bite wound. If the diagnosis is in doubt, the joint may be aspirated and the fluid sent for white count and Gram stain. Suspected septic arthritis, particularly after a "fight bite," requires immediate surgical drainage aimed at preventing damage to the articular cartilage (Figure 2).

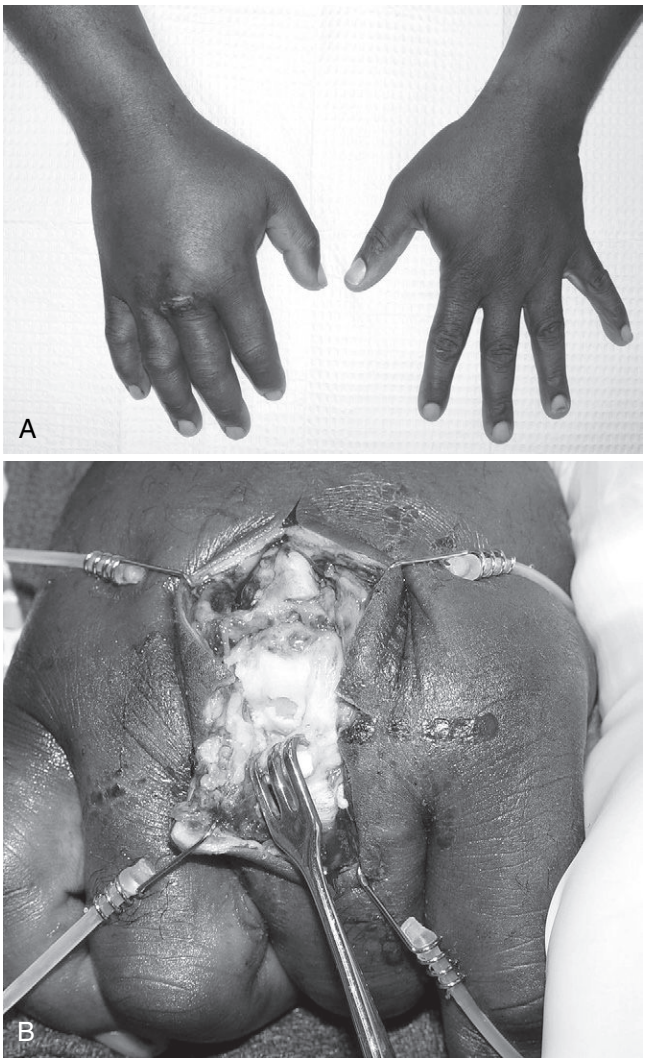

FIGURE 2 **A,** Human bite to the metacarpophalangeal joint of the right long finger following a fight. **B,** Surgery revealed a complete laceration of the extensor digitorum communis, violation of the joint space, and damage to the articular cartilage.

FINGER INFECTIONS

Many finger infections that require surgical drainage can be treated under local anesthesia using a digital block. Care should be taken to critically evaluate the patient to be certain that the infection is localized to only the finger and that a more proximal infection (such as a flexor tenosynovitis) is not present. If there is an indication of a more proximal infection, a wrist block or general anesthesia should be considered to allow formal operative débridement.

A digital block is performed by inserting the needle through the flexor tendon at the level of the palmar digital crease of the affected digit, contacting the underlying bone and then slowly injecting 2 mL of lidocaine without epinephrine into the space between the periosteum and the flexor tendon as the needle is withdrawn. Alternatively, the digit can be approached dorsally with the needle entering the dorsal skin of the finger over the metacarpal head of the affected digit and then introducing 2 mL of lidocaine without epinephrine volarly into each webspace flanking the digit. A digital tourniquet can then be made by clamping a penrose drain around the base of the digit. Care must be taken to remove the tourniquet at the completion of the drainage procedure.

Paronychia

Diagnosis

A paronychia is an infection involving the tissue surrounding the lateral fingernail (paronychial fold), proximal nail fold (eponychial fold), or extending into the nail matrix (Figure 3). Risk factors include nail biting, hangnails, and manicures. The most common inciting organism is *Staphyloccocus aureus,* but it can also include oral flora. Typically a painful swollen area with erythema along the lateral border of the fingernail or beneath the proximal nail fold is the hallmark of an acute paronychia. Purulent drainage or failed conservative therapy with warm soaks necessitates surgical drainage.

Treatment

Early paronychia can be treated with warm soaks several times a day. Simple paronychia that have developed an abscess are treated with incision and drainage. This can be done at the bedside or in the office with a digital block. Superficial paronychia can be treated by simple elevation of the paronychial/eponychial fold off of the nail plate with an elevator or scalpel to drain the abscess. Infections that have spread

FIGURE 3 Acute paronychia of the thumb involving the inferior aspect of the thumb nail fold.

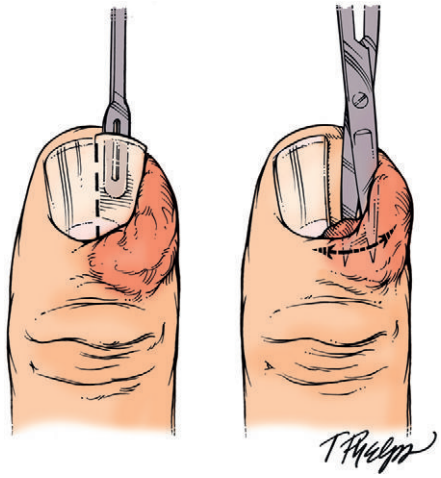

FIGURE 4 Surgical drainage of acute paronychia. The lateral nail on the affected side is gently elevated from the nail bed, and a longitudinal strip of nail is removed. If this does not decompress the infection adequately, the margins of the nail fold are opened gently to drain the adjacent soft tissues.

below the nail plate require removal of at least part of the nail plate. The nail fold is elevated, and a longitudinal strip of nail is cut away on the affected side (Figure 4). If needed, the entire nail is removed. The wound should be irrigated and dressed with daily soaks in warm, soapy water or diluted hydrogen peroxide beginning soon thereafter. Empiric antibiotics treatment should be initiated with either cephalexin or amoxicillin/clavulanate (Augmentin) to cover the most common pathogens. In areas with frequent community-acquired MRSA, trimethoprim/sulfamethoxazole (Bactrim) or clindamycin should be used.

Felon

Diagnosis

A felon represents a compartmentalized abscess in the fat pad of the distal phalanx. There are numerous vertical septae that extend from the distal phalanx to the dermis, and once inoculated with bacteria, small abscesses can develop. The patient usually presents with a swollen fingertip, throbbing pain, and erythema (Figure 5). The swelling is mostly distal to the distal interphalangeal (DIP) joint, and any extension proximally should raise the suspicion of a flexor tendon sheath infection.

Care should be taken to distinguish a felon from herpetic whitlow, which can have a similar appearance when present at the fingertip. Herpetic whitlow is a viral lesion caused by the herpes simplex virus. Whitlow is common in children, dental workers, and other populations frequently exposed to saliva. The disease appears as clear vesicles and mild finger swelling that may resemble a felon. Although the fluid may be turbid or hemorrhagic, it is not purulent, and unlike a felon, the pulp space does not have increased tension. The diagnosis can be made by sending scrapings from an open vesicle for a Tzanck smear.

FIGURE 5 Acute felon. Blistering is evident distally, where tissue pressure is significantly elevated.

Treatment

In the earliest stages of a felon, a trial of warm soaks, elevation, and antibiotics may be initiated; however, surgical decompression is often necessary. Surgical drainage requires a thoughtful skin incision and then blunt dissection with disruption of the pulp septae. Multiple incisions have been described, and care and planning should be performed in order to adequately treat each patient. A distal-based fish mouth incision at the tip of the finger should be avoided because it may result in painful scarring and deformation of the fingertip. If the felon is located along the volar midline, then a volar longitudinal incision can be made. Otherwise, a high lateral incision just below the nail can be performed, avoiding the digital artery or nerve (Figure 6). This incision should be placed on the noncontact side of the affected digit (radial for the thumb and ulnar for the remaining digits) to avoid painful scarring that interferes with pinch. Once careful disruption of the septae has been performed and the fingertip is adequately decompressed, it should be packed and dressed. Empiric antibiotics are started, followed by soaks and dressing changes the next day.

Pyogenic Flexor Tenosynovitis

Diagnosis

Bacteria that inoculate the flexor tendon sheath, often from penetrating trauma, may lead to a pyogenic flexor tenosynovitis. The flexor sheath runs from the distal interphalangeal joint to the A1 pulley over the metacarpal head, and bacteria may enter the sheath anywhere along this course. Failure to institute treatment in a timely manner can have devastating consequences, ranging from tendon adhesions

to finger necrosis. Kanavel described four cardinal signs of flexor tenosynovitis: tenderness along the course of the sheath, fixed flexed position of the finger, extreme pain with passive extension of the finger, and fusiform swelling of the affected digit (Figure 7). All of these signs may not be present, but the clinician should evaluate for each and have a low threshold to begin treatment. Early infections (<24 hours) in healthy individuals may be managed with a trial of antibiotics; however, failure to respond or delayed presentation is an indication for surgical débridement.

Treatment

Surgical treatment of flexor tenosynovitis includes operative exploration, débridement of necrotic tissue, and flushing of the tendon sheath. Surgery should be performed in the operating room and may consist of either open or closed sheath irrigation. In open sheath irrigation, the flexor sheath is exposed using either a Brunner-type or midlateral incision, taking care not to injure the digital neurovascular bundles that reside laterally. The tendon sheath is opened in order to remove all infectious material. Care should be taken to preserve the critical annular pulleys of the digit, with the A2 pulley being located over the proximal part of the proximal phalanx and the A4 pulley located over the midportion of the middle phalanx. The sheath is copiously irrigated with sterile saline until all purulent material is removed. Any large incisions should be loosely closed.

The alternative method is the closed sheath technique, which involves limited incisions located proximally and distally to allow access to the sheath. The proximal incision is located at the level of the A1 pulley volarly, and the distal incision is placed either midlaterally or volarly at the distal interphalangeal crease. The sheath is then accessed at both sites, and a pediatric feeding tube or other small intravenous catheter is introduced to allow copious antegrade irrigation. Catheters can be left in place for postoperative irrigation, but this technique is messy and cumbersome and has not proved to be more useful than routine wound care.

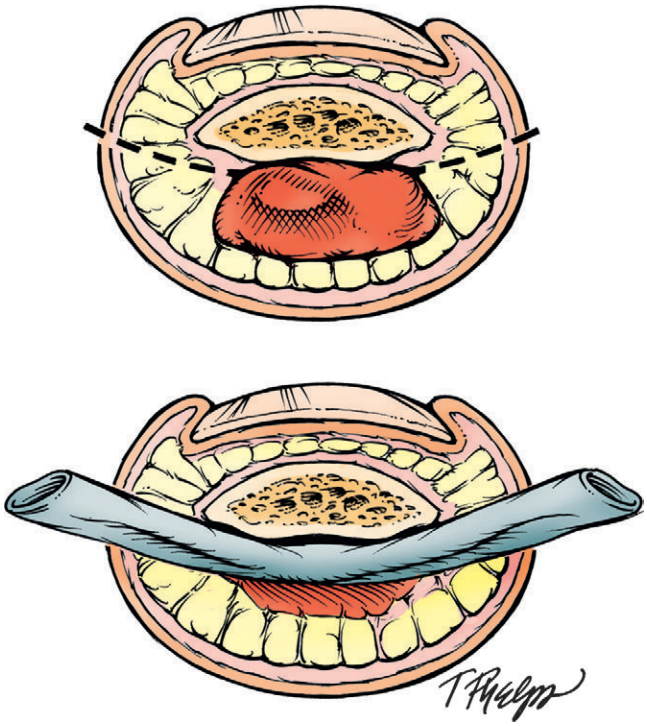

FIGURE 6 Through-and-through drainage of a felon ensures complete decompression and minimizes the risk of incomplete treatment. A drain is placed and maintained for 48 hours.

After open or closed tendon sheath irrigation, the hand should be splinted and elevated, and a course of antibiotics should be prescribed. Wound soaks are then performed several times a day. The wounds can be dressed with gauze and allowed to heal secondarily.

HAND INFECTIONS

Some hand infections, such as a dorsal abscess, may be treated in the emergency room with just a local field block. The patient requires débridement in the operating room when the infection involves closed volar spaces or joints.

Bursal Infections

Diagnosis

The flexor tendon sheath of the thumb is continuous with the radial bursa, a thin envelope extending from the flexor pollicis sheath at the level of the metacarpophalangeal joint through the carpal canal into the forearm. The small finger flexor sheath is continuous with the ulnar bursa, another fine envelope tracking ulnar to the flexor tendons and into the carpal canal and forearm. Infections of the thumb and small finger flexor tendons may propagate along these bursa and into the distal forearm. The "Parona space," a potential space that lies between the pronator quadratus and flexor tendons, may communicate infections between the radial and ulnar sides of the hand. This space may also communicate with the thenar and midpalmar spaces deep in the palm. Bacterial extension through this communication is generally associated with a severe generalized deep volar infection. Sometimes the result is a more limited but nonetheless serious radial and ulnar bursal space infection referred to as a "horseshoe" abscess. It is important for the surgeon to be aware of the potential spaces and communications when treating the infected hand. Failure to recognize bacterial extension into these spaces can lead to an incomplete débridement and increased morbidity (Figure 8).

Treatment

Infections that spread along bursa require aggressive débridement in the operating room under general anesthesia. The infected digits should be thoroughly debrided as previously described in flexor tenosynovitis. Often the extent of the disease is not recognized until the time of surgery. Because the infection is followed proximally, care should be taken to avoid making large, continuous incisions across the hand. Separate thenar or hypothenar incisions can be made in the palm, in line with skin creases, while another incision can be placed on the distal volar forearm to inspect for infection in the Parona space. The most severe infections will require an extended carpal tunnel release in order to adequately debride necrotic tissue and infected tenosynovium. After copious irrigation, the wounds can be closed loosely over a drain and the hand splinted. Postoperative care includes appropriate antibiotics, daily dressing changes and soaks, and hand therapy.

Deep Space Infections: Thenar, Hypothenar, and Midpalmar Space Abscesses

Diagnosis

Three potential spaces exist in the palm that can become infected with resultant abscess formation. The interosseous muscles are deep to these spaces, and the flexor tendons are superficial (Figure 9). The thenar space is bordered by the adductor pollicis dorsally, the index finger flexor volarly, the adductor pollicis insertion on the proximal

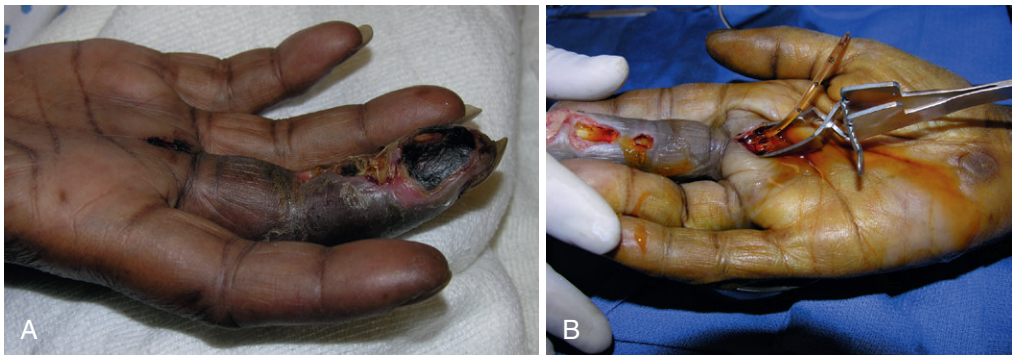

FIGURE 7 **A,** Late pyogenic flexor tenosynovitis in a diabetic immunocompromised patient. Swelling and a slightly flexed posture are evident. **B,** Necrotic tissue has been debrided, and the sheath is irrigated in a closed fashion.

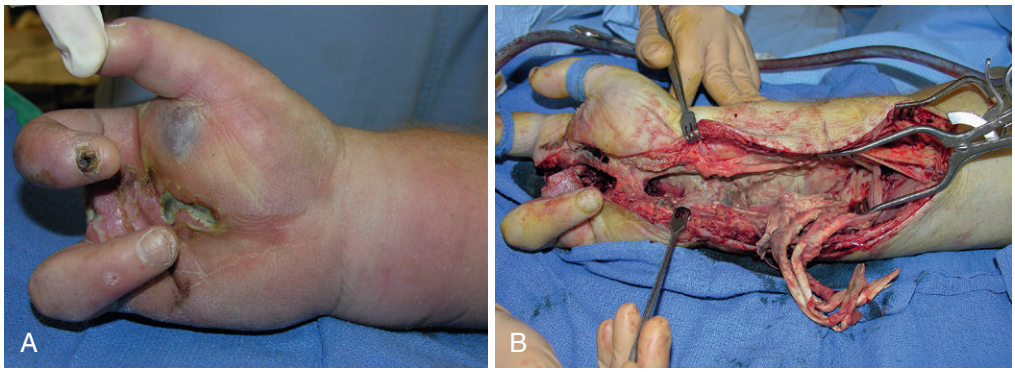

FIGURE 8 **A,** Inadequate treatment of "finger infections" is manifest as generalized hand and forearm swelling. **B,** Bacterial extension through the carpal tunnel and the Parona space results in a severe generalized deep volar forearm infection.

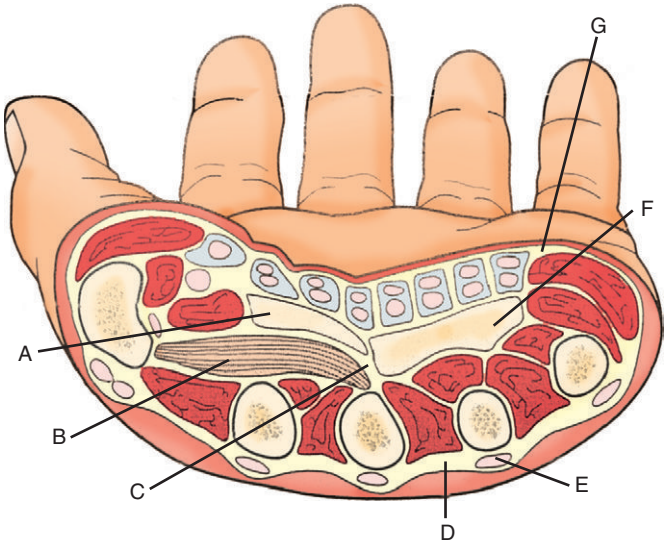

FIGURE 9 Cross-section anatomy of the hand. **A,** Thenar space. **B,** Adductor pollicis. **C,** Midpalmar septum. **D,** Dorsal subaponeurotic space. **E,** Extensor tendon. **F,** Midpalmar space. **G,** Hypothenar space.

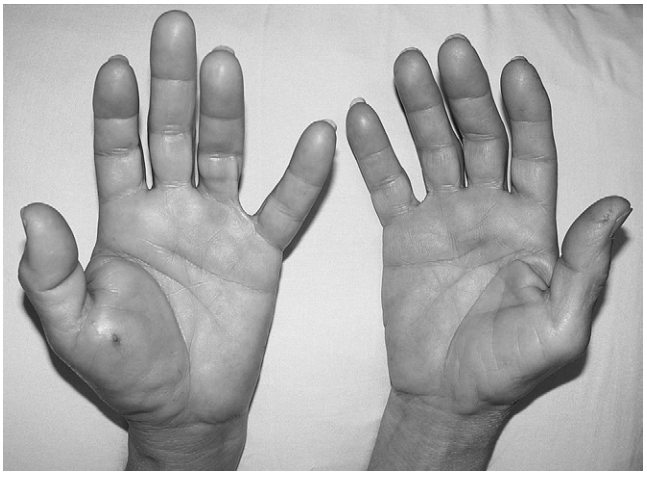

FIGURE 10 Thenar space infection resulting from a cat bite, showing thenar edema and abduction of the thumb.

phalanx radially, and the midpalmar septum ulnarly. Infections are often the result of penetrating trauma. The first webspace area becomes swollen and exquisitely tender to palpation as the potential space becomes filled with purulent fluid. The thumb may be abducted with extreme pain on passive adduction or opposition (Figure 10).

The midpalmar space lies between the thenar and hypothenar eminences. The floor is the fascia of the second and third volar interosseous, and the superficial border is the flexor sheaths of the long, ring, and small fingers. The radial and ulnar borders are defined by septae running from the third and fifth metacarpals to the dermis. These septae are termed the oblique septum and the hypothenar septum, respectively. Infections are most often a result of penetrating trauma or extension from an adjacent infection.

The hypothenar space lies between the hypothenar septum and the hypothenar muscles, with the periosteum of the fifth metacarpal as the floor. Infection of this space is rare, as is spread of infection to adjacent areas. The patient may present with localized pain and swelling along the hypothenar eminence, with absence of swelling elsewhere in the palm or fingers.

Treatment

The thenar space can be approached either dorsally or volarly (Figure 11). The volar approach typically involves an incision along the

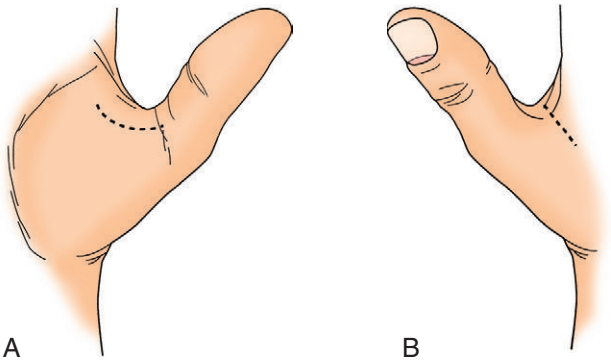

FIGURE 11 Surgical approach for incision and drainage of a thenar space infection. **A,** Transverse incision. **B,** Dorsal longitudinal incision.

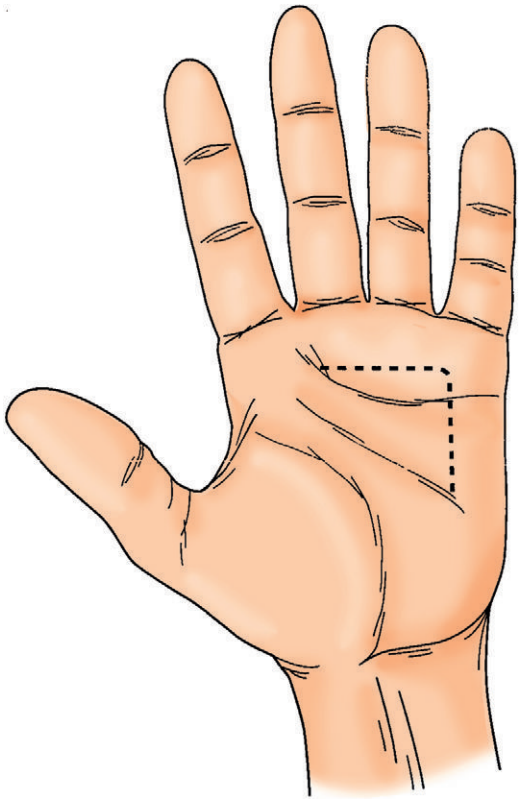

FIGURE 12 Combined longitudinal and transverse incision for drainage of midpalmar space abscess.

thenar crease approximately 1 cm proximal to the webspace and proceeding proximally. Blunt dissection is then carried out to the adductor pollicis, and the abscess is drained. Care should be taken proximally where the motor branch from the median nerve may be encountered. Dorsal incisions may be transverse or longitudinal, and blunt dissection is then performed to the interval between the first dorsal interosseous and the adductor pollicis, where the abscess should be encountered. The radial artery may be encountered in this region.

The midpalmar space is approached volarly, with a transverse incision at or about the distal palmar crease, a longitudinal incision, or a combination of the two (Figure 12). Blunt dissection is again used to avoid damage to the palmar neurovascular bundles and then carried out longitudinally on either side of the flexor tendons until the abscess is expressed.

Similar to the thenar space, the hypothenar space can be accessed with an incision along the hypothenar eminence, parallel to the fifth metacarpal. The dissection is carried to the level of the hypothenar fascia, where the abscess should be encountered and drained.

After drainage and irrigation, all wounds should be closed loosely over drains or packing, and the hand should be splinted. Dressing changes, soaks, or irrigation should be begun the next day, along with therapy attempts to restore hand function.

Web Space Abscesses

Diagnosis

Often referred to as "collar-button abscesses" because of their hourglass shape, these infections may result from a fissure in the skin between adjacent fingers, from a distal palmar callus, or track from dorsal to volar. There is localized pain and swelling in the affected webspace, and classically the adjacent fingers are abducted away from the abscess.

Treatment

Drainage of a webspace abscess can be performed with a single dorsal incision or a combined dorsal and volar approach. Care should be taken not to place the incision across the webspace or to connect the dorsal and volar incisions because this will decrease the ability of the fingers to abduct due to the contracting scar. After skin incision, dissection is performed bluntly to allow full egress of purulent material. After irrigation, a drain should be placed in each incision, but a through and through drain for both incisions should be avoided. The hand should be splinted, and daily dressing changes and soaks should begin the following day.

Dorsal Hand Abscesses

Diagnosis

Dorsal hand abscesses can be either deep—occupying the so-called "subaponeurotic" potential space below the extensors—or subcutaneous. The depth of the abscess may be difficult to distinguish clinically. The patient typically presents with focal pain, swelling, and erythema. Dorsal abscesses may also develop in the fingers (Figure 13).

Treatment

While simple cellulitis responds favorably to antibiotics, fluctuant infections must be drained. Most dorsal hand abscesses may be drained in the emergency department under a local field or regional block. If the clinician is certain that the abscess is in the subcutaneous tissue, a simple longitudinal incision can be made over the most prominent part of the abscess in order to fully express the infectious material. If the abscess seems deep, a longitudinal incision should be biased toward the region over the second metacarpal or the space between the fourth and fifth metacarpal to avoid the extensor tendons. Blunt dissection is then performed to expose the abscess below the extensor tendons and fully express the pus. Irrigation is performed, followed by loose closure and a splint. Early hand motion is initiated when possible.

NECROTIZING FASCIITIS OF THE UPPER EXTREMITY

Diagnosis

Necrotizing fasciitis is a rapidly progressive, potentially fatal bacterial infection that most commonly spreads along the fascial planes of the

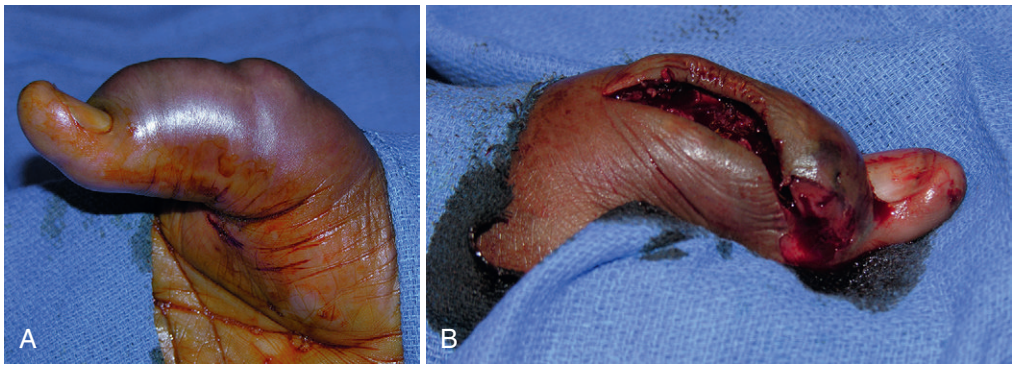

FIGURE 13 **A,** A large dorsal abscess is anatomically separated from the palmar tissues by finger ligaments (Cleland and Grayson). **B,** The abscess is drained by a linear incision made over the path of greatest fluctuance.

FIGURE 14 A 78-year-old man presented with systemic illness and a rapidly progressing dominant arm soft tissue infection. Early and aggressive management with serial wide surgical débridement, negative pressure therapy, and subsequent delayed closure allowed for preservation of the limb. Tissue sample confirmed the diagnosis of necrotizing fasciitis. *(From McDonald LS, Bavaro MF, Hofmeister EP, et al.: Hand infections,* Journal of Hand Surgery *36(8):1403-1412, 2011.)*

muscles (Figure 14). In the upper extremity it is most common in diabetics, alcoholics, and intravenous (IV) drug users, with some reports showing more than half of these infections being precipitated by self-injection. The presentation may be delayed several days after initial symptoms. It is essential that the clinician maintain a high suspicion for this disease in patients presenting with severe upper-extremity infections. Symptoms may include extreme pain, blistering and bullae, skin hemorrhage or loss, rapid progression, and crepitus. If there is any suspicion for necrotizing fasciitis, immediate resuscitation and empiric intravenous antibiotics should be initiated, followed immediately by surgical débridement. The most common pathogen is *Streptococcus pyogenes* (Group A strep), although some cases may be polymicrobial or contain other bacteria such as anaerobes. With the rising incidence of MRSA, more MRSA-related necrotizing fasciitis cases are being encountered.

Treatment

After resuscitation, the patient should be urgently taken to the operating room. Patient outcomes for necrotizing fasciitis are directly linked to adequacy and timing of débridement. Exsanguination of the extremity should be avoided so as not to milk the bacteria proximally. Débridement requires longitudinal incisions along the affected extremity, with liberal removal of infected and devitalized tissue. Amputation may be necessary. Tissue samples should be taken for culture. The classic finding is "dishwater pus," a thin, foul-smelling fluid along the fascial planes, along with thrombosis of the microvasculature in the affected area. The fascia may appear gray or grayish-green and swollen. The surgeon should have a low threshold for extending incisions and further débridement because the possibility of missing large pockets of purulent material can have devastating consequences. After removal of all infected tissue, the wounds should be copiously irrigated out and left open. Dressing changes should be started within the next 24 hours and be done two to three times a day. The patient will likely require multiple débridements occurring every couple of days until it is certain that all infectious and devitalized tissue has been removed. These patients may require soft tissue reconstruction once the infection is eradicated.

OSTEOMYELITIS

Diagnosis

Osteomyelitis in the hand can result from penetrating trauma, septic arthritis, other deep infections, or seeding of the bone from bacteremia. Injured bones, either from trauma or surgery, are particularly susceptible due to the damaged cortex, which allows pathogen penetration. Plain x-rays may show signs of bony destruction, although this typically appears several weeks after the infection has begun (Figure 15). MRI or bone scan will help with early detection. The gold standard for diagnosis is tissue culture and bone biopsy with pathologic confirmation.

Treatment

Although it is possible for early cases of osteomyelitis to be treated with IV antibiotics alone, treatment often requires surgery. Draining wounds, abscesses, and areas of necrotic bone should be washed out and debrided to a margin of healthy bone and soft tissues. Necrotic soft bone is easily debrided with a rongeur or osteotome until hard bone is encountered. The presence of hardware may make eradication of the infection difficult. Any implantable hardware should be considered for removal, especially if it is loose or no longer needed for stability. External fixators can provide provisional fixation during the interim. Antibiotics should be culture driven when possible and should be administered intravenously for 4 to 6 weeks. The surgeon should have a low threshold for an infectious disease consultation to aid with antibiotic tailoring and duration.

Nerve Injury and Repair

Pablo A. Baltodano, MD, and Gedge D. Rosson, MD

INTRODUCTION

During the past 40 years, and mainly due to the availability of surgical operating microscopes, surgeons have been routinely repairing nerves. This has paralleled the advance of microvascular free flap reconstruction and digital replantations. Performing optimal nerve repairs requires meticulous microsurgical operative techniques and the use of both the science and the art of peripheral nerve surgery.

Nerve repair is an exercise in patience and delayed gratification. The surgeon must exercise patience and care to appropriately direct sensory fibers into sensory end organs and motor fibers into appropriate muscles. In many cases, it can take months or even years for the final results.

GENERAL PRINCIPLES

Basic Anatomy

Prior to embarking on peripheral nerve surgery, it is critical to understand the basics of peripheral nerve anatomy (Figure 1) and physiology. Knowing the anatomy and physiology for potentially injured nerves enables the clinician to adequately assess the magnitude of peripheral nerve injuries. Additionally, an adequate understanding of the histology of peripheral nerves sets the basis for performing optimal nerve repairs.

The most basic subunit of the peripheral nerve is the axon. Each axon is surrounded by the endoneurium. Axons are grouped into fascicles, and these fascicles are surrounded by a thin perineurium. The grouped fascicles are also surrounded by interfascicular epineurium. The main nerve itself is surrounded by an external epineurial

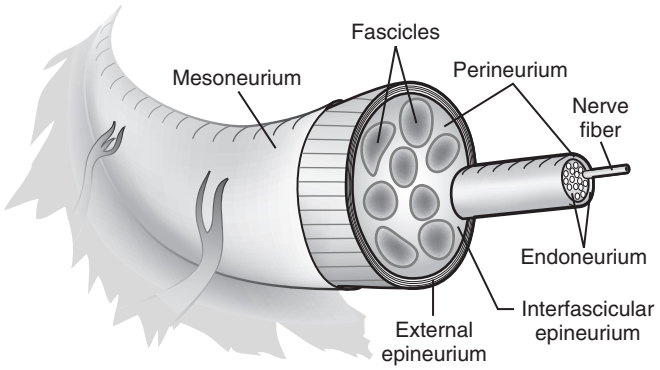

FIGURE 1 The normal anatomy of the peripheral nerve.

sheath. The external segmental blood supply to the nerve travels through a final layer of connective tissue referred to as the mesoneurium, which also allows nerve gliding during normal range of motion.

Fascicular Topography

When performing nerve repairs, it is important to understand the difference between the fascicular topography in the proximal nerve trunk and the fascicular topography in the distal nerve. Most nerves have a significant intermingling of sensory and motor fibers with plexus formation in the nerve trunks proximally. The more distal nerve fascicles have usually become groups of sensory fibers and groups of motor fibers. This partially explains why more distal nerve repairs have better long-term functional outcomes. For example, repairing facial nerve injuries within the temporal bone often leads to a significant amount of disabling synkinesis and dyskinesis due to the lack of distinctive fascicular architecture in the proximal facial nerve trunk. This is in contradistinction to repair of the facial nerve in the parotid gland branches or distally because these fascicles are now in their final configuration.

Pathophysiology of Nerve Injury

The surgeon willing to perform a successful nerve repair should have a clear concept of the mechanism of injury, zone of injury (Figure 2), degree of injury, and the nerve components involved. Based on the mechanism of injury, lesions may be classified as open (sharp or raggedy laceration) or closed (overstretching, blunt, or compressive trauma). Gunshot wounds, although technically open, behave more like closed injuries because the nerve damage is more likely due to the blast effect than to transection. Second, the zone of injury should be determined. A very clean injury to the nerve such as that with a scalpel will have a small zone of injury, whereas avulsion nerve injury with a table saw can have a very wide zone of injury. It is nearly impossible to accurately detect the zone of injury during the initial exploration if there is any crush or avulsion component.

Subsequently, the degree of injury may be classified as neurapraxia, axonotmesis, and/or neurotmesis using the Seddon's classification or as degrees I to V by the Sunderland's classification. Mackinnon and Dellon added a degree VI (combined nerve injury) to the Sunderland's classification. Determining the degree of nerve injury provides guidance as to when nerve injury requires surgical intervention (Table 1).

Regarding the nerve components injured, three scenarios are possible. The first is when there is focal or segmental demyelination with preservation of the axons (clinically manifested as neurapraxia). In this scenario, functional recovery will occur spontaneously (as the myelin heals, within minutes or days but up to 6 weeks). Thus, no surgical intervention is required. Hitting your "funny bone" is an example of an ulnar nerve neurapraxia that lasts minutes. The so-called "Saturday night palsy" (radial nerve injury with wrist drop) is another common example of neurapraxia.

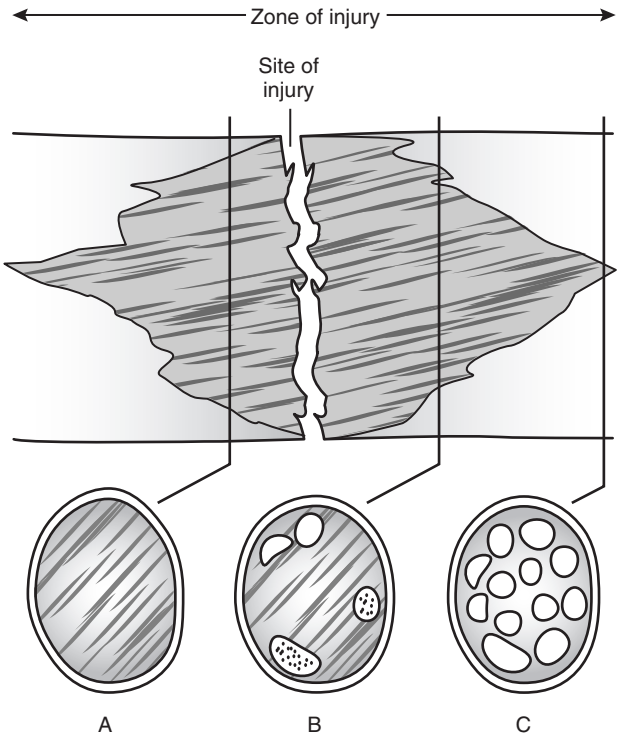

FIGURE 2 Following nerve injury, the zone of injury may extend well beyond the site of injury. **A**, The nerve consists entirely of scar tissue. **B**, Scar tissue and a fascicular pattern are seen in the more remote zones of injury. A fascicular pattern may be seen, but it may be scarred (stippled). **C**, Normal fascicle (clear) will protrude from the plane of the cut nerve because of increased endoneurial pressure.

The second scenario is characterized by axonal injury (axonotmesis). In this context, the axon itself will die back to the nearest node of Ranvier. Once the injury has stabilized over the next several hours, the injured axon will begin to grow. These axons form multiple "growth cones" (nerve sprouting) and attempt to grow at a rate of approximately 1 mm per day or 1 inch per month into the distal endoneurial tubes, if available. The segment of the nerve distal to the injury will undergo Wallerian degeneration. In this case, the myelin sheath and cellular debris are phagocytosed, and the axon is completely replaced over a period of 3 to 6 weeks.

Axonotmesis can result in a range from complete recovery to no recovery; the ultimate recovery is based on the degree of damage to the axonal surrounding tissues (endoneurium, perineurium, and epineurium) and the scar tissue that may result from it. Axonotmetic injuries may have intact or partially severed surrounding tissues. If the surrounding tissues remain intact (Sunderland's degree II), the axon sprouts will likely reach the distal endoneurial tubes and spontaneous recovery will occur. In contrast, if the surrounding tissues are partially severed (Sunderland's degree IV), the axonal sprouts will not reach the distal endoneurial tubes and a neuroma in continuity will develop.

The third scenario is when the axons and their surrounding tissues are completely injured (neurotmesis). After a transection injury, the regenerating axonal sprouts will not reach the distal endoneurial tubes and a neuroma will develop. Whenever substantial

TABLE 1: Classification and expected recovery of nerve injuries

Classification		Nerve component injured					Expected recovery		Surgery indicated
Seddon's	Sunderland's Degree (Modified)	Myelin	Axon	Endoneurium	Perineurium	Epineurium	Extent	Rate	
Neurapraxia	First	Yes	No	No	No	No	Complete	Fast	None
Axonotmesis	Second	Yes	Yes	No	No	No	Good	Slow	None
Axonotmesis	Third	Yes	Yes	Yes	No	No	Variable	Slow	None or neurolysis
Axonotmesis	Fourth	Yes	Yes	Yes	Yes	No	None	None	Nerve repair
Neurotmesis	Fifth	Yes	Yes	Yes	Yes	Yes	None	None	Nerve repair
	Sixth	Combination of injury					Variable	Variable	Variable

damage to the surrounding tissues precludes the axonal sprouts from reaching the distal endoneurial tubes (as is the case with Sunderland's degrees III to VI), a neuroma will develop and surgery will be required.

It is critical to highlight that the distal nerve segment will still have viable axons, which can transmit electrical stimulation for up to 72 to 96 hours. This is most important when repairing small motor nerves such as distal branches of the facial nerve. Thus, when confronted with a sharp facial laceration with nerve injury, it is critical to bring the patient to the operating room within 72 hours, if at all possible, because the distal nerve endings can be located with electrical stimulation.

It has also been found that the changes in the denervated muscles are different from the changes in the sensory end organs. When muscles are denervated, the muscles suffer from both disuse atrophy and denervation atrophy. Also, most of the motor endplates themselves will die within 12 months, and by 18 to 24 months they will all be gone. After that time, even if a functional axon could reach the muscle, the muscle cannot be reinnervated. At this point, reconstructive repairs addressing muscles, tendons, bones, and joints remain the only options. The sensory end organs, on the other hand, do not undergo degeneration, and reports have been made of reinnervating sensory targets and improving sensibility even many years after the original injury.

Timing

Optimal surgical timing is an essential factor for successful nerve repair. Closed injuries must be approached differently from open injuries. Additionally, with a limited time window for repair, "the earlier the better" remains a fundamental concept. Surgical timing for nerve repair can be summarized by the "3 plus 1" rule (Table 2), with early repair occurring within 3 days, subacute repair around 3 weeks, delayed repair around 3 to 6 months, and late repair after 1 year.

Whenever a *subacute repair* (around 3 weeks) is being considered, but another team (e.g., an orthopedic surgical team) is performing an acute surgery, it makes sense to explore the nerve at the same time. Nerve action potential (NAP) testing helps to determine recovery across a nerve injury by evaluating the capacity of a nerve segment to conduct an action potential (i.e., proximal and distal to an injury). Lesions-in-continuity with (+) NAP should be observed for several months. If a blunt or ragged transection is found, or after injuries with a significant crush or avulsion component, performing the repair at a second stage allows time for better definition of the zone of injury. The scarred, damaged nerve endings are not readily apparent until 2 or 3 weeks after the injury, and scarred nerve endings should not be sutured together because the axons cannot regenerate through scar tissue. Nerve endings should be fixed under tension using radiopaque clips, staples, or a small Prolene. This will prevent retraction and allow easy identification of the nerve stumps during the second-stage surgery (subacute repair).

Delayed repair (around 3 to 6 months) is indicated when it is difficult to determine whether the injury will recover spontaneously. A closed injury may be a simple stretch traction injury with neurapraxia and regenerate well on its own. Therefore, these patients must be followed clinically every month, and sensation should be monitored by noninvasive neurosensory testing of the skin distal to the nerve injury. A formal nerve conduction study and electromyography should be performed at 6 weeks and 12 weeks following significant closed injury of a motor nerve. Observation can be continued in patients with signs of spontaneous recovery. An important concept is that 90% of the spontaneous nerve recoveries occur within 4 to 6 months, so it is reasonable to wait for that period (especially with distal injuries) before proceeding with nerve reconstructive surgery. Surgery is indicated when there is no evidence of clinical or electrophysiologic recovery after this period of observation. Motor nerves should be repaired within 4 to 6 months to give the regenerating axons time to grow into the target muscles.

As said before, gunshot wounds, although technically open, behave more like closed injuries because the nerve damage is more likely due to the blast effect than to transection. This often results in neurapraxia or axonotmesis, and it may not require surgical repair. Similarly, close observation should be implemented, and surgery should be performed if there are no signs of improvement.

Lesions-in-continuity can be evaluated with intraoperative NAP testing. As mentioned above, lesions-in-continuity with (–) NAP should undergo early repair. On the other hand, lesions with (+) NAP should be observed for a period of 4 months, after which surgery is performed if no signs of recovery are evident.

Late repair (after 1 year) may be considered a salvage procedure for patients presenting late or patients with incomplete recovery or failure to recover. Some surgeons consider repairs performed 9 months after the injury as late repairs. Especially in the case of motor nerves, the results of late repair are typically suboptimal because of permanent changes at the muscular level.

Treatment Options

Several treatment options for nerve injuries are available (Table 3).

TABLE 2: "3 plus 1" rule for timing of nerve repair

Timing	Time	Indications	Injury classification
Early	3 days	• Nerve transection with sharp injuries • Lacerations of the face (repairing in <72 hours adds the benefit of intraoperative nerve stimulation) • Acute nerve compression due to vascular (e.g., hematoma, pseudoaneurysm) and/or bony injuries • Acute neurologic worsening under close observation • Lesions-in-continuity with (–) NAP	Neurotmesis
Subacute	3 weeks	• Blunt or ragged transections (e.g., propeller blades, chain saws) • Injuries with significant crush or avulsion component	Neurotmesis
Delayed	3 months	• Nonpenetrating injuries (stretching injuries, contusive injuries, gunshot wounds) • Lesions-in-continuity with (+) NAP without adequate recovery	Axonotmesis
Late	>1 year	• Salvage procedures	Neurotmesis or axonotmesis

TABLE 3: Treatment options and indications for the repair of nerve injuries

Options	Indications
Observation	• Recovering nerve injury • Partial nerve injury
Neurolysis	• Lesion-in-continuity with positive NAP
Direct coaptation	• Laceration • Tension-free direct coaptation possible
Nerve graft or conduit	• Laceration with retracted stumps (delayed repair) • Direct repair without tension not possible
Nerve transfer	• Avulsions (e.g., brachial plexus avulsion) • Specific cases of nerve injury for which nerve transfer may lead to a more rapid or reliable recovery (i.e., because of proximity to the end-organ) than proximal nerve grafting • Innervation of free-functioning muscle transfers
Direct neurotization	• Under investigation/used for direct muscle reinnervation after severe trauma
Tendon and/or muscle transfers	• Delayed (>1 year) for improvement of function
Bony and/or joint procedures	• Delayed (>1 year) for improvement of function
Amputation	• Rarely indicated; sometimes desired by patients

NAP, Nerve action potential.

PREOPERATIVE MANAGEMENT

Patient Education

Patients must be adequately informed and well educated as to realistic expectations. Microsurgical techniques can yield good functional outcomes; unfortunately, patients rarely obtain excellent results in terms of motor and sensory regeneration. Several limitations to nerve repair exist. The speed of regeneration (up to 1 mm/day or 1 inch/month), a large distance from repair site to end organ, muscle atrophy or neuromuscular junction degeneration, limited availability of functional donors or graft materials, and unrealistic expectations may all result in unsatisfactory outcomes.

These limitations become evident depending on the clinical scenario. When treating an individual distal sensory nerve injury, these limitations are reduced. When treating a single, simple distal sensory nerve injury, success is more likely and these limitations are not as critical. Conversely, these limitations severely impact the outcome of multiple proximal motor nerve injuries, such as proximal brachial plexus lesions. Making patients aware of the limitations of nerve reconstruction surgery can produce more realistic expectations and more satisfied patients.

Preoperative Assessment

The optimal approach to nerve injury assessment includes a detailed history of the mechanism of injury and the onset of the deficit; a physical exam (neurologic, vascular, and musculoskeletal examination); and electrodiagnostic studies, such as electromyelogram and nerve conduction studies. These three pillars (history, physical exam, and electrodiagnostic studies) help the clinician to determine the extent and severity of the nerve injury. Additionally, imaging studies (radiographs, ultrasound, computed tomographic scan, magnetic resonance imaging and neurography, and/or myelogram) can further enlighten the clinical scenario and the operative planning. Specifically, high-resolution (3 Tesla) magnetic resonance neurography (MRN) has been increasingly used to better define the anatomy of injured nerves. MRN provides a substantial benefit for the evaluation of large proximal nerve elements such as the brachial plexus, the lumbosacral plexus, the sciatic nerve in the pelvis, and other nerves that follow deep or complex courses, where electrodiagnostic studies are difficult to use. The clinician must also remember to use sensory and motor function grading scales, which will facilitate follow-up and assessment of the results of interventions (including observation).

Equipment

Prior to any nerve exploration or repair, proper equipment must be readily available. Nerve repairs should be performed only on medically stable patients. The surgical team should be well rested and well trained in microsurgical techniques. The equipment and room setup is similar to microvascular surgery as needed for free flap reconstruction. A well-maintained operative microscope or a minimum of 4× loupe magnification should be available. Microsurgical instruments such as microforceps, microscissors, microbipolar, and microsurgical needle drivers are required, as well as 9-0 or 10-0 nylon sutures. Heparinized saline solution is needed if a nerve conduit will be utilized.

Positioning and Planning

Patients must be positioned on the operating room table to allow ease of access to both the site of injury and any potential donor sites if nerve grafting will be required. These areas should be simultaneously prepped and draped for ease of access. For nerve repairs in the upper extremities, the patient's arm is placed on an arm board, and comfortable seating should be available. Nerve repairs of the lower extremities can also be performed with the surgeons seated if the patient is placed on the operating table so there is room under the

table for the surgeon and the assistant to sit comfortably across from each other. If the operating room table is not positioned appropriately, the base of the table will be at the same level as the surgeon's knees. Common potential donor sites for nerve grafting include the sural nerve in the leg, the medial or lateral antebrachial cutaneous nerves, the superficial sensory radial nerve, the superficial peroneal nerve, the distal posterior interosseous nerve, the great auricular nerve, and the cervical plexus nerves.

The initial exploration should be under loupe magnification and tourniquet control if possible. If repair of a motor nerve is planned (and it is within 72 hours of the original injury), it is critical to remember that a tourniquet applied longer than 30 minutes can cause ischemia of the distal nerve, and intraoperative nerve stimulation will no longer be possible. Thus, the initial dissection must be well planned, focused, and directed to make sure there is enough time to dissect the putative distal nerve and apply stimulation for 30 minutes afterward.

OPERATIVE TECHNIQUE

Both an organized approach to exposing the injured nerve (Table 4) and a thorough knowledge of the anatomy are essential, especially when significant scarring is expected. To expose the injured segment of the nerve, dissection should be performed between two muscle groups parallel to the long axis of the nerve to identify a normal segment of the nerve, both proximally and distally, before dissecting to expose the injured segment. If it is near a compression site, such as the ulnar nerve near Osborne's band, then the site of compression should be released at this time. The regenerating nerve will become swollen during the regenerative phase, and potential future compression should be prophylactically removed.

After exposing the injured segment, there are two possibilities: the identification of a lesion-in-continuity versus nerve stumps. Intraoperative inspection of a lesion-in-continuity does not necessarily predict outcomes. A very firm lesion, particularly if a preoperative MRN showed a severe injury, most likely should be resected and reconstructed. However, if a lesion-in-continuity is identified, intraoperative NAP testing can be performed. If NAP (+), conservative management is indicated (observation will render better outcomes than resection, so only neurolysis should be performed). If NAP (–), resection of the lesion followed by nerve reconstruction will improve outcomes.

If nerve stumps are identified, reconstruction is indicated. NAP, somatosensory-evoked potentials (SSEP), and motor-evoked potentials (MEP) may be used to help determine if the proximal nerve stump can be used for reinnervation.

TABLE 4: Key operative principles of nerve repair

Modified from Cameron, 10th Edition, Table 4. All rights reserved.
NAP, Nerve action potential.

Preparation of Nerve Endings

The most critical step is the preparation of the nerve endings. In fact, nerve resection is nerve repair's most neglected technique. Care must be made to adequately resect damaged nerve endings; this will be based on the mechanism of injury and the zone of injury. As previously mentioned, if there is any crush or avulsion, then it may be wise to tag the nerve endings using radiopaque clips, staples, or a small Prolene suture and come back in 3 weeks to adequately assess the scar formation. If the nerve repair was done 3 weeks or more after the original injury, it should be possible to adequately assess the scarred nerve endings. Any neuroma and scar are excised sharply using a scalpel, with the nerve placed on a flat, sterile wooden tongue depressor. The nerve stumps should be sliced proximally and distally (like slicing a loaf of bread) until a healthy fascicular pattern is visualized. This is called *les yeux d'escargot* (snail's eyes) (Figure 3). This pattern of healthy fascicles protruding from the cut nerve endings is due to the pressure within the endoneurium. The fascicles that protrude past the cut nerve ending should be further divided until all the fascicles lie flush with the epineurial sheath. This is critical so that the fascicles do not overlap once the epineurium is sutured. Any overlap of fascicles could lead to failure of the axonal sprouts to find the distal endoneurial tubes.

Tension-Free Nerve Coaptation

Direct coaptation is the traditional gold standard for nerve reconstruction. This technique delivers the axonal sprouts into their distal targets via a single suture line, which increases the feasibility of fascicular alignment. Thus, by decreasing fascicular mismatch, it theoretically improves outcomes (Figure 4).

Following meticulous preparation of the nerve endings, the tourniquet is usually deflated. Nerve coaptation by direct end-to-end suture of nerve stumps is then performed using several interrupted 9-0 or 10-0 nylon sutures. As a rule of thumb, the smaller the number of sutures used to approximate the nerve accurately, the better the outcome. Good results with fibrin glue have been reported, and it

FIGURE 3 The damaged nerve ending, which in this case is a neuroma, is cut back until healthy fascicles are visualized, called *les yeux d'escargot*.

can be combined with minimal interrupted nylon sutures. Nerves are generally repaired with an end-to-end coaptation.

It is extremely critical that there be no tension whatsoever on the repair. One recent significant finding in nerve repair studies is that nerve repair success decreases significantly if there is any tension on the repair. It is more important to have a tension-free repair than to perform a primary nerve coaptation. Some studies have reported that leaving a submillimeter gap between the nerve stumps can improve axonal migration, reduce fascicular mismatch and improve outcomes. If needed, a nerve graft or interpositional bioabsorbable nerve conduit can be used. Some additional length on the nerve can be achieved for certain nerves such as the ulnar nerve at the elbow, which can be transposed anteriorly to the medial humeral epicondyle to give several centimeters of extra length. Most nerves do not have the ability to be transposed to add length. It is critical to never use positioning of joints, such as flexion of the elbow, to give added length to the nerve. This will result in stretching of the nerve and poor outcome when the limb is straightened later.

Epineurial Versus Grouped Fascicular Repair

For primary nerve repair, an epineurial repair is usually the most predictable (see Figure 4). The external epineurial vessels can be arranged to ensure that the fascicles are appropriately aligned. Additionally, to facilitate restoration of fascicular orientation, it is important to be familiar with the serial cross-sectional fascicular topography, fascicular stimulation, histochemical stains, and gross fascicular matching. Often, only two or three interrupted sutures are necessary to align and coapt the nerve endings. It is critical at this stage to ensure there is no overlapping of the fascicles (Figure 5). The fascicles should just be gently coapted within the epineurium. It is also important to make sure the needle passes only through the epineurium and does not catch a portion of one of the fascicles because this can lead to a small intraneural neuroma, and the fascicle will not heal properly.

Occasionally, it is appropriate to perform fascicular or grouped fascicular repairs. In a large nerve where the fascicles are easily identifiable, it may be possible to suture the internal epineurium between the fascicles with a few small, interrupted nylon sutures and then perform the epineurial repair. Some researchers have reported that grouped fascicular repair results in more intraneural scarring, so most peripheral nerve surgeons continue to use the epineurial repair.

Management of the Nerve Gap

Most often the resection of the scarred nerve endings will result in some amount of nerve gap. Nerve gaps require alternative methods of nerve repair such as interpositional nerve grafting or use of an off-the-shelf bioabsorbable nerve conduit, which is excellent for gaps less than 3 cm (Figure 6). Prospective double-blind trials have shown that using a bioabsorbable nerve conduit results in better two-point discrimination than primary repair with nerve grafts in digital injuries with gaps less than 3 cm. Nerve transplants and decellularized nerve allografts have been reported, and the specific indications and outcomes are still evolving.

Using a nerve conduit requires an entubulation technique. The nerve conduit must be the correct diameter to accommodate the nerve. The nerve conduit should be approximately 10 mm longer than the nerve gap (e.g., a nerve gap of 3 cm would require up to a 4-cm nerve tube). The entubulation technique involves placing the proximal nerve ending 5 mm within one end of the nerve tube and the distal nerve ending 5 mm within the distal end of the nerve tube. Using a horizontal mattress suture, enter the nerve conduit 5 mm from the ending, suture the epineurium of the nerve ending itself and pull it 5 mm into the nerve tube, and tie the suture on the outside of the nerve conduit. A couple of extra epineurial interrupted sutures can be placed from the epineurium to the end of the nerve tube. This, of course, should be performed without the tourniquet so perfect hemostasis can be determined. Blood from the nerve ending must not be allowed to enter the nerve tube and coagulate. The final step is to flush any blood or debris out of the nerve conduit with heparinized saline. If a synthetic, biodegradable nerve conduit is not available, an acceptable alternative is autogenous vein grafting. These do tend to collapse, however, and the final results are not as predictable.

For nerve gaps greater than 3 cm, an interpositional nerve graft should be used. There are many potential donor sites for nerve grafts, and the patient must give consent preoperatively if a nerve graft is a possibility.

To calculate the length of the graft, measure the gap and add 10%. Calculating the graft length by this method will prevent tension on the reconstruction. To maximize the surface area at the repair sites, one or several "cable" grafts may be used (Figure 7). Either individual suturing or grouped suturing of the cable grafts is acceptable.

The nerve graft should be sutured into place in a reversed fashion from its usual anatomic course (i.e., the more distal end of the nerve graft should be sutured to the proximal end of the nerve gap being repaired, and the proximal end of the nerve graft should be sutured to the distal end of the nerve gap). This ensures that axons will not be lost through small side branches in the nerve graft as the axons grow through the graft. When the diameter of the nerve at the site of repair is much larger than the diameter of the nerve graft, grouped fascicular repair may be utilized. As mentioned before, it is critical to know the appropriate anatomic topography of the fascicles in the nerve to guarantee that motor fascicles are grafted to motor fascicles

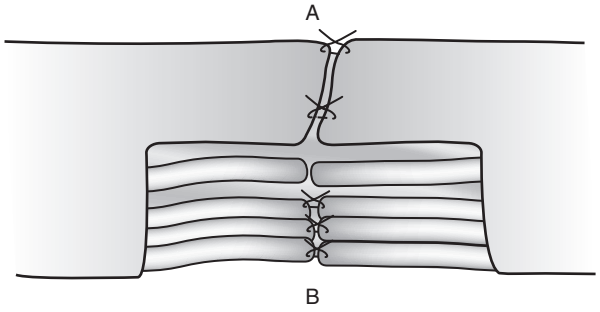

FIGURE 4 Nerve repairs. **A**, Epineurial repair. Note that the visible fascicles under the epineurium are opposed without overlap, and epineurial vessels are used to align nerve ends. **B**, Grouped fascicular repair.

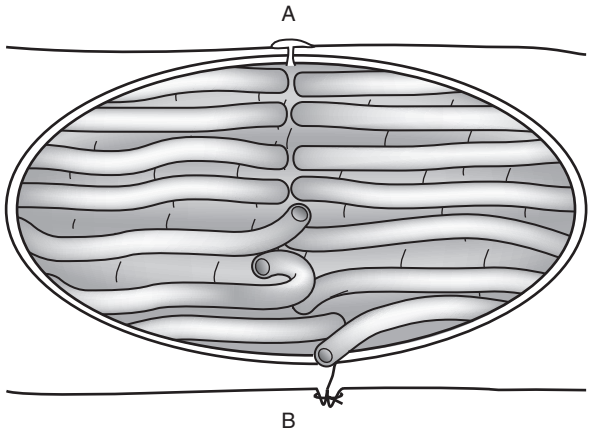

FIGURE 5 **A**, Appropriately trimmed fascicles will lightly oppose when the epineurium is gently approximated. **B**, Fascicular overlap and disorder may arise when fascicles have not been trimmed and protrude from the epineurium or when the epineurial repair is too tight.

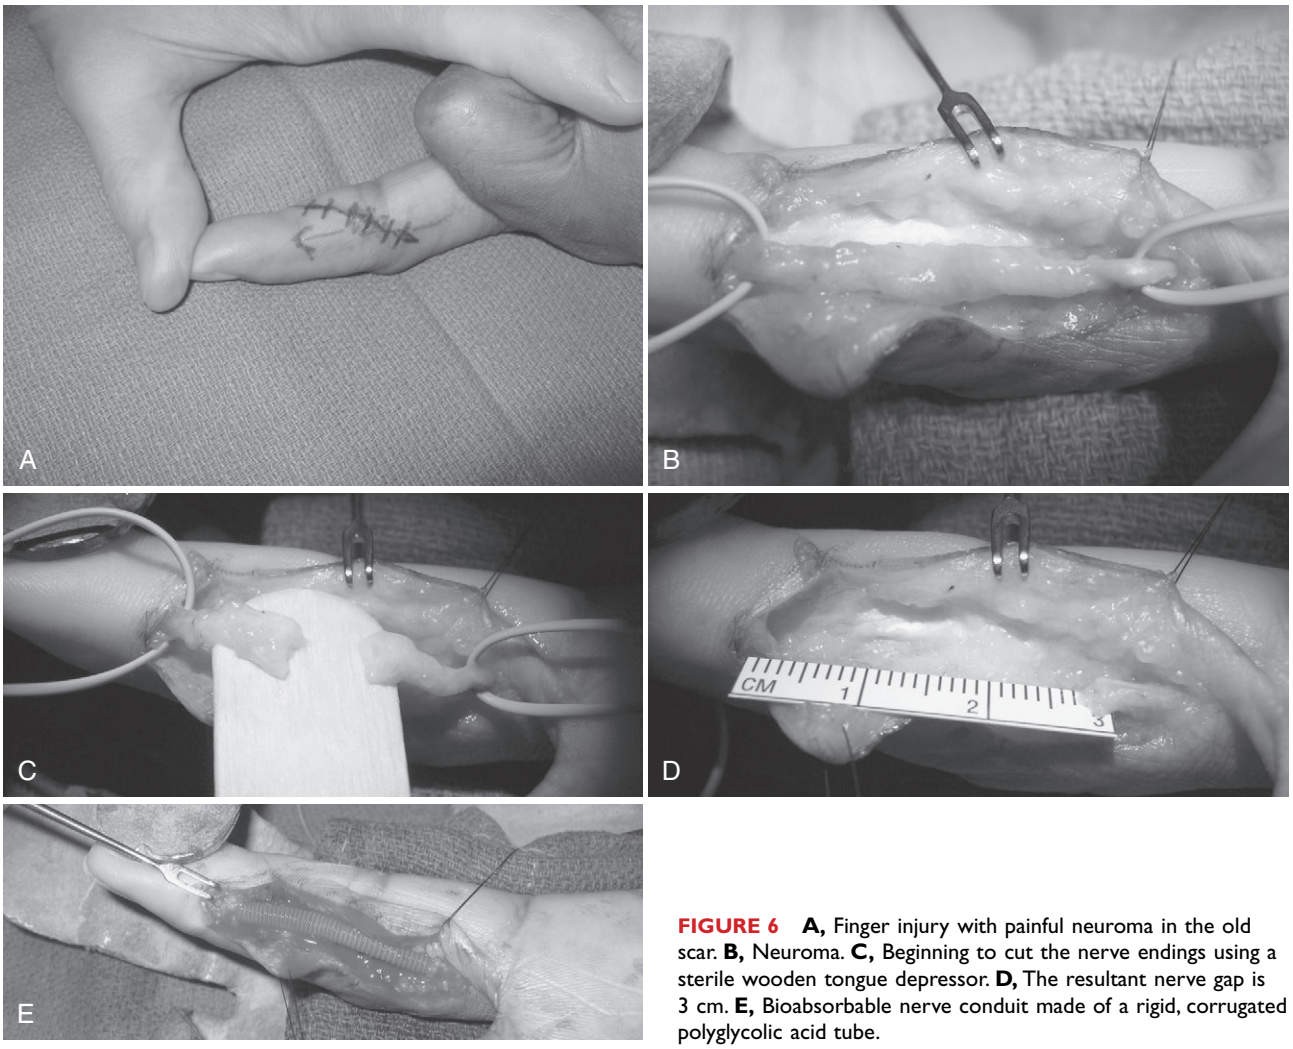

FIGURE 6 **A,** Finger injury with painful neuroma in the old scar. **B,** Neuroma. **C,** Beginning to cut the nerve endings using a sterile wooden tongue depressor. **D,** The resultant nerve gap is 3 cm. **E,** Bioabsorbable nerve conduit made of a rigid, corrugated polyglycolic acid tube.

and sensory fascicles are grafted to sensory fascicles. An inevitable disadvantage of nerve grafting is donor site morbidity. Permanent sensory loss is expected, and a small chance of neuropathic pain exists. The practice of using vascularized nerve grafts to improve the speed and quality of regeneration remains controversial.

Nerve Transfers

Nerve transfer *(neurotization)* refers to the procedure of transecting an expendable working nerve, branch, or fascicle in the vicinity of an injured nerve to coapt it to the nonfunctioning nerve. The main advantages of nerve transfers are better proximity to the end organ (which in turn decreases the time to reinnervation) and the fact that distal nerves contain a larger number of relatively "pure" (motor or sensory) axons (i.e., since nerve transfers involve the distal components of the nerve, at this level the axons are either motor or sensory). Indications for nerve transfers are summarized in Table 3.

When nerve transfer is indicated, outcomes are improved because this can be performed more distally and closer to the muscles in question than other repair techniques (i.e., proximal reconstruction with coaptation, conduits, and grafts). For example, an upper trunk brachial plexus injury would result in a loss of flexion of the elbow. If the lower trunk is intact, redundant fascicles of the ulnar nerve to the flexor carpi ulnaris muscle or from the median nerve going to

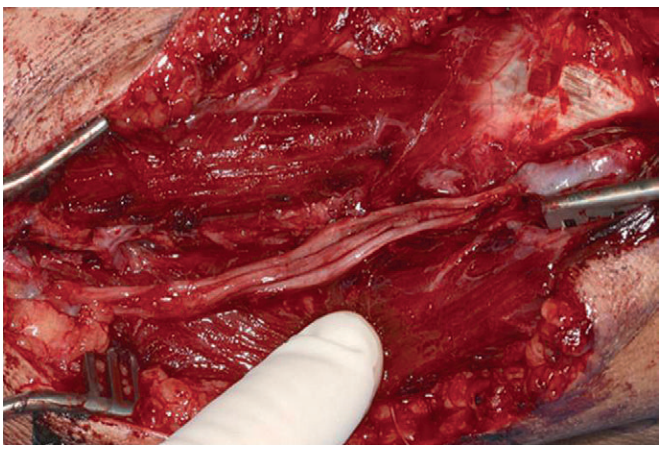

FIGURE 7 Intraoperative photograph of three sural nerve segments bridging a radial nerve gap in the distal arm following a humeral fracture.

superficial flexor muscles can be transferred to either the brachialis or the biceps motor nerve. This will result in faster reinnervation of the muscles than if a repair of the upper trunk of the brachial plexus was performed because it would take many months for the axons to grow all the way down into the arm.

Based on the expected time to reinnervation, the benefits of nerve transfers versus nerve grafts should be carefully evaluated for each clinical scenario. Most surgeons advocate distal nerve transfers closer to the end organ as opposed to proximal nerve grafting farther from the end organ.

Nerve Compression

Some nerve injuries do not result in interruption of the nerve but rather in a lesion-in-continuity with a (+) NAP. These nerve injuries do not need resection of the nerve with grafting, but rather they can improve dramatically with appropriate decompression of the nerves with neurolysis (i.e., releasing scar tissue and compressive bands or fascia surrounding the injured nerve). Generally, external neurolysis completed during the nerve exposure will suffice.

POSTOPERATIVE MANAGEMENT

Postoperative management begins in the operating room, even before closing the skin. Once the nerve has been repaired, the joints should go through the full range of motion to look for any signs of nerve tension. It is critical to detect tension on the nerve repair at this stage because tension can greatly diminish the functional outcome. Once the skin closure is complete, the extremity should be immobilized in a very well-padded, protective splint for 7 to 10 days. At this point, gradual protective range of motion to promote neural gliding can begin under the careful direction of a physical therapist or occupational therapist experienced in nerve injuries. Range of motion should be gradually increased over the next 6 to 8 weeks. Physical therapists are integral to keeping the limb supple and free from contractures. Occasionally, patients have paraesthesia/dysesthesias of the neurosensory territories. These can be treated with Neurontin or Lyrica, and the occupational therapist or physical therapist can begin desensitization programs. Follow-up of nerve repairs is required for at least 2 years in children and up to 5 years in adults. The regeneration period is longer, and sensory/motor reeducation is more challenging in adults.

Sensory and Motor Reeducation

Any sensory nerve repair can have an improved outcome if sensory reeducation regimens are implemented. When motor nerves are repaired, it is critical for a physical therapist and occupational therapist to assist the patient with motor retraining as the muscles become reinnervated.

SUMMARY

A thorough knowledge of anatomy, the nerve injury process, and available repair and reconstructive options along with specific microsurgical skills in the context of a multidisciplinary team are required for optimal nerve injury management. The basic tenets of nerve repair are summarized in Table 5, and the expected outcomes are provided in Table 6. Figure 8 summarizes the proposed nerve injury management algorithm.

TABLE 5: Principles of nerve repair

1. Medical stability of patient
2. Preoperative and postoperative quantitative assessment of sensory and motor function
3. Early surgical exploration if open injury for microsurgical repair with appropriate magnification, sutures, and instrumentation
4. Bloodless field under tourniquet control, when possible
5. Extent of zone of injury assessed appropriately. All scarred nerve must be resected.
6. Primary nerve repair when clinical and surgical judgment permits
7. Secondary repair if zone of injury indeterminate at initial exploration
8. Tension-free nerve repair
9. Interpositional nerve graft or bioabsorbable nerve conduit, if direct repair would result in tension
10. Avoidance of positional or postural maneuvers to facilitate tension-free repair
11. Epineurial repair unless intraneural topography dictates group fascicular repair
12. Postoperative immobilization for 7 to 10 days, followed by early-protected motion
13. Postoperative sensory and motor reeducation
14. Routine postoperative monitoring with noninvasive neurosensory testing

TABLE 6: Expected outcomes from repair and reconstruction

Relevant factors	Functional outcomes
The "best surgery is no surgery"	Spontaneous recovery > nerve repair
Patient age	Younger patient > older patient
Level of injury	Distal > proximal
Type of nerve injured	Pure nerves > mixed nerves
Specific nerve involved	Radial nerve > median nerve > ulnar nerve Nerves C5 and C6 and those of the upper trunk > nerves C8 to T1 and those of the lower trunk Tibial nerve > peroneal nerve

TABLE 6: Expected outcomes from repair and reconstruction—cont'd

Relevant factors	Functional outcomes
Mechanism of injury	Lacerations > low-velocity gunshot injuries > high-velocity gunshot injuries Transections > crush or avulsion injuries Stretch injuries > ruptures > avulsions
Timing of repair and reconstruction	The "earlier the better." Waiting 2 to 3 weeks might be reasonable in some instances (blunt or ragged transections or injuries with significant crush or avulsion component) to allow time for better definition of the zone of injury.
Type of repair or reconstruction	Neurolysis alone because of a (+) NAP has good results 90% of the time. Direct end-to-end nerve repair > interpositional nerve grafting Distal nerve transfer > proximal nerve grafts Direct nerve transfers > nerve transfers with interpositional grafts

Extremity Gas Gangrene

Sharon Henry, MD

INTRODUCTION

Hippocrates in 5 BC provided the earliest description of the generic disease process of a severe necrotizing soft tissue infection (NSTI). Many additional descriptions appeared later in the medical literature, especially around the time of the Civil War. The term gas gangrene is used specifically to describe clostridial myonecrosis. These infections are rare and may only be seen a few times in the career of a community surgeon. An estimated 1000 to 3000 cases occur annually in the United States. Furthermore, these infections are life and limb threatening. Prompt identification and quick and efficient treatment are imperative.

The presentation of patients with infection from clostridium is frequently dramatic. The infection can begin innocuously but progresses rapidly. The initial signs are nonspecific and include erythema, swelling, and pain. The erythema transforms into necrosis, often first becoming violaceous or purpuric. The swelling becomes indurated, and the pain abates as the tissue necrosis progresses. Systemically, the patient often describes flulike symptoms of nausea, vomiting, fever, and muscle aches. The patient may describe lightheadedness and present to the hospital with full-blown sepsis.

The infection occurs most commonly in traumatic or postoperative wounds. Cases have also been described after illicit and therapeutic drug injection, and in some studies, as many as 50% of cases are idiopathic. Some patients with development of gas gangrene have no underlying medical conditions. Others have a variety of medical conditions (Table 1).

BACTERIOLOGY

Clostridia bacilli are toxin-producing bacteria that invade tissue and cause tissue necrosis, gas formation, and tissue destruction. They are anaerobic, spore-forming, gram-positive bacteria that are found in the soil. The spores are heat resistant and can persist in the environment for extensive time periods. Areas of tissue hypoxia are fertile sites for growth that can be rapid. More than 150 species of clostridia have been identified, but perfringens, novyi, histolyticum, septicum, bifermentans, and fallax are most commonly involved with infection.

Infections caused by *C. septicum* are frequently associated with malignancy, either overt or occult. These are frequently gastrointestinal malignancies. All species produce a variety of exotoxins (Table 2), but the alpha toxin is most associated with the tissue destruction that allows the organism to invade the muscle. The toxins produce capillary and small vessel thrombosis, which results in necrosis of tissue augmenting the hypoxic environment and facilitating the spread and growth of the organisms. The toxin also has a direct negative effect on movement of neutrophils to the site of injury or infection.

DIAGNOSIS

Clinical Examination

The challenge of treatment of gas gangrene begins with the challenge of the diagnosis. Tissue crepitus is pathognomonic but not always present. The skin findings of multiple bullae with violaceous or purpuric skin discoloration occur late. Systemic sepsis is also a late finding. The objective is identification of the process early, before the patient has suffered significant tissue damage and is in profound shock.

Laboratory Tests

Laboratory tests may reveal profound derangements as a result of damage from toxin elaboration. Severe leukocytosis or leukopenia, hyponatremia, lactic acidosis, thrombocytopenia, coagulopathy, elevation of C-reactive protein, creatine kinase, and liver function tests can be seen but are nonspecific. Some attempts have been made to use routine diagnostic laboratory tests to discriminate necrotizing soft tissue infection from cellulitis. Wall and associates found serum sodium (Na) <135 mEq/L, white blood cell count (WBC) ≥15 × 10^9/L, and blood urea nitrogen (BUN) >15 mg/dL to be found more commonly in patients who are diagnosed with NSTI than those with cellulitis. Wong and his colleagues created a scoring system based on C-reactive protein, leukocyte count, hemoglobin, sodium, creatinine, and glucose measured at admission. Patients with scores of more than six had an increased likelihood of NSTI.

Diagnostic Radiography

Diagnostic radiology can be helpful. Plane x-rays may show air in the soft tissues not appreciated on physical examination. Ultrasound

scan with duplex of the extremity can show venous and arterial occlusions. Sonography can also show air and fluid collections that may not be appreciated on physical examination. Computed tomographic (CT) scan is even more sensitive for the identification of air in the tissues. In addition, it is capable of identifying subfascial or intramuscular fluid collections. When performed with intravenous contrast, it can also identify unperfused muscle. Magnetic resonance tomography can also show gas, fluid collections, and edema and perfusion abnormalities of the muscle, which may aid in the diagnosis of NSTI. These studies are frequently most useful for demonstrating the extent of disease, which helps to guide operative intervention. Unfortunately, nonspecific findings on radiologic studies are not necessarily helpful in excluding the infection. Thus, a CT scan that shows only tissue edema in a patient with severe cellulitis and blistering with a high WBC and hypotension does not rule out the possibility of an NSTI.

TREATMENT

The approach to the treatment of patients with NSTI in general or gas gangrene specifically begins with resuscitation. These patients often experience significant delays in reaching medical therapy because the diagnosis was missed early, either because they were thought to have simple cellulitis or they did not present for medical evaluation until physiologic decompensation had already occurred. In either case, a rapid and aggressive attempt to correct the abnormal physiology should be undertaken. Volume resuscitation begins, with the administration of isotonic crystalloid. Blood, fresh frozen plasma, platelets, or other component therapy is given to begin correction of abnormalities identified. Adequate quantities of blood and components should be available for the operating room (OR) because extensive blood loss is possible. Even after adequate volume resuscitation, shock can commonly persist. This can result from the inflammatory response to the sepsis or toxemia. In these cases, addition of pressors and inotropes may be necessary to allow for safe administration of anesthesia. Broad-spectrum antibiotics should be given to cover the suspected pathogens. Clostridia are generally responsive to penicillin G, but resistance is increasing. Many other antimicrobials are also effective against clostridia (Table 3). The combination of penicillin and clindamycin is considered the most effective. Gram-negative and methicillin-resistant staphylococcus coverage should be added until definitive diagnosis has been made. Placement of large-bore intravenous access for resuscitation and monitoring is necessary.

An arterial line is frequently necessary, especially if pressors or inotropes have been required.

Tetanus immunization status should be assessed and the patient appropriately treated (Table 4).

Operative Treatment

Although these patients present with severe physiologic derangements and some attempt at correction must occur before surgery, it is important to recognize that the physiology will not be restored with medical therapy alone and proceeding to the OR, even with persistent abnormalities, is a risk that must be taken. The resuscitation can continue into the operative phase of treatment. The extremity must be circumferentially prepped and draped, extending to the joint above and below the involvement. When the diagnosis is in question, exploration of the extremity can be diagnostic. Vertical skin incisions are made usually over the area of maximal skin abnormality because the skin has to be removed with evidence of necrosis or purpura. The dissection must continue through the deep fascia and muscle thoroughly inspected. Tissue cultures should be obtained; if any diagnostic uncertainty exists, pathology should also be sent. Stat gram stains can give an indication of the types of bacteria present and influence antibiotic choice. Frequently the subcutaneous fat and superficial fascia are involved. Extensive débridement of this layer often produces skin compromise that results in large surface area wounds that require skin grafting for closure. Toxin production and bacterial spread along the fascial plane make blunt dissection easy, with the superficial layers separate from the deep, offering minimal resistance. With operation on patients with intravenous drug use, needles may be found in the subcutaneous tissues, and tissues should be handled preferentially with instruments rather than finger dissection. Compromised muscle either has a congested appearance or is very pale, depending on the time course of the process. Nonviable muscle is friable and peels away easily, offering little resistance to removal. The cut edges often do not bleed or produce only venous blood. The muscle does not contract when stimulated with the cautery; this is independent of muscle relaxation. Knowledge of the distribution of the neurovascular bundles in the compartments is important when performing these débridements because functional outcome can be impaired through inadvertent or unnecessary transection of blood vessels or nerves. Historically, amputation has been the only procedure recommended to treat gas gangrene. The goal is to get ahead of the infection. The limb is removed above the level of gross involvement of the infection. If amputation is planned, through joint amputation should be considered because it is frequently less time consuming and results in lower blood loss. It also spares tissue that can be used for reconstruction or closure. Blood loss can also be diminished through the use of a tourniquet during surgery. Tourniquet use is generally discouraged in the patient with vascular disease or diabetes undergoing an amputation; however, in a patient with an unstable condition with coagulopathy or thrombocytopenia, use of this device may prevent further destabilization from blood loss. Unfortunately, if hip or forequarter amputation is necessary, tourniquets are not an option. There is a balance between aggressive débridement to remove compromised tissue and arrest growth of bacteria and extension of the infection with tissue preservation for future reconstruction. Reexploration is the rule rather than the exception. Caring for these patients is resource intense. Hospital and intensive care unit stays are long. The patients are initially returned to the operating room within 24 to 72 hours, and sooner if they have progression of the infection. Repeated operating room washouts and inspections are necessary in these large wounds. Reconstruction or stump closure is only performed when the infection is well controlled and the patient has been assessed for adequacy of blood flow, arterial and venous. Sepsis and the large surface area of the wound combine to increase the basal metabolic rate and increase nutritional requirements. Supplemental tube feeding is frequently necessary. Reconstruction should be delayed until markers of nutrition are improving.

TABLE 4: Tetanus toxoid recommendations for high-risk wounds

	Yes	No	Never immunized or immunocompromised
Immunized within 5 years	No booster	Booster	Vaccine and tetanus immunoglobulin 250 IU

Hyperbaric Oxygen

When available, hyperbaric oxygen (HBO) is used to aid the treatment of this infection. Very high levels of dissolved oxygen are produced and may result in bacterial killing of anaerobic organisms. Some animal data suggest that HBO is synergistic with antibiotics and deactivates exotoxin. Resuscitation, antibiotic administration, and surgical débridement should never be delayed to allow for the use of HBO.

OUTCOME

Elliot and colleagues found that mortality correlated with the presence of organ failure at admission and delay in first débridement. Anaya and associates found death to occur more commonly in patients who had a WBC >30 × 10^9/L, serum creatinine >2 mg/dL, or preexisting heart disease. Others have found that mortality increased with the presence of premorbid conditions. Mortality was more than 50% in patients who had three or more of the following risk factors: age more than 50 years, malnutrition or obesity, diabetes, injection drug use, and hypertension.

Necrotizing Skin and Soft Tissue Infections

Patrick B. O'Neal, MD, and
Kamal M.F. Itani, MD, FACS

OVERVIEW

Necrotizing skin and soft tissue infections (NSTIs) represent a range of infectious conditions that cause deep tissue necrosis. NSTI is described by terms based on location of infection, pathogen, and depth of necrosis. The most frequently used terms are necrotizing fasciitis, Fournier's gangrene, clostridial myonecrosis, synergistic necrotizing cellulitis, and gas gangrene. Necrotizing fasciitis represents infection that extends through the deep fascia below the subcutaneous layers. Fournier's gangrene is a similar condition that originates in the perineum, whereas clostridial myonecrosis and synergistic necrotizing cellulitis extend into the deep muscle compartments and cause muscular necrosis. These diseases have received extensive media attention and have been lumped under the catchy rubric of "flesh-eating" bacterial disease. Hippocrates (500 BC) acknowledged necrotizing fasciitis as "diffuse erysipelas caused by trivial accidents, where flesh, sinews, and bones fell away in large quantities, leading to death in many cases." The elaborate categorization of these conditions has caused confusion regarding this disease. Put simply, the pathophysiology of these infections in all categories is the same and is the result of bacterial penetration of skin defenses causing widespread necrosis and leading to rapid systemic deterioration and death. Any patient with signs or symptoms concerning for NSTI should raise a sense of urgency in the clinician for rapid diagnosis and early treatment. Unfortunately, the diagnosis of NSTI can be difficult and tempt the clinician to postpone lifesaving treatment while obtaining time-consuming diagnostic studies. This should be absolutely avoided in favor of urgent operative management.

PATHOPHYSIOLOGY

NSTI occurs when bacteria gain entry into the subcutaneous layers of the body where areas of relatively poor blood flow and relative hypoxia exist. Such conditions allow for poor immune response to infection and rapid overgrowth and spread of bacteria. Often, these microorganisms elaborate toxins that lead to both direct necrosis and indirect necrosis through thrombosis of perforating vessels and vasoconstriction increasing tissue hypoxia. Furthermore, these bacteria elaborate exotoxins that can lead to shock and multiorgan dysfunction.

DIAGNOSIS

Necrotizing fasciitis is a rare disease with an incidence rate estimated at 0.4 cases per 100,000 individuals by the U.S. Centers for Disease Control. Because delay in adequate treatment can have tremendous deleterious effects on outcome with increased morbidity and mortality, early diagnosis is paramount with necrotizing soft tissue infections. A thorough history and physical examination should be performed because this diagnosis relies more on clinical judgment rather than diagnostic testing. Certain comorbidities may predispose patients to this disease. Such conditions include advanced age, obesity, diabetes mellitus, alcoholism, cirrhosis, chronic debilitation, vasculopathy, intravenous drug use, immunosuppression, malignancy, chemotherapy, hypertension, chronic obstructive pulmonary disease (COPD), congestive heart failure (conditions that impair oxygen delivery), end-stage renal disease, perirectal abscess, perforated viscus, and recent surgery. A thorough history for assessment of patient comorbidities and risk factors may help raise suspicion of this problem. Despite this extensive list of predisposing conditions, as many as 20% of NSTIs occur in patients with no apparent predisposing factor. Although NSTI may seem to occur spontaneously without any clear injury or portal of entry, NSTI often originates in the perineum, diabetic foot ulcers, decubitus ulcers, incision sites, and puncture and traumatic wounds and as a result of perforated viscus with subsequent seeding of soft tissues.

Initial physical examination findings may range from minimal to quite dramatic (Table 1). One may appreciate swelling, induration, mild to exquisite tenderness, mild to violaceous erythema, tenderness beyond areas of erythema, cutaneous anesthesia, necrotic tissue or skin with a blue or purplish hue, and wounds with exuding purulent, gray, or foul-smelling drainage (Figure 1). The skin may blister or slough, and crepitus may be present, indicating gas formation in the tissues. Crepitus, however, is present in only a fraction of patients and should not be relied on for diagnosis. One must keep in mind that obvious stigmata of NSTI may be subtle. Any patient with soft tissue pain out of proportion to examination findings should be considered to be potentially harboring an elusive deep NSTI that has yet to make itself obvious because early skin changes may be minimal despite extensive subcutaneous fat, fascia, or muscle destruction. Tenderness beyond areas of erythema may be particularly ominous because it is indicative of rapidly progressive infection in the deep layers beneath the skin.

The hallmark of NSTI is its rapidly virulent and destructive behavior. Tracking within the fascial planes beneath the skin, a place with poor vascularity and thus host defenses, allows for the rapid spread of bacteria and overwhelming infection. Most patients have quick development of signs of systemic toxicity, which include high fever, nausea, vomiting, malaise, tachycardia, hypotension, shock, mental status changes, and oliguric renal failure.

Laboratory values are nonspecific. White blood cell counts may reveal extreme leukocytosis, leukopenia, and high bandemia. Other common laboratory abnormalities include those that indicate

TABLE 1: Necrotizing fasciitis signs and symptoms

Early	Late
Local

LRINEC Score

Points, sum	Risk category	Necrotizing fasciitis probability
≤5	Low	<50%
6-7	Intermediate	50%-75%
≥8	High	>75%

For patients at intermediate and high risk, the model has positive predictive value of 92% and negative predictive value of 96%.
Wang YS, Wong CH, Tay YK: The LRINEC [Laboratory Risk Indicator for Necrotizing Fasciitis] score: a tool for distinguishing necrotizing fasciitis from other soft tissue infections, Crit Care Med *32:1535-1541, 2004.*

dehydration/fluid sequestration, such as low bicarbonate levels, elevated blood urea nitrogen, creatinine, and lactate levels. In addition, patients may present with hypoalbuminemia, elevated creatine phosphokinase, hyponatremia, and coagulopathy. The Laboratory Risk Indicator for Necrotizing Fasciitis (LRINEC) score system (Table 2) can be used as an adjunct for assessment of probability of necrotizing fasciitis. This should not, however, discourage operative débridement when clinical suspicion is high.

Because of the rapid lethality of necrotizing soft tissue infection, one should be cautious about obtaining advanced radiographic evidence of disease as this can delay lifesaving operative treatment. If obtained quickly in patients with relatively stable conditions, plain films may reveal air tracking in the soft tissues. Computed tomographic scan and magnetic resonance imaging may show air tracking in soft tissues, fascial separation, and abscess formation, but often these studies do not add much because they may only reveal nonspecific fat stranding. In patients with unstable conditions, these studies should be avoided in favor of rapid transfer to the operating room.

Biopsy of involved tissue typically reveals liquefaction necrosis of subcutaneous tissues and fascial layers with polymorphonuclear infiltrates and thrombosis of the perforating vessels to the skin. The fascial plains may weep a dishwater-appearing or hemorrhagic fluid.

MICROBIOLOGY

Necrotizing fasciitis has recently earned a classification system based on the pathogen of origin. Type I represents polymicrobial infections, type II represents monomicrobial infections, type III represents marine organisms, and type IV represents fungal organisms. In all classifications, the organisms gain entry to the subcutaneous spaces, multiplying in areas of relative hypoxia and low blood flow and allowing for rapid proliferation.

As many as 75% of necrotizing soft tissue infections are polymicrobial, with an average of four organisms in a single infection (Table 3). For this reason, initial antibiotic treatment should be broad

TABLE 3: Organisms recovered from 198 consecutive patients with necrotizing soft tissue infections

Organism	No. of cultures	No. of isolates (% of cultures)
Aerobic		
Streptococci	182	83 (45.6)
Enterococci	182	61 (33.5)
Staphylococci	182	64 (35.2)
Escherichia coli	182	57 (31.3)
Proteus spp.	182	38 (20.9)
Other gram-negative bacilli*	182	76 (41.8)
Anaerobic		
Peptostreptococci	131	45 (34.4)
Bacteroides spp.	128	70 (54.7)
Clostridium perfringens	129	12 (9.3)
Other clostridia	128	17 (13.3)
Other anaerobic species	128	27 (21.1)
Fungal species	171	9 (5.3)

*In order of prevalence: *Klebsiella* spp., *Enterobacter* spp., *Pseudomonas*, *Acinetobacter* spp., *Eikenella corrodens, Citrobacter feundii.*
Elliott DC, Kufera JA, Myers RA: Necrotizing soft tissue infections: risk factors for mortality and strategies for management, Ann Surg *224:672-683, 1996.*

in spectrum. Polymicrobial infections often cause extensive local damage but on the whole are less lethal than other highly virulent monomicrobial infections. The most commonly isolated gram-positive organisms in polymicrobial infections include *Staphylococcus aureus*, *Streptococcus pyogenes*, and *Enterococcus*. *Escherichia coli* is the most common gram-negative organism isolated, whereas *Bacteroides* and *Peptostreptococcus streptococcus* are the most common anaerobes isolated from polymicrobial infections.

The patient's history and physical examination may provide clues as to which organisms may be the culprit of the soft tissue infection. Soft tissue infections located in the perineum, those secondary to perforated viscus, and those secondary to decubitus ulcers or diabetic foot ulcerations tend to be polymicrobial in nature. These infections may contain all three, gram-positive, gram-negative, and anaerobic, organisms.

Bite wounds and water-borne infections are unique subdivisions of polymicrobial infections that, in addition to the more common bacteria species, tend to harbor unusual organisms, including *Pasteurella multocida* in cat and dog bites and *Capnocytophaga carnimorsus* from dog bites. In human bite wounds, *Eikenella corrodens* is common. Water-borne infections often contain *Vibrio* and *Aeromonas* species.

Monocrobial infections tend to be more aggressive, commonly presenting with acute onset and rapid progression to fulminant infection. Highly virulent pathogens include *Streptococcus pyogenes* (group A β-hemolytic *Streptococcus*), *Clostridium* species, community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA), *Vibrio vulnificus*, and *Pseudomonas aeruginosa*.

Group A β-hemolytic *Streptococcus*, by far the most common monomicrobial isolate, can result in a rapidly progressive NSTI with systemic toxicity and high mortality rates. These bacteria produce exotoxins that independently cause systemic toxicity and result in multisystem organ failure. In addition, exotoxins released include powerful proteolytic enzymes such as hemolysins, fibrinolysins, hyaluronidases, antiphagocytic M proteins, leukocidins, and streptolysins O and S. These allow for rapid tracking through otherwise healthy tissue.

Clostridium species such as *Clostridium perfringens* are of particular concern in puncture and traumatic wounds and in intravenous drug users. *Clostridium* also produces exotoxins that are responsible for its rapid destructive spread, systemic toxicity, and high mortality. Clostridium reproduces every 8 minutes and produces α-toxin (phospholipase C) and θ-toxin (perfringolysin). These toxins cause direct tissue injury, kill neutrophils and impede migration, lead to hemolysis and microvascular thrombosis, and increase vascular permeability, which leads to rapid destruction of soft tissues including muscle tissue. In addition, α-toxin directly inhibits myocardial contractility, resulting in shock.

With the rise in MRSA in the community, the practitioner now sees NSTI as a result of MRSA infection. Community-acquired MRSA is able to produce coagulases that lead to direct tissue invasion and necrosis. In addition, these bacteria have the ability to produce Panton-Valentine leukocidin, which is a potent white blood cell and dermonecrotic toxin. Common populations affected with this disease include contact sports teams, prisoners, military recruits, injection drug users, institutionalized residents, and those who attend child and adult day care centers.

TREATMENT

Support

On identification of patients with necrotizing soft tissue infection, rapid operative management should be made the priority treatment and not be delayed for other therapeutic or monitoring measures. Nonetheless, supportive measures should be initiated as soon as possible, and these cases can be labor intensive from a supportive standpoint. Appropriate antibiotic therapy should be immediately delivered. Invasive monitoring should be implemented, including arterial lines for blood pressure monitoring and central venous lines for the delivery of medications and central venous pressure monitoring. Patients should receive aggressive fluid resuscitation and vasopressor and inotropic support when needed. Aggressive glycemic control can improve outcomes; thus, an insulin drip may be appropriate. Serial laboratory values should be obtained because these patients can have rapid fluid and electrolyte shifts. Foley catheter placement and lactic acid measurements can be used to direct fluid resuscitation. Urine myoglobin and creatine kinase levels should be obtained when myonecrosis is suspected. Blood products should be made available because development of coagulopathies or excessive operative blood loss is not unusual. Early parenteral or enteral support should be initiated on a patient-dependent basis. These patients exhibit high protein and caloric requirements because of their highly catabolic state.

Antibiotic Therapy

Antibiotic therapy should be initiated immediately on presentation and continued until no further evidence of infection in the involved tissues or sign of systemic toxicity is found. Antibiotic choice should initially be broad spectrum and then tailored to microbiology obtained from samples retrieved at the time of surgery (Table 4). One should acknowledge the likely origin of infection in choosing antibiotics. For example, infections from perineal and intraabdominal sources or from diabetic foot ulcers and pressure sores are more likely

TABLE 4: Suggested empiric antimicrobial therapy for necrotizing infections based on suspected causative organism

Agent	Dose	Comments
Infections from Mixed Organisms (e.g., intraabdominal source, diabetic foot infections)		
Piperacillin/tazobactam (Zosyn)	3.375 g IV q6h	Use aminoglycoside with anaerobic coverage in patients with severe penicillin allergy
Ertapenem (Invanz)	1 g IV q24h	Also provides MRSA coverage; may require added anaerobic coverage
Meropenem (Merrem IV)	1 g IV q8h	
Imipenem/cilastatin (Primaxin)	1 g IV q6-8h	Requires added anaerobic coverage
Tigecycline (Tygacil)	100 mg IV, then 50 mg IV q12h	Requires added anaerobic coverage
Ciprofloxacin (Cipro)	400 mg IV q12h	
Cefotaxime (Claforan)	1 g IV q8h	Provides anaerobic coverage and inhibits bacterial exotoxin production by ribosomes
Consider adding to any of these regimens:		
Clindamycin	600-900 mg IV q8h	
Infections from Streptococci (e.g., upper extremity/torso infections not associated with intraabdominal source)		
Penicillin	2-4 MU IV q4-6h	Use vancomycin, linezolid (Zyvox), or daptomycin (Cubicin) in patients with severe penicillin allergy
Plus:		
Clindamycin	600-900 mg IV q8h	Inhibits bacterial exotoxin production by ribosomes
Infections from Methicillin-Resistant *Staphylococcus aureus* (MRSA; e.g., institutionalized patients, athletes, IV drug users)		
Vancomycin	1 g IV q12h	Does not inhibit toxin production
Linezolid	600 mg IV q12h	Bacteriostatic; inhibits toxin production
Daptomycin	4 mg/kg IV q24hr	Bactericidal, myopathy, excellent tissue penetration
Ceftaroline	600 mg IV q12h	Bactericidal
Infections from *Clostridium* spp. (e.g., puncture wounds, traumatic wounds, severe early postoperative wound infection)		
Penicillin	2-4 MU IV q4-6h	
Plus:		
Clindamycin	600-900 mg IV q8h	
Infections from Animal and Human Bites		
Ampicillin/sulbactam	1.5-3 g IV q6-8h	
Cefuroxime (Ceftin, Zinacef)	1 g IV q24h	Good activity against *Pasteurella multocida* and *Eikenella corrodens*
Cefoxitin	1 g IV q6-8h	
Ciprofloxacin	400 mg IV q12h	
Infections from *Vibrio* spp. (water-borne infections; e.g., shellfish workers)		
Cefotaxime	2 g q8h	
Plus:		
Minocycline	200 mg IV load then 100 mg q12h	

h, Hour; *IV,* intravenous; *q,* every.

to be polymicrobial, whereas extremity infections are more likely to be monomicrobial. Extremity infections, infections related to intravenous drug use, and infections in patients from certain backgrounds, including prison inmates, Alaskan natives, institutionalized individual, and athletes, are more likely to harbor community-acquired MRSA.

Infections that are likely polymicrobial should be treated with broad-spectrum agents, such as imipenem-cilastin, meropenem, piperacillin-tazobactam, ticarcillin-clavulanate, and tigecycline. In patients with rapid spread or severe systemic toxicity, multiagent therapy should be considered. *Streptococcal* and *Clostridial* infections should generally be treated with high-dose penicillin and high-dose clindamycin. In addition to toxicity to said pathogens, evidence suggests clindamycin's ribosomal inhibitory properties may reduce toxin production responsible for widespread organ dysfunction, thus reducing toxicity. Infections at high risk for MRSA should be treated with antibiotic combinations including vancomycin or other anti-MRSA agent. Like clindamycin, linezolid also has ribosomal-blocking properties that may reduce toxin production.

A combination of penicillin and clindamycin with a gram-negative agent as empiric therapy provides several advantages, such as covering of a polymicrobial infection, the high prevalence of streptococcus in polymicrobial and monomicrobial infections, a better antibiotic tissue penetration, and the reduction in bacterial toxin production.

Surgery

Surgery should focus on rapid identification of affected tissue with complete excision of all devitalized skin and soft tissue (Figure 2). Reports show a sevenfold to ninefold increased risk of death with inadequate or delayed initial débridement. Incision should be made with dissection through all soft tissue layers until the deep muscle layers are encountered. A thorough probing of all tissue and fascial planes to assess for tracking should be made to direct further dissection. Typical findings that indicate devitalized tissue include murky dishwater-appearing fluid in the subcutaneous fat and fascial layers, tissue that dissects from deeper tissue with minimal resistance, nonbleeding tissue, and vascular thrombosis. Noncontractile muscle indicates devitalized muscle tissue. All tissue overlying involved fascial planes should be immediately débrided along with the affected fascia. Easy separation of fascia from underlying tissue with use of the "finger test" indicates active infection and indicates tissue that should be débrided. All fluid collections should be drained. Débridement should extend back to viable soft tissue and muscle that exhibit brisk bleeding. Tissue (including fascia) should be sent to microbiology for Gram stain and culture for aerobic, anaerobic, and fungal organisms to help tailor antibiotic usage.

In certain patient populations and NSTI presentations, operative management should be further tailored. Amputation may be necessary for infections that rapidly progress toward the trunk, involving major joints, or for extensive myonecrosis. Guillotine amputations of lower extremities should be considered, especially in patients with peripheral vascular disease for rapid containment of infection. In patients with Fournier's gangrene, all affected perineal soft tissue, including the scrotum and penile skin, should be débrided and colonic diversion considered. Colonic diversion may need to be delayed until a second operation depending on patient stability. Testicles can usually be preserved because they have an independent blood supply, although removal should not be delayed if they are involved. Patients with perforated viscus need the intraperitoneal injury to be addressed, likely with diversion if secondary to perforated colon.

Return to the operating room within 24 hours or earlier for a second look should strongly be considered, and débridement of any missed devitalized tissues performed. Patients may need multiple trips to the operating room before the infection is eradicated completely, with a median number of returns around four.

Wounds should be treated with serial wet-to-dry dressing changes until all infection has been cleared. Some authors prefer Dakin's solution–soaked or iodine-soaked gauze dressings, and some authors recommend the use of topical antibiotics, such as silver sulfadiazine. No tissue grafting should be attempted until the infection is fully treated and the patient's condition has stabilized.

Adjunct Treatments

Although urgent surgical débridement is the most important therapeutic maneuver for NSTI and should never be postponed in favor of other treatment modalities, it is worth mentioning a number of mostly theoretic adjunct treatments. These include hyperbaric oxygen therapy, intravenous immunoglobulin, and plasmapheresis. Hyperbaric oxygen therapy works on the premise that increased oxygen supply to infected tissues inhibits bacterial growth and improves host response to infection. Evidence supporting hyperbaric oxygen therapy is limited. Furthermore, because urgent surgical débridement is the most lifesaving therapy, no patient should be transferred to a facility housing a hyperbaric oxygen chamber without first undergoing adequate surgical débridement. Intravenous immunoglobulin works on the premise that the immunoglobulin binds exotoxins that cause systemic toxicity. Plasmapheresis works on the premise that it filters bacterial exotoxins that result in shock and multiorgan dysfunction. By reducing circulating toxin, intravenous immunoglobulin and plasmapheresis may hasten recovery from systemic shock. Again, evidence for these treatment modalities is controversial.

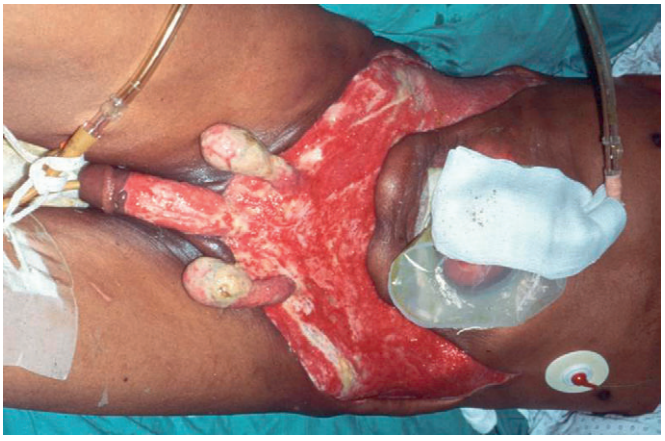

FIGURE 2 Extensive débridement of the scrotum, penis, perineum, and lower abdomen was performed. A sigmoid loop colostomy was also created. *(From Dolghi O, Itani KMF: Necrotizing infection of the perineum,* Hosp Physician *44(1):39-45, 2008.)*

RECONSTRUCTION

Reconstruction should be initiated as soon as possible once all infection has been eradicated and systemic toxicity has subsided. This aids in restoring hemostasis, speeds healing, decreases fluid losses, and improves final cosmetic outcome. Split thickness skin grafts are favored. Staging reconstructions are used for complex reconstructions. The assistance of a plastic surgeon or urologist may be beneficial for difficult areas such as the hands, face, and perineum, particularly if flaps are needed or pockets need to be made for uncovered testicles.

COMPLICATIONS

Multiple complications can occur with NSTI. Despite attempts at improving recognition and speed to surgical management of necrotizing fasciitis, improvement in mortality has been plagued with death rates remaining around one in four. Obviously, with the extent of débridement necessary, disfigurement and disability are considerable. Contractures can occur in involved limbs. Secondary infections in the critically ill are common and include line infections, pneumonias, urinary tract infections, and secondary soft tissue infections. For those with Fournier's gangrene, impotence and decreased sperm count or motility are common. In addition, débridement of the perirectal muscles may result in fecal incontinence and the need for a permanent colostomy.

CONCLUSION

Necrotizing soft tissue infections should be promptly recognized to expedite surgical treatment and minimize morbidity, long-term disability, and death. Diagnosis can be difficult, and no firm diagnostic criteria exist. The clinician must recognize the clues and have a low threshold for surgically exploring areas of concern.

Chest Wall, Mediastinum, Trachea

The Management of Primary Chest Wall Tumors

George J. Arnaoutakis, MD, and Avedis Meneshian, MD

OVERVIEW

A chest wall mass may represent any one of a broad spectrum of entities, ranging from benign or malignant primary chest wall tumors; locally invasive tumors originating from the lungs, pleura, mediastinum, or breast; metastatic lesions; and nonneoplastic (infectious or inflammatory) lesions. Of these, primary chest wall tumors, whether benign or malignant, are the least common; they comprise only 5% of all thoracic neoplasms. They are best classified according to their tissue of origin and are further subdivided as either benign or bearing malignant potential (Box 1). In this chapter, we review the most common primary chest wall tumors and focus on surgical management options, including chest wall resection and reconstruction.

DIAGNOSIS

The vast majority of patients with primary chest wall tumors present with a painless, enlarging mass. Other patients who are entirely asymptomatic may have a primary chest wall tumor detected with thoracic imaging studies performed for unrelated indications. Pain in a patient with a primary chest wall tumor likely represents bony erosion or involvement of adjacent nerves and is often a harbinger of malignant tumor behavior. Workup includes a history and physical examination, with attention directed to a history of other malignancies, radiation exposure (therapeutic or environmental), and overt signs of infection or inflammation on physical examination.

A plain film chest radiograph may reveal a soft tissue or bony abnormality. Contrast-enhanced thoracic computed tomographic (CT) scan can help delineate the extent of bony, soft tissue, pleural, lung, or mediastinal involvement and can also exclude nodal or pulmonary metastatic disease. Contrast-enhanced magnetic resonance imaging (MRI) can help delineate vascular or nerve involvement. A freely mobile mass less than 2 cm in size can generally be excised with clear margins, with achievement of both diagnostic and therapeutic purposes. In contrast, larger lesions or those that are fixed to the underlying bone or soft tissue should undergo core needle biopsy or open incisional biopsy before definitive resection. Care must be taken to plan these biopsies with a subsequent curative resection in mind, with incisions placed appropriately so as not to preclude subsequent complete resection as indicated. Tissue diagnosis before surgical resection can help exclude infectious or inflammatory lesions in which resection may not be necessary for treatment and may allow for neoadjuvant radiation or chemotherapy in the induction setting if the lesion is malignant.

BENIGN BONY AND CARTILAGINOUS TUMORS

Fibrous Dysplasia

The most common benign bony tumor of the chest wall, fibrous dysplasia represents a lesion in which normal marrow and cancellous bone is replaced with a fibrous stroma. It typically presents as a painless mass of the rib, commonly located posteriorly or laterally on the chest wall. Radiographic findings are variable but often include a central ground-glass appearance with punctate calcifications and peripheral cortical thinning. The tumors most commonly present as a solitary lesion in otherwise healthy individuals 20 to 30 years of age. However, these lesions can rarely be multiple and associated with the McCune-Albright syndrome, which includes cutaneous manifestations and endocrine abnormalities in the context of short stature and precocious puberty. No surgical therapy is indicated, unless the diagnosis remains questionable or the lesion is symptomatic. If so, limited partial rib resection is the definitive treatment.

Osteochondroma

A benign bony lesion that typically presents in the third decade of life, an osteochondroma classically involves the costochondral junction. These lesions can present either as a palpable painless mass or can grow unnoticed within the chest cavity to a larger size. Punctate central calcifications with a mineralized hyaline cartilage cap are characteristic radiologic findings. When these lesions are asymptomatic or small, observation with serial imaging is appropriate. Symptomatic or enlarging lesions can be resected with local excision. Although malignant degeneration is rare (<1% of patients), if the cartilage cap becomes greater than 2 cm in thickness, resection should be considered because malignant transformation to chondrosarcoma or osteosarcoma has been reported.

Chondroma

Chondromas are benign cartilaginous tumors that originate from the medullary cavity. They are more commonly found anteriorly in the

rib and have no gender predilection. They too present either as a painless mass or an incidentally documented lesion on imaging. On chest radiograph, characteristic findings include an osteolytic lesion with well-defined sclerotic margins. On CT scan or MRI, punctate calcifications and cortical scalloping may be seen. These benign lesions are difficult to differentiate from low-grade chondrosarcomas, radiographically and often histologically, and therefore should be resected with wide local excision.

MALIGNANT BONY AND CARTILAGINOUS TUMORS

Chondrosarcoma

The most common malignant chest wall tumor, chondrosarcomas most commonly occur in the fourth to seventh decades of life. Most involve the costochondral junction or the sternum. On imaging, irregular margins and bony destruction are typical (Figure 1). Early stage lesions can retain a thickened cortical cap, whereas more advanced tumors progress to complete cortical destruction and an associated soft tissue mass. Suspected benign chondromas in which the cortical cap thickens over time may be in the process of malignant degeneration into chondrosarcoma. All suspected chondrosarcomas should undergo wide local excision; they often require chest wall reconstruction. Poor prognostic factors include hypercellularity, cytologic atypia, high mitotic index, and tumor size. High grade tumors have a 75% chance of distant spread at the time of diagnosis. Because these tumors respond poorly to chemotherapy or radiation, complete surgical (wide-local) excision is the primary modality of therapy.

Osteogenic sarcoma
Ewing's sarcoma
Askin's tumor (primitive neuroectodermal tumor)
Plasmacytoma

Osteosarcoma

Osteosarcomas of the chest wall generally present at puberty as a rapidly expanding mass and arise from the rib, scapula, or clavicle. Environmental factors (fluoride exposure, farm workers) and genetic predispositions (young age at puberty, familial history, retinoblastoma gene defect, Li-Fraumeni syndrome) increase the lifetime risk of development of osteosarcoma. Radiographic findings include bony destruction with an associated large heterogeneous mass comprised of necrotic tumor and hemorrhage. There is often central punctate calcification. Because distant metastasis (typically to the lung) is common and good systemic options for therapy exist, biopsy for tissue confirmation is indicated for suspected osteosarcomas. Induction chemotherapy followed by surgical resection (wide local excision with reconstruction as needed) is the treatment of choice; however, overall 5-year survival rates remain poor, at less than 20%.

Ewing's Sarcoma

These malignant, small, round cell tumors have in common the genetic translocation between chromosomes 11 and 22 and include both Ewing's sarcomas and primitive neuroectodermal tumors (PNETs; also known as Askin's tumors). With a typical occurrence in children and young adults, 15% of Ewing's sarcomas and up to 50% of PNETs arise in the chest wall and can involve a single rib, the clavicle, or the scapula, in descending frequency. They often present as a painful enlarging chest mass with constitutional symptoms that include fever, weight loss, and generalized malaise. Associated pleural effusions are also common. On imaging, radiographic findings include a large noncalcified mass with bony destruction. As with osteosarcomas, systemic disease at diagnosis is frequent, and therapy should include neoadjuvant chemotherapy followed by complete surgical resection and chest wall reconstruction. Postoperative radiation should be reserved for a margin-positive resection. Bilateral whole lung irradiation may be used in the adjuvant setting to improve

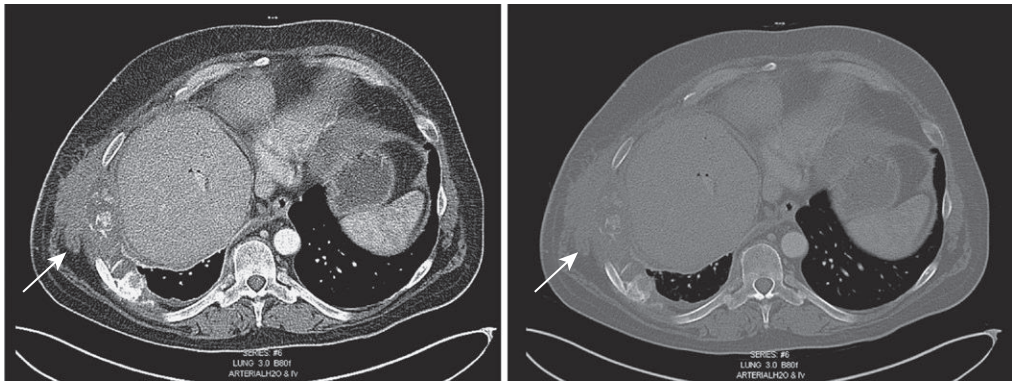

FIGURE 1 Computed tomographic scans of a patient with malignant tumor of the chest wall. Both *white arrows* denote the chest wall tumor. The image on the left shows soft tissue involvement with soft tissue settings. The image on the right shows extent of bony involvement and destruction with bone windows.

event-free survival in patients with documented pulmonary metastases. Overall 5-year survival rates for Ewing's sarcoma can approach 65%, whereas for PNETs, long term survival remains approximately 15%.

Solitary Plasmacytoma

Plasmacytomas tend to occur in men in their 60s and 70s and present with pain, typically without a palpable mass. Imaging documents an expansile multicystic mass. Plasmacytoma is associated with multiple myeloma but is not necessarily a systemic disease. After tissue diagnosis is confirmed, local therapy with radiation is indicated. Up to two thirds of patients may have development of systemic involvement with multiple myeloma; the 5-year survival rate is 25% to 35%. However, solitary plasmacytomas that are successfully irradiated and do not progress to systemic multiple myeloma have an excellent long-term prognosis. Indications for surgical resection as local therapy include those patients in whom radiation therapy is not an option.

BENIGN SOFT TISSUE TUMORS

Lipomas

Chest wall lipomas are typically larger and deeper than those soft tissue lipomas found in other anatomic locations. They are rarely symptomatic. Imaging reveals homogenous masses consistent with mature fatty tissue. Resection is only indicated for symptomatic or enlarging lesions or for suspicion of low-grade liposarcoma.

Fibromas (Desmoid Tumors) and Fibromatosis

Desmoid tumors arise from fibroblasts deep within the chest wall musculature and often occur in patients in their teenage years to early 30s. They present as a slowly growing, sometimes painful mass, often in the context of prior trauma or prior thoracotomy or in the context of systemic fibromatosis (Gardner's syndrome). Complete surgical resection with wide margins (up to 4 cm if possible) with chest wall reconstruction is the optimal therapy because local recurrence rates are quite high. Adjuvant radiation therapy can be used both prophylactically and in the context of microscopically positive margins. Recurrence rates for margin-positive disease, despite radiation therapy, remain as high as 90%.

Hemangiomas

Hemangiomas of the chest wall are benign proliferations of blood vessels that form in the context of muscle, rib, or subcutaneous tissues. They typically occur in children. MRI or ultrasound scan can be used to confirm the diagnosis. Resection is only indicated if symptoms develop, such as bleeding, ulceration, or rarely heart failure from arteriovenous malformation and shunting (cavernous hemangiomas). When indicated, local excision is curative, with chest wall reconstruction reserved for larger lesions.

Benign Peripheral Nerve Sheath Tumors

Chest wall schwannomas are encapsulated tumors that develop from intercostal nerves or thoracic spinal nerve roots. They are typically asymptomatic and identified incidentally during thoracic imaging. CT scan and MRI are usually sufficient for diagnosis, and in asymptomatic cases, serial imaging and observation suffice. If the diagnosis is in doubt, needle biopsy can be confirmatory. Resection is reserved for symptomatic or enlarging lesions. This may require contiguous chest wall or vertebral body resection and reconstruction.

MALIGNANT SOFT TISSUE TUMORS

Malignant Fibrous Histiocytoma

Malignant fibrous histiocytoma (MFH) has two age peaks at diagnosis: 20 to 30 years and 50 to 60 years, with the latter the more common period of diagnosis. They rarely arise from the chest wall; when they do, they are generally associated with prior radiation exposure. Imaging reveals a heterogeneous mass with irregular borders; bony involvement is rare. Tissue confirmation with a well-planned needle biopsy is indicated because induction chemotherapy followed by surgical resection and reconstruction is the therapy of choice. Postoperative radiation can be reserved for margin-positive disease. Even with complete resection and systemic therapy, metastases can be documented in 30% to 50% of patients and 5-year survival rates remain less than 40%.

Synovial Sarcomas

These malignant tumors rarely present as a primary chest wall malignancy, and the thoracic surgeon is more typically involved with the management of oligometastatic lung involvement from systemic disease. Nevertheless, primary synovial cell sarcomas of the chest wall can occur, typically in early adulthood. Imaging generally reveals heterogeneous centers as a result of necrosis or hemorrhage within cystic components. Nearly 50% may have calcification. Treatment involves complete surgical resection with adjuvant chemotherapy or radiation. Induction paradigms with chemotherapy or chemoradiation followed by surgical resection have also been used. Five-year survival rates approach 50%.

Rhabdomyosarcomas

Rare in adults, rhabdomyosarcomas are the second most common malignant primary chest wall tumor in children. The vast majority of cases present with distant metastases, and complete staging should be undertaken to determine which patients are candidates for primary site resection. Staging in children can include CT scan of the thorax, abdominal ultrasound scan, and bone scan, although positron emission tomography (PET)/CT scans are being increasingly used. Tissue confirmation is important because when these aggressive tumors are resectable, they are treated with induction chemoradiation, followed by wide local excision with chest wall reconstruction, and adjuvant chemotherapy or radiation as indicated. Five-year survival rates remain poor with surgical resection alone; trimodality therapy has resulted in significant improvement in 5-year survival rates, with rates as high as 75% in selected series in patients without documented metastases at the time of diagnosis.

SURGICAL TREATMENT OF CHEST WALL TUMORS

Chest Wall Resection

Surgical resection remains the mainstay of therapy for primary chest wall malignancies, whether benign or malignant. Benign lesions should be resected to microscopically clear margins. Many malignant chest wall lesions have high recurrence rates; therefore, aggressive wide local excision with chest wall reconstruction as indicated has

been advocated. The general guidelines for planning surgical resection of primary chest wall tumors are as follows. Primary malignant tumors of the chest wall should be resected with a 4-cm margin. This margin width has been shown to afford better long-term survival. Tumors arising from adjacent structures (most commonly lung cancers) should be resected to include the involved rib and a rib above and below the area of invasion. Metastatic lesions can generally be resected to microscopically clear margins but only in carefully selected patients in whom the solitary chest wall metastasis is thought to be the only site of systemic disease.

Given the large defects often left with wide local excision of these lesions, careful planning to ensure an adequate oncologic operation and excellent functional and cosmetic results from reconstruction is critical. Planning for resection must begin at the time of original tissue diagnosis, with care taken to place biopsy incisions in areas that can subsequently be incorporated into wide local excisions. Therefore, the involvement of the surgeon in planning therapy for these patients, and collaboration with plastic and reconstructive surgeons as needed, must occur early in the treatment course.

Chest Wall Reconstruction

The thorax is a rigid structure that protects the underlying viscera, supports the upper extremities and shoulder girdle, and allows for ventilation. Anatomic defects in the bony framework of the chest may result in exposure of vital structures to the external environment or alteration of chest wall mechanics that leads to subsequent ventilatory impairment. Large defects may result in lung herniation, contraction of the resected hemithorax, scapular entrapment, and suboptimal cosmesis. The goals of reconstruction are to mitigate these alterations of the chest wall and their potential complications.

No formal guidelines exist for mandating skeletal reconstruction after chest wall resection, thus rendering surgical judgment essential. General preference as discussed in textbooks and the authors' own practice takes into account defect location, size, local tissue condition, and patient comorbidities. Posterior defects, which are supported by the overlying scapula and back musculature, may be left without skeletal reconstruction if less than 10 cm in diameter. If the posterior rib defect encompasses the fourth or fifth ribs, special attention must be paid to the location of the scapular tip because it may become entrapped within the chest if no reconstructive support is provided. Anterior and lateral defects of two consecutive ribs with a resultant defect less than 5 cm in size are generally well tolerated with no functional consequence. Anterior resections of the first through third ribs may be especially well tolerated without reconstruction because of the support provided by the overlying pectoralis muscles. When more than three adjacent ribs in the anterolateral location are resected, or the resulting defect is 5 cm or greater, the possibility of paradoxical chest wall motion and its inherent complications arises, suggesting reconstruction should be undertaken. The authors' practice is to reconstruct defects 4 cm in size if pulmonary function is borderline, thus minimizing the chance of postoperative pulmonary insufficiency in these patients with marginal reserve. In patients who have dense underlying adhesions or pulmonary scarring from prior radiation or surgery, the authors may leave defects larger than 5 cm unreconstructed as ventilation may not be affected. Tolerance for defect size also increases in the setting of infection, as graft infection may develop.

OPTIONS FOR CHEST WALL RECONSTRUCTION

After the decision has been made to perform skeletal stabilization, a suitable graft option must be selected for the bony defect and the overlying soft tissue coverage needed. Options for chest wall reconstruction include autogenous fascia and bone, metals, plastics, and prosthetic meshes and patches, with or without muscle flap reconstruction. The authors' preference is to use acellular dermal matrices (ADM) for skeletal reconstruction in conjunction with muscle flaps for soft tissue coverage of defects as needed (Table 1).

The authors' greatest clinical experience with ADMs for chest wall reconstruction has been with AlloDerm (Lifecell Corporation, Bridgewater, NJ) (Figure 2). At times, the resection is small, and soft tissue coverage is the major issue facing the team of surgeons. At other times, the defect is massive, and chest wall stabilization is critical. Based on the estimated size of the defect during surgery before resection, the authors request the AlloDerm be brought to the operating room (OR) for rehydration, which can take on average 30 to 40 minutes. The authors recently moved to the use of the extra-thick (2.30-mm to 3.30-mm) noncrosslinked graft because this seems to provide better skeletal support, although this observation is based on anecdotal evidence and objective data do not currently exist. Size selection is based on the defect, and multiple grafts may be sutured together for additional coverage.

After skeletal resection is complete, rib margins are blunted to avoid sharp ends, which may injure the graft or underlying viscera. Thorough inspection for hemostasis is performed, and the wound is irrigated with copious saline solution. The authors generally do not prestretch the graft more than 10% to 15% before implantation but undersize the graft relative to the defect to allow for ideal tension when placed. A tense, drum-like feel of the graft is ideal to prevent redundancy and leaking. During sizing, it is essential to account for patient positioning. Most surgical approaches are with the patient in a lateral decubitus position on the OR table, with maximal table flexion to increase interspace distance for chest entry. Restoration of the OR table to a neutral position during determination of allograft size reduces the chance of inadequate graft tension. The AlloDerm matrix has two distinct surfaces, and proper orientation of the allograft before insertion is important. The authors use a number 1

TABLE 1: Flaps used to cover thoracic soft tissue defects after chest wall resection

Type of flap	Arterial supply	Indications
Latissimus	Primary: thoracodorsal Secondary: perforating vessels from posterior intercostal vessels	Anterolateral and posterior defects
Pectoralis major	Primary: Thoracoacromial artery Turnover flap: internal mammary perforators	Anterior chest wall defects
Serratus	Subscapular artery	Intrathoracic coverage
Rectus abdominis	Deep superior or inferior epigastric artery	Lower sternal defects
External oblique	Segmental blood supply from posterior intercostal arteries	Inframammary fold defects

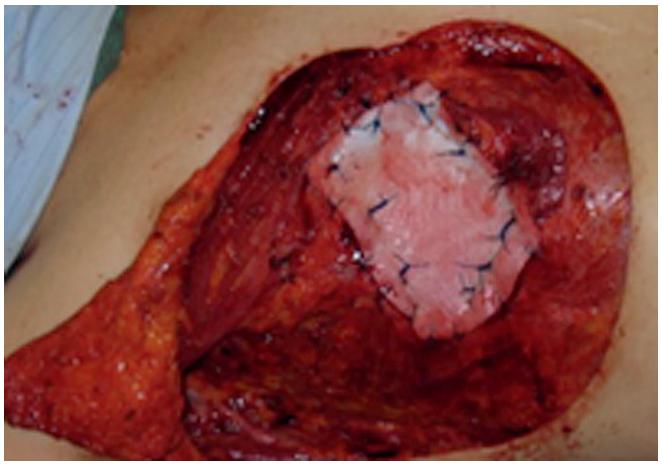

FIGURE 2 Intraoperative photograph of a chest wall reconstruction with AlloDerm (Lifecell Corporation, Bridgewater, NJ) acellular dermal matrix. The periphery of the AlloDerm is sutured to the chest wall with interrupted, nonabsorbable Prolene sutures.

polypropylene (nonabsorbable) suture with a cutting ½-circle 40-mm needle for graft implantation. This suture allows for ease of passage through the dense dermal graft and facilitates bone penetration when necessary. Single interrupted sutures for secondary support are placed in four quadrants or at any area where there is pleating and a tighter seal is desired. A combination of running or interrupted sutures is then placed circumferentially depending on the surgeon's preference. Suture is passed through fascia when available or directly through the adjacent rib when fascia is not in proximity, and the superficial portion of the tissue flap is sutured to the ADM to obliterate the dead space.

After implantation, the graft is thoroughly irrigated and tested for leakage by insufflating the underlying lung after submersion of the graft in saline solution. Once the acellular dermal matrix has been placed to provide the structural support, soft-tissue coverage generally with a muscle flap with healthy well vascularized tissue is critical. It is the overlying soft tissue flap that allows for cellular infiltration and revascularization and therefore preserves viability of the ADM. The type of tissue flap and the method for reconstruction is based on the surgeon's preference (see Table 1). The authors then place a 28F chest tube in a posteroapical position through the interspace ideally two ribs below where the ADM is secured. The pleural tube is managed as for any standard lung resection. To prevent seroma formation, 19F subcutaneous closed-suction drains are placed to close the dead space below the tissue flap and ADM. The drains remain in place until the patient has been ambulating for 24 to 48 hours and once the drain output is less than 30 cm^3 over 24 hours. If the postoperative course is complicated by a wound infection or infected seroma, the ADM, unlike synthetic mesh, can be treated conservatively and salvaged. This is accomplished oftentimes with percutaneous drainage of the fluid collection, débridement of infected tissue, antibiotics, negative pressure wound vacuum placement, and local wound care without implant removal.

SUMMARY

Primary chest wall tumors are rare. When therapy is indicated, surgical resection remains the primary modality of treatment, alone or in combination with chemotherapy or radiation, in the neoadjuvant or adjuvant setting. Margin-negative resection affords the best chance of cure. Careful planning and collaboration to ensure outstanding oncologic outcomes with optimal functional and cosmetic results after reconstruction are critical for the surgical therapy of primary chest wall tumors.

MEDIASTINAL MASSES

Ashok Muniappan, MD, and Douglas Mathisen, MD

INTRODUCTION

The mediastinum extends from the thoracic inlet to the diaphragm and is surrounded by the pleural cavities, spine, and sternum. The mediastinum is commonly and arbitrarily divided into anterior, middle, and posterior compartments. According to Shields's system, introduced in 1972, the anterior compartment contains all of the structures anterior to the heart and great vessels, including the thymus, fat, lymph nodes, and connective tissue (Figure 1). The middle compartment, also called the visceral compartment, contains the heart, trachea, main-stem bronchi, great vessels, esophagus, vagus nerves, thoracic duct, and lymph nodes. The posterior compartment refers to the paravertebral sulci, which contain the proximal intercostal nerves, intercostal vessels, thoracic spinal ganglion, sympathetic trunk, and lymph nodes. There are slightly different definitions of the mediastinal compartments in the anatomic, radiologic, and surgical literature. In anatomy texts, the mediastinum also includes a superior compartment, which is arbitrarily defined as occupying the space above a line connecting the sternomanubrial joint and the caudal border of the fourth vertebra. Other descriptions place certain structures in different compartments. For instance, classification systems that predate Shields's often place the proximal esophagus in the middle compartment and the distal esophagus in the posterior compartment.

A wide variety of masses, of both benign and malignant origin, arise in the mediastinum. A systematic approach to diagnosis is necessary to select appropriate therapy. Careful documentation of the patient's age, symptoms, and physical signs, as well as critical review of pertinent imaging, can greatly simplify the differential diagnosis. Although a biopsy often refines the differential, occasionally the diagnosis is uncertain until definitive resection.

CLINICAL PRESENTATION AND DIAGNOSIS

Signs and Symptoms

Only about one third of mediastinal masses present with symptoms, while most are found incidentally on imaging performed for other reasons. The most common symptoms are chest pain, cough, or shortness of breath, and are related to compression of normal structures by the mass. Invasion of the stellate ganglion can lead to Horner's syndrome, compression of the superior vena cava (SVC) can result in SVC syndrome, and involvement of the phrenic nerve can present as diaphragmatic paralysis. Malignant masses are more likely to be symptomatic, given their potential for invasion and rapid growth. Some mediastinal masses are also associated with characteristic paraneoplastic syndromes.

Imaging

Chest computed tomographic (CT) scan is the ideal imaging modality to evaluate mediastinal masses. The resolution of CT imaging precisely localizes the mass and establishes its relationship to normal structures. Moreover, CT imaging can distinguish whether the mass is cystic, solid, fatty, or vascular. Magnetic resonance imaging (MRI) is an adjunctive imaging modality that improves soft tissue assessment, but it is not routinely necessary. MRI can reliably identify the presence of bronchogenic and enteric cysts, evaluate involvement of the neural foramen by posterior mediastinal masses, and assess involvement of the heart and great vessels. Specialized studies such as sestamibi scanning (mediastinal parathyroid), octreotide scanning (thymic carcinoid), and metaiodobenzylguanidine scanning (mediastinal paraganglioma) are useful when these diagnoses are suspected.

Tumor Markers

Circulating tumor markers are elevated in patients with certain mediastinal masses. Malignant germ cell tumors (GCTs) of the anterior mediastinum produce elevations of alpha fetoprotein (AFP), beta human chorionic gonadotropin (β-HCG), and lactate dehydrogenase (LDH). The pretreatment marker levels in patients with GCTs correlates with prognosis, while the posttreatment level measures response to therapy. Thymic carcinoids produce ectopic adrenocorticotropic hormone in about 50% of patients, which may be associated with Cushing's syndrome. Malignant ganglionic tumors and pheochromocytomas of the posterior mediastinum can produce excess catecholamines, leading to abnormal elevations of catecholamine metabolites such as dopamine, vanillymandelic acid, and homovanillic acid. Ectopic mediastinal parathyroid glands produce increased parathyroid hormone.

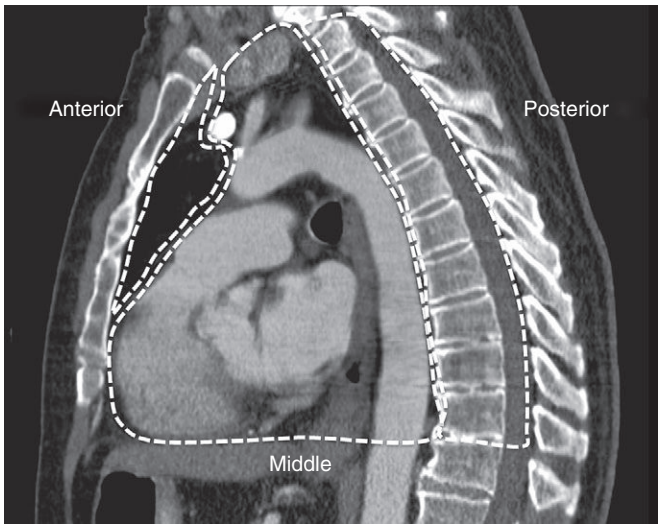

FIGURE 1 A sagittal view of the mediastinum and its anterior, middle, and posterior compartments. The posterior compartment includes the paravertebral sulci, while excluding the spine itself.

Biopsy Techniques

Pretreatment biopsy of mediastinal masses is not always necessary. A well-encapsulated mass in the anterior mediastinum, with imaging features consistent with a thymoma, is resectable without preoperative biopsy. Biopsy of an early thymoma may seed the pleura or mediastinum, increasing the chance of recurrence. Other masses of the anterior mediastinum that appear resectable and show no signs of invasion should undergo resection, which is both diagnostic and therapeutic.

Similarly, posterior mediastinal masses, with benign features on imaging, are resectable without a biopsy. Biopsy of a mediastinal cyst is also unnecessary and can complicate resection if the biopsy causes hemorrhage or infection of the cyst.

In contrast, advanced thymoma, lymphoma, malignant germ cell tumors, and other malignant-appearing lesions of the mediastinum require a pretreatment histopathologic diagnosis to guide therapy. CT-guided needle biopsy is especially suitable for masses in the anterior or posterior mediastinum. Core needle biopsy is superior to fine-needle aspiration (FNA), as some preserved architecture is necessary to reliably distinguish between thymoma and lymphoma. Needle biopsy is often inadequate for establishing a diagnosis of lymphoma, and additional tissue obtained with an open incisional biopsy is necessary to perform flow cytometric and cytogenetic tests to allow lymphoma subclassification. In this situation, a Chamberlain procedure (anterior mediastinotomy) is the optimal procedure to perform an incisional biopsy of a mass in the anterior mediastinum.

The middle mediastinum can be accessed with cervical mediastinoscopy, as is frequently done in staging lung cancer or evaluating mediastinal lymphadenopathy. Increasingly, endoscopic ultrasound, either with endobronchial ultrasound (EBUS) or endoesophageal ultrasound (EUS), complements cervical mediastinoscopy and provides a noninvasive technique for biopsy of a mass in the middle mediastinum. Recent reports suggest that EBUS is useful for biopsy of indeterminate mediastinal masses that are adjacent to the central airway and may make open biopsy unnecessary (Yasufuku K, et al., 2011).

Diagnosis

The identity of the mass is surmised by evaluating its location and radiographic features and accounting for the patient's age, signs, and symptoms. The most common mediastinal masses and location are presented in Table 1. In adults, thymomas and thymic cysts are the most commonly encountered primary mediastinal mass (approximately 25% of all mediastinal masses, and almost 50% of anterior mediastinal masses), while in children neurogenic tumors are the most common (approximately 40%). In both adult and pediatric series, mediastinal masses are malignant in approximately 35% to 50% of patients. The mediastinal location of masses in adults is approximately 55% in the anterior mediastinum, 20% in the middle mediastinum, and 25% in the posterior mediastinum. The increased proportion of neurogenic tumors in pediatric patients explains why

TABLE 1: Common mediastinal masses and their usual locations

Anterior	Middle	Posterior
Thymoma	Bronchogenic cyst	Schwannoma
Lymphoma	Lymphoma	Neurofibroma
Substernal thyroid goiter	Pericardial cyst	Ganglioneuroma
Parathyroid adenoma	Neuroenteric cyst	Ganglioneuroblastoma
Germ cell tumor		Neuroblastoma Pheochromocytoma

the majority of pediatric masses are seen in the posterior mediastinum (35% in the anterior mediastinum, 15% in the middle mediastinum, and 50% in the posterior mediastinum). Evaluation of tumor markers and biopsy results refines the differential diagnosis. In some patients, final diagnosis is not established until the lesion is resected.

Anterior Mediastinum

Thymic Tumors

Although thymomas are relatively rare tumors, they are the most common anterior mediastinal tumor. The mean age at presentation is approximately 55 years, and there is no gender predilection. Approximately 50% of patients present with chest pain, dyspnea, cough, or one of the paraneoplastic syndromes, while the remainder are incidentally discovered masses. Thymoma is associated with myasthenia gravis (~30% to 50%), aplastic anemia (~5%), and agammaglobulinemia (~1%). While a thymoma is present in only about 15% of patients with myasthenia gravis, up to 50% of patients with thymomas have myasthenia gravis.

CT imaging usually reveals a well-circumscribed soft tissue mass in the anterior mediastinum, often adjacent to the ascending aorta. The mass may ascend into the neck, approach either pulmonary hilum, or descend to the diaphragm. Lymphadenopathy is atypical for thymoma and if present suggests a diagnosis of lymphoma or an advanced thymic malignancy. Both pleural spaces should be carefully examined on CT imaging, looking for evidence of pleural metastases. Advanced thymic tumors are bulky, encase vascular structures, and have irregular borders on CT imaging.

The World Health Organization (WHO) classification system for thymic epithelial neoplasms correlates with tumor biology and prognosis. In order of worsening prognosis, there are Type A (medullary thymoma), Type AB (mixed thymoma), Type B1 (predominantly cortical thymoma), Type B2 (cortical thymoma), Type B3 (well-differentiated thymic carcinoma), and Type C (thymic carcinoma) thymic tumors. Not surprisingly, surgical resection of the tumor is more accurate for WHO classification than core needle biopsy. Types A and AB thymomas are quite benign, and complete resections are associated with freedom from recurrence and significant chance of cure.

The Masaoka system stages resected thymomas (Masaoka A, 2010). As CT imaging does not reliably assess capsular invasion, surgical resection and histopathologic assessment are necessary to distinguish between stage I and II thymomas (Table 2). The Masaoka stage also predicts survival.

A median sternotomy and total thymectomy is the most appropriate operation for the majority of early-stage thymomas. As mentioned earlier, preoperative biopsy is not necessary for anterior mediastinal masses that appear resectable; biopsy is relatively contraindicated, given the risk of tumor seeding. Transcervical thymectomy, video-assisted thoracic surgery (VATS), and robotic thoracoscopic techniques are also utilized for thymoma resection. Although a recent multicenter report suggested that robotic thymectomy can safely resect early-stage thymomas and is associated with low morbidity, long-term oncologic outcome is unclear because the median follow-up was relatively short (Marulli G, et al., 2012). For now, minimally invasive thymectomy for thymoma is most suitable for centers with a clinical research protocol.

TABLE 2: Masaoka staging system of thymoma

Stage	Criteria
I	No evidence of capsular invasion
II	Microscopic capsular invasion or gross involvement of surrounding fat or pleura
III	Gross involvement of adjacent organs including pericardium, great vessels, and lung
IVa	Pleural or pericardial metastases
IVb	Hematogenous or lymphogenous metastases

Thymic tumors that appear unresectable at presentation (Masaoka stages III and IV) should undergo CT-guided core needle biopsy or a Chamberlain procedure to establish the diagnosis (Figure 2). Resection follows induction chemotherapy, with adjuvant radiation for concerning margins. SVC or innominate vein reconstruction may be necessary for resection of tumors that extensively involve the innominate vein or SVC (Lanuti M, et al., 2003).

Recurrent disease is usually local, either in the anterior mediastinum or in the pleural spaces. Consideration of resection is usually appropriate, and control of the disease can be possible given the slow growth of most thymomas. In small single-center series, pleuropneumonectomy has been undertaken in highly selected patients in an attempt to eradicate extensive unilateral pleural recurrences (Wright C, 2011).

Germ Cell Tumors

The anterior mediastinum is the most common extragonadal site of a GCT. Tumors are histologically either seminomas or nonseminomatous GCTs, which differ markedly in terms of prognosis and treatment. Mature teratomas of the mediastinum behave in a benign manner and are not associated with any elevation of tumor markers. Nonseminomatous masses, including yolk-sac tumors, choriocarcinomas, embryonal carcinomas, and mixed tumors, are malignant. AFP and β-HCG are often significantly elevated in patients with malignant GCTs, while patients with seminomas have normal or minimally elevated levels. A clinical picture with elevations of AFP and β-HCG, as well as characteristic CT imaging, is pathognomonic,

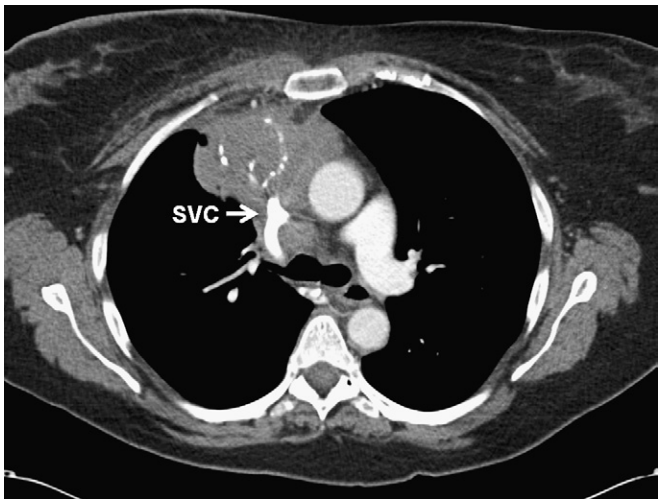

FIGURE 2 Axial computed tomography image of 66-year-old patient with a WHO B3 thymoma encasing the superior vena cava *(SVC)*. After neoadjuvant chemotherapy, the patient underwent sternotomy and resection of the mass, which required SVC reconstruction. Adjuvant radiotherapy was administered to close margins in the right pulmonary hilum.

although CT-guided core biopsy is usually performed to confirm the diagnosis.

Mature Teratomas

Mature or benign teratomas occur equally in men and women, and the mean age at presentation is approximately 30. Mature teratomas are the most common germ cell neoplasm of the mediastinum and account for approximately two thirds of such tumors. CT imaging is typically very suggestive, revealing characteristics such as bone, teeth, and fat within a well-defined cystic structure. A median sternotomy enables complete resection and cure. Although these lesions are benign, resection is indicated, as the mass may continue to grow and cause respiratory or cardiovascular compromise from compression or rupture.

Seminomas

Primary mediastinal seminomas occur predominantly in men, and the mean age at presentation is approximately 30. They account for approximately one third of mediastinal GCTs. Testicular seminomas also metastasize to the mediastinum, although this is typically associated with significant retroperitoneal disease. While small mediastinal seminomas may be diagnosed after complete resection, most seminomas are bulky and appear to be infiltrative or "pushing" surrounding structures on CT imaging. A core needle biopsy, or in some cases a Chamberlain procedure, establishes the diagnosis. At presentation, seminomas are often metastatic. Metastases are common in local lymph nodes and slightly less often in lungs or liver. Seminomas are very sensitive to platinum-based chemotherapy and radiotherapy. Chemotherapy is preferable to avoid cardiac toxicity of mediastinal radiation. Residual masses are often observed, while surgery is occasionally considered in selected patients. Treated patients who present without visceral metastases are expected to have greater than 90% 5-year survival.

Nonseminomatous Germ Cell Tumors

Primary mediastinal nonseminomatous germ cell tumors (PMNSGCTs) are rare tumors (1% to 5% of mediastinal masses) that occur predominantly in young men aged 20 to 40. Patients present with symptoms such as chest pain, cough, and dyspnea, caused by a large mass in the anterior mediastinum. CT imaging reveals a large, bulky tumor that appears infiltrative and pushes adjacent structures, including the aorta, brachiocephalic vein, SVC, heart, and lung. The central airways may be narrowed, and it is important to recognize this before delivering an anesthetic; access to rigid bronchoscopy and appropriate anesthetic techniques are vital in these patients, as severe respiratory or cardiac compromise may occur with anesthetic induction. Although elevations in AFP or β-HCG are virtually diagnostic combined with the imaging findings, needle biopsy is usually performed to confirm the diagnosis. When biopsy findings return with benign features consistent with a mature teratoma, the elevation of tumor markers is due to malignant elements within the mass that were not sampled, and a mixed tumor with benign and malignant elements is diagnosed. Primary surgical therapy is rarely undertaken, as these masses are often metastatic at presentation and the bulky and infiltrative presentation precludes a complete resection. Cisplatin-based combination chemotherapy regimens such as VIP (ifosfamide, etoposide, and cisplatin) and BEP (bleomycin, etoposide, and cisplatin) produce responses in most patients, with normalization of tumor markers and regression of the mass on CT imaging. Bleomycin is associated with pulmonary toxicity and should be avoided when pulmonary resection is anticipated. In patients with normalized markers, surgical resection of the remaining mass is recommended if technically feasible. While the anterior mediastinal mass is typically approached via median sternotomy, alternative incisions such as a posterolateral thoracotomy or a sternothoracotomy (clamshell incision) are useful when the mass involves the pulmonary hilum or lung. In a patient with continued marker elevation, second-line chemotherapy is appropriate, and surgical resection is rarely undertaken. Five-year survival is approximately 50% for all patients with PMNSGCTs, with an improved prognosis for patients who undergo resection and no viable malignant tissue remains.

Lymphoma

Lymphomas represent about 20% of anterior mediastinal masses. They can also occur in the middle mediastinum and rarely in the posterior mediastinum. Lymphomas are often not confined to the mediastinum, and disease may be seen elsewhere. Patients may present with symptoms related to compression as well as harbor "B" symptoms (fevers, night sweats, and weight loss).

Hodgkin's lymphoma is the most common primary mediastinal lymphoma, with nearly half of all Hodgkin's disease occurring in the mediastinum. It has a tendency to occur in thymic tissue, but it can also involve lymph nodes in the middle mediastinum. Patients are typically younger than patients with thymomas (20s to 30s) and are slightly more often female. While needle biopsy may identify lymphoma, it usually fails to provide enough tissue for lymphoma subclassification. Differentiating from thymoma may also be difficult on a needle biopsy. Additional tissue obtained by a Chamberlain procedure, VATS, or cervical mediastinoscopy is necessary to distinguish between Hodgkin's lymphoma and non-Hodgkin's lymphoma. Obtaining tissue is the primary role for the surgeon, as these tumors are typically treated with a combination of chemotherapy and radiation, and resection is usually not indicated. Greater than 90% of patients are cured if they present with low-volume disease.

Primary mediastinal B-cell lymphoma (PMBL) and lymphoblastic lymphomas are the other lymphomas frequently encountered in the anterior mediastinum (Figure 3). These non-Hodgkin's lymphomas are more likely to present with SVC syndrome, compared with Hodgkin's lymphoma. Chemotherapy regimens are chosen based on lymphoma subclassification. While prognosis is typically inferior to that of Hodgkin's lymphoma, cure is still possible.

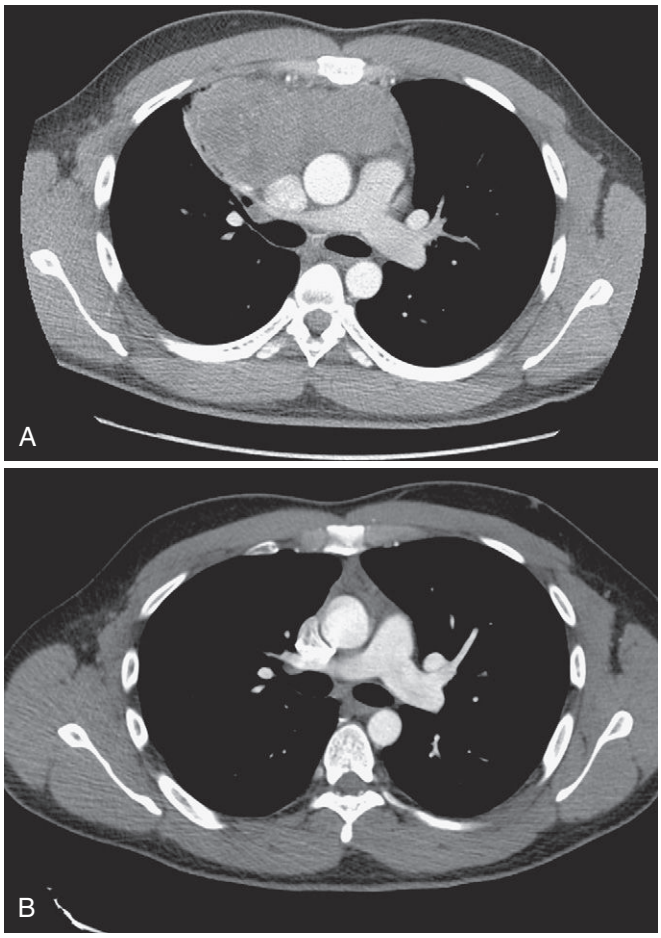

FIGURE 3 **A,** Axial computed tomography image of a 28-year-old man with a primary mediastinal B-cell lymphoma. The diagnosis was established with a biopsy performed through a right Chamberlain procedure. **B,** The patient received six cycles of multiagent chemotherapy (R-CHOP) with a complete response.

Thyroid and Parathyroid

Substernal goiters are typically extensions of cervical thyroid tissue that descend into the anterior mediastinum. Occasionally, large substernal goiters can also wrap around the trachea and approach the esophagus. Rarely, substernal goiters arise in ectopic thyroid tissue, and the diagnosis may not be suspected preoperatively. While substernal goiters are not universally symptomatic, many patients report dyspnea or dysphagia, secondary to compression. Substernal goiters do not have a higher incidence of occult carcinoma compared with cervical goiters. When a substernal goiter is identified, subtotal thyroidectomy is typically indicated and is easily performed through a low cervical collar incision. Medical therapy for symptomatic goiters only delays definitive therapy and may complicate resection. Extremely large goiters occasionally require a partial upper sternotomy to facilitate resection. A total sternotomy would be excessive in most patients. The vasculature of a substernal goiter originates in the neck, except in the case of an ectopic thyroid, which derives perfusion from the internal mammary or innominate arteries, or even the aorta in some cases. While postoperative morbidity is minimal, recurrent laryngeal nerve injury and hypoparathyroidism may occur.

Ectopic mediastinal parathyroid adenomas are responsible for 5% of primary hyperparathyroidism. By far, the most common location for a mediastinal parathyroid adenoma is in the thymus or anterior mediastinum. Rarely, parathyroid adenomas are found in the middle mediastinum in a paratracheal position or in the posterior mediastinum, adjacent to the esophagus. A common clinical scenario is one in which a patient has persistent hyperparathyroidism after cervical exploration. Localization studies such as Sestamibi scanning, CT imaging, and selective venous sampling help to detect the mediastinal parathyroid adenoma. While median sternotomy has historically been the procedure of choice, increasingly, minimally invasive techniques such as VATS and mediastinoscopy reliably remove mediastinal parathyroid adenomas. Intraoperative documentation of at least 50% reduction in parathyroid hormone and histologic confirmation of resection ensure correction of hyperparathyroidism (Wei B, et al., 2011).

Middle Mediastinum

Castleman's Disease

Castleman's disease is a rare lymphoproliferative disorder that produces benign lymph node masses. While Castleman's disease may occur virtually anywhere in the body, in 70% of patients the nodal masses develop in the chest. They predominantly occur adjacent to the central airways or in the pulmonary hilum, and occasionally in the anterior or posterior mediastinum. They commonly appear as enhancing masses on CT imaging, and patients are often asymptomatic. There are characteristic histopathologic findings, with the hyaline vascular follicular form being the most prevalent type. Castleman's disease is often discovered at the time of incisional biopsy and frozen section analysis. If the patient has unicentric disease and resection is technically feasible, the mass should be resected, and cure is achieved in the vast majority of patients. Systemic therapy with an agent such as rituximab that targets proliferating B-cells in the mass is more appropriate for multicentric disease (Talat N, et al., 2012). Long-term prognosis is inferior in patients with multicentric disease, as recurrences and progression are likely.

Mediastinal Lymphadenopathy

The most common benign conditions that produce mediastinal lymphadenopathy are sarcoidosis and granulomatous disease. Sarcoidosis is a systemic inflammatory disorder that occurs usually in patients aged 30 to 40. CT imaging reveals significant paratracheal, subcarinal, and hilar lymphadenopathy. While patients are often asymptomatic, they may have symptoms related to involvement of organ systems such as the lungs, liver, skin, and nervous system. The diagnosis is supported by an elevation in circulating angiotensin-converting enzyme. Biopsy of the involved lymph nodes reveals noncaseating granulomas. Ultimately, sarcoidosis is a diagnosis of exclusion, once other disorders are ruled out.

Granulomatous disease causing mediastinal lymphadenopathy is especially prevalent in regions where fungal infections such as coccidiomycosis (e.g., southwestern United States) and histoplasmosis (e.g., Ohio and Mississippi River Valleys) are prevalent. While patients are often asymptomatic, airway obstruction or hemorrhage may occur due to erosion by broncholiths, which are heavily calcified mediastinal lymph nodes. Biopsy of these nodes is often necessary to establish the diagnosis, and the characteristic histopathologic finding is the presence of necrotizing granulomas. Resection is typically unnecessary, and systemic therapy, with antibiotics, is occasionally indicated.

The most common malignant cause of mediastinal lymphadenopathy is metastatic lung cancer. While CT and PET imaging are often suggestive of mediastinal lymph node metastases, tissue diagnosis is often required to avoid false positive diagnosis. Mediastinal lymph node involvement represents a higher stage of disease and influences various treatment decisions. Cervical mediastinoscopy readily samples the lymph nodes adjacent to the trachea and proximal main-stem bronchi in the middle mediastinum. The Chamberlain procedure or VATS are necessary to sample nodes in the aortopulmonary window.

Increasingly, EBUS is used to complement, and in some cases replace, cervical mediastinoscopy in mediastinal staging. Although EBUS can reliably assess a number of benign and malignant abnormalities in middle mediastinal lymph nodes, FNA needle biopsy is usually inadequate for subclassification of lymphoma, and mediastinoscopy is indicated.

Mediastinal Cysts

Mediastinal cysts typically occur in the middle mediastinum and represent approximately 20% of mediastinal masses. Bronchogenic cysts are the most common type of mediastinal cyst (approximately 60%), while esophageal duplication cysts and pericardial cysts make up the remainder. Mediastinal cysts are lined with epithelium responsible for secretion of fluid. Communication with the adjacent airway, foregut, or pericardium is possible but rare. CT imaging reveals a smooth and homogenous mass of soft tissue density adjacent to the airway or esophagus. MRI is occasionally useful to confirm that the cyst is fluid filled.

Bronchogenic and esophageal cysts are typically resected, even in asymptomatic patients. The precise natural history of bronchogenic and esophageal cysts is unknown, but there are anecdotal reports of malignant degeneration. The primary indications for resection are that these lesions often become symptomatic during the patient's lifetime, and infection or hemorrhage makes resection more complicated. While minimally invasive VATS and robotic techniques are increasingly employed to resect mediastinal cysts, the safe and complete resection of the cyst remains the primary goal. When cysts cannot be completely resected without injuring the adjacent airway or esophagus, the residual epithelium is fulgurated to reduce the likelihood of recurrence.

Pericardial cysts typically occur in the right cardiophrenic border and are often asymptomatic. Pericardial cyst resection is appropriate when a patient is symptomatic or the cyst is rapidly growing; the majority of patients can be observed. VATS techniques are particularly suited for resection of pericardial cysts.

Posterior Mediastinum

Neurogenic tumors in the posterior mediastinum account for approximately 15% of mediastinal masses in adults and nearly 50% in children. They are typically asymptomatic and benign in adults and are discovered incidentally on chest imaging. Neurogenic tumors most often occur in the paravertebral sulcus and originate from cells in the peripheral nerves, the ganglion, or the paraganglionic cells. Malignancy is more common in pediatric patients.

Schwannomas and neurofibromas are benign tumors that account for the majority of posterior mediastinal neurogenic tumors. They arise from the nerve sheaths of the peripheral nerves. Ganglioneuromas are also benign tumors, but they arise from the ganglia. Ganglioneuroblastomas and neuroblastomas are malignant tumors arising from the ganglia and are encountered in children far more often than in adults. Symptomatic masses are more likely to be malignant. CT imaging best characterizes these masses, which usually appear as solid, round, and well-demarcated lesions. Extension into the neural foramen is carefully assessed, and findings such as neural foramen widening should be further evaluated with an MRI. Dumbbell tumors are those that originate in the paravertebral sulcus but have significant neuroforaminal extension (Figure 4). While most posterior mediastinal masses are easily removed by a standard posterolateral thoracotomy or VATS, dumbbell tumors require a coordinated approach with a spine surgeon to achieve a safe resection (Shadmehr M, et al., 2003). Paraplegia is a known, but very preventable, complication of dumbbell tumor resection; unrecognized hemorrhage and hematoma formation in the foramen or foreign bodies such as bone wax and antithrombotic agents may result in spinal cord compression and injury. Malignant tumors may require adjuvant radiation for positive or close surgical margins and adjuvant chemotherapy for metastatic disease.

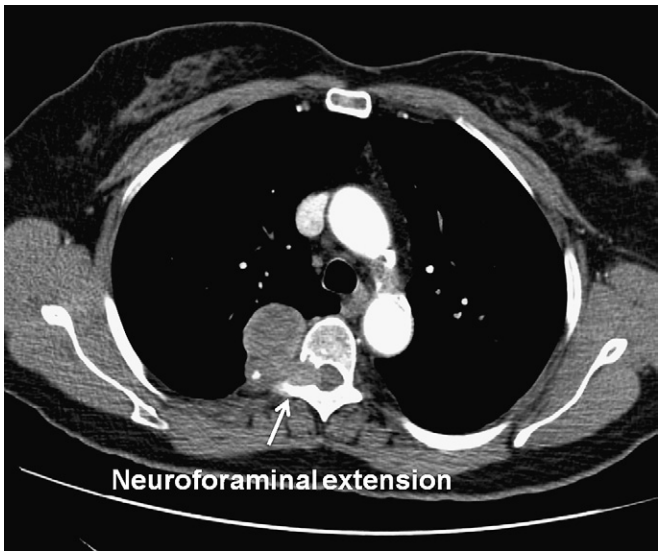

FIGURE 4 Axial CT image of 66-year-old woman with right posterior mediastinal schwannoma with neuroforaminal extension (dumbbell tumor). Resection was accomplished by a combined approach (staged laminectomy followed by thoracotomy).

Pheochromocytomas and chemodectomas arising in the posterior mediastinum are less common and are derived from paraganglionic cells. Mediastinal pheochromocytomas require preoperative preparation to avoid hemodynamic complications, as with those that are located in the abdomen. Chemodectomas are typically very vascular tumors, and consideration of preoperative embolization is warranted to reduce operative blood loss.

CONCLUSION

Expert diagnosis and management of mediastinal masses require familiarity with a diverse set of diagnostic tools and therapeutics. Imaging is the cornerstone for forming the differential diagnosis, and CT imaging, in particular, is the most versatile test. Diagnosis is facilitated by familiarity with various biopsy techniques, including needle biopsy by CT guidance or EBUS, mediastinoscopy, the Chamberlain procedure, and VATS. Minimally invasive techniques are perfectly suited for resecting many mediastinal masses, reducing morbidity and recovery time. Invasive or bulky masses still require conventional approaches, such as median sternotomy, to safely resect the lesion and occasionally reconstruct adjacent structures. Surgery alone is inadequate for mediastinal masses such as germ cell tumors, and close collaboration with medical and radiation oncology is necessary.

Primary Tumors of the Thymus

Michal Hubka, MD, and Douglas E. Wood, MD

ANATOMY

The thymus is located in the anterior mediastinum. It lies just posterior to the sternum and anterior to the pericardium; the upper horns of the H-shaped gland extend into the neck. The arterial blood supply comes from small branches of the inferior thyroid arteries, and venous drainage is via a single or multiple branches into the left innominate vein. Bilateral phrenic nerves are intimately associated with the upper aspect of the thymus, inasmuch as they course distally on the pericardial surface. Understanding the location of the phrenic nerves is of critical importance during surgical resection.

PATHOLOGY

Thymic tumors are the most common anterior mediastinal neoplasms and include both thymomas and thymic carcinomas. No risk factors are known to predispose a person to thymic disease, although there is an association of thymomas and myasthenia gravis. In addition to thymic neoplasms, the differential diagnosis of an anterior mediastinal mass includes intrathoracic thyroid tumors, parathyroid tumors, lymphomas, and germ cell tumors.

Thymomas can be associated with a wide variety of systemic syndromes. The neuromuscular disease myasthenia gravis is caused by autoantibodies' blocking acetylcholine receptors in the neuromuscular junction. The disease manifests as weakness that tends to worsen with activity, and its effects can be observed in the muscles that control speech, respiration, the eyes, and limbs. It is estimated that 30% to 50% of patients with a thymoma have myasthenia, whereas only 15% of patients with myasthenia have a thymoma. Thymectomy improves the symptoms in up to 60% of patients with myasthenia, but this improvement occurs slowly over time and is variable in degree. Thymectomy results in a decreased incidence of exacerbations and a decrease in the need for medications, as well as a higher incidence of long-term remission. Because the improvement in symptoms is not immediate, thymectomy is not undertaken in the midst of a myasthenic crisis. Patients with severe neurologic symptoms should be treated with plasmapheresis or intravenous gamma globulin before surgery. Serum levels of antiacetycholine receptor antibodies can be measured if the diagnosis of myasthenia is unclear. Management of patients with severe symptoms should be in conjunction with a neurologist.

Thymomas are also associated with hematologic abnormalities, especially red blood cell aplasia, immunodeficiencies, and collagen vascular diseases. Resection of the thymoma does not reliably improve the symptoms in such patients.

Thymic carcinoid is a rare tumor. It can be associated with multiple endocrine neoplasia type 1 (MEN 1) and Cushing's syndrome. Many patients have nodal metastases or distant metastases, or both, at the time of presentation. Other rare thymic neoplasms include small-cell tumors and sarcomas.

Unlike thymoma, thymic carcinoma is an aggressive tumor with a poor prognosis. There are two histologic types: squamous and lymphoepithelioma. Median length of survival of all patients with thymic carcinoma is only 2 years, but this can be improved when complete surgical resection is accomplished. Aggressive resection is warranted, but overall results remain poor. Partial responses to chemotherapy and radiation therapy have been reported.

EVALUATION

About half of thymic tumors are initially asymptomatic and found on radiographs obtained for other reasons. Patients with symptomatic tumors typically report chest pain, but less commonly compression of the airway or venous return is observed, or compromise of the phrenic or recurrent laryngeal nerves is evident. Patients with a thymoma may also show symptoms and signs of paraneoplastic syndromes. Beta-human chorionic gonadotropin and alpha-fetoprotein levels should be evaluated to rule out germ-cell tumors. Serum levels of antiacetylcholine antibodies should be examined in patients with even mild symptoms suggestive of myasthenia gravis.

Computed tomographic scan of the chest with intravenous contrast agent is the most valuable diagnostic procedure (Figure 1), although magnetic resonance imaging is occasionally helpful in evaluating invasion into the chest wall and vascular structures. CT and positron emission tomography can be helpful in evaluating for distant metastasis in advanced-stage thymic carcinoma. It is most important to distinguish lesions that can be treated primarily by resection from those that can be treated primarily with chemotherapy. Frequently, these lesions can be differentiated by their radiographic appearance. Thymic tumors tend to originate in the area of the thymus itself, rarely extend into the neck, and usually do not produce associated adenopathy. Thymomas tend to have smooth contours, whereas thymic carcinomas often contain necrotic centers or calcifications. In contrast, mediastinal lymphoma is generally a more bulky and infiltrative tumor and is usually associated with additional adenopathy. Thyroid goiter or tumors usually have characteristic radiologic features and continuity with the cervical thyroid. Radiologic suspicion of thymoma can be established with a high degree of reliability in a majority of affected patients. Pleural or pericardial effusions are the most common manifestation of locally advanced disease and may also cause thoracic symptoms. The pleural surfaces should be carefully examined for evidence of possible pleural "drop" metastases.

For resectable lesions, it is appropriate to forgo biopsy and proceed directly to complete resection to make the diagnosis. Tissue sampling should be reserved only for locally advanced or unresectable cases or in patients in whom an alternative diagnosis, such as lymphoma, is the primary diagnosis. This can be done with a CT-guided core needle biopsy or an incision via an anterior mediastinotomy. For an anterior mediastinotomy, or Chamberlain's

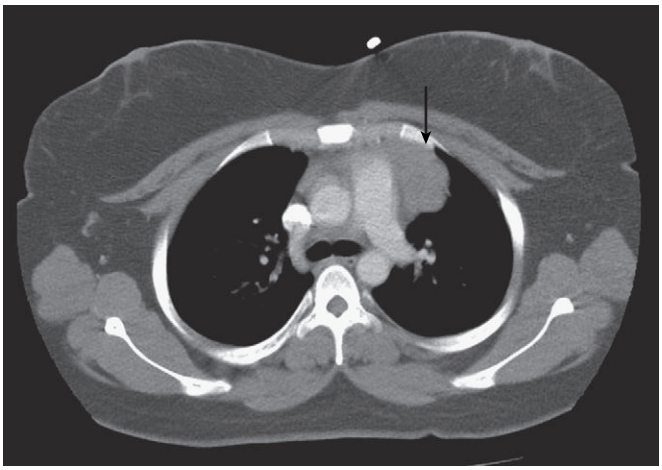

FIGURE 1 Computed tomographic scan of a thymoma *(arrow)* in the left anterior mediastinum.

procedure, an incision is made over the second rib, and the second costal cartilage is optionally excised for additional exposure. Biopsy samples can usually be obtained directly, and a video mediastinoscope can be inserted into the wound to allow for further visualization if necessary. Videoscopic transpleural tissue sampling short of complete (R0) resection should be avoided because of the major concern of pleural space seeding and the possible tragic consequences of iatrogenic spread of tumor. If the mass compresses the airway, great care must be used in administering a general anesthetic.

STAGING

A number of different staging systems have been proposed for thymomas. At this time, two systems are used in conjunction: the World Health Organization (WHO) histologic classification and the Masaoka system, which describes invasion and metastasis. The WHO classification is outlined in Table 1. Tumors with A, AB, and B1 histologic features carry a better prognosis. The Masaoka classification is shown in Table 2. Most affected patients initially present with early-stage disease, and these patients have an excellent overall prognosis when treated. The incidence of distant metastasis is very low.

PRINCIPLES OF THERAPY

Treatment of thymomas and thymic carcinomas should be carried out in tertiary and quaternary medical centers by a multidisciplinary team consisting of thoracic surgeons, medical oncologists, and radiation oncologists.

The primary treatment for early-stage thymoma is surgical resection. Patients who have Masaoka stage I disease should undergo resection; R0 resection is correlated with excellent rates of 5-year survival. Stage II disease—microscopic (IIA) or macroscopic (IIB) invasion through the tumor capsule—found on final pathologic studies after an R0 resection also carries a very good prognosis with regard to 5-year survival. However, adjuvant radiation therapy can be considered in cases with increased risk of recurrence: close surgical margins, WHO grade B tumor, or both. Adjuvant chemotherapy for stages I and II thymomas is reserved for patients with microscopically and macroscopically positive margins of the resected specimen.

Stage III disease includes tumor invasion into the pericardium or lung, with or without great vessel invasion; stage IVa involves metastatic disease localized to pleura or pericardium. Patients with stage III or IVa disease should be treated with multimodality therapy. Resectable tumors with solitary pleural or pulmonary metastasis (IVa) can be treated with upfront surgery followed by chemotherapy or with neoadjuvant chemotherapy followed by a resection. Neoadjuvant chemotherapy is preferred for stage III disease. Most chemotherapy regimens that have been used for neoadjuvant therapy are cisplatin-based. Response to neoadjuvant chemotherapy is seen in over two thirds of patients with most patients proceeding to resection. Complete pathologic response at the time of resection was seen in 14% of patients treated with neoadjuvant cisplatin, doxorubicin, and cyclophosphamide plus prednisone. A complete resection should be then attempted after restaging imaging. Patients who are found not to be candidates for an R0 resection intraoperatively should undergo maximum debulking followed by postoperative radiation therapy. Unilateral phrenic nerve resection is usually appropriate if needed to accomplish a complete resection. However, bilateral phrenic nerve resection should be avoided because of the high likelihood of respiratory compromise. Postoperative radiation therapy regimens vary from 45 to 50 Gy for microscopic residual disease or close surgical margins and up to 60 Gy for gross residual disease.

Adjuvant radiation therapy with completely resected stages II and III disease is controversial because there is no evidence for improved survival or decreased recurrence rates.

Stage IVb thymomas, unresectable tumors, and biopsy-proven thymic carcinoma are treated with definitive platinum-based chemotherapy. Thymic carcinoma metastasizes to the liver, bone, and brain as well as the thorax. No randomized trials have been conducted to guide the choice of treatment because of the rarity of the disease. Regimens studied include cisplatin, doxorubicin, and cyclophosphamide; partial and complete response rates of 50% and 10% were observed, and the median length of survival was 37.7 months. Etoposide with cisplatin appears to produce slightly better results, with partial and complete response rates of 56% and 31%, respectively. Median length of survival was also better, at 52 months.

TABLE 1: World Health Organization staging: histologic categories

B2	Cortical thymoma
B3	Epithelial thymoma
C	Thymic carcinoma

OPERATIVE MANAGEMENT

Before surgical resection, pulmonary function testing should be performed both to stratify the risk for perioperative pulmonary complications and to obtain baseline values.

Classically, the surgical approach to early-stage thymomas is usually through a partial or complete median sternotomy. With solitary pulmonary or pleural metastasis, a separate thoracotomy or videoscopic approach can facilitate access to the pleural space. However, invasive or locally disseminated thymomas, Masaoka stage III or IV, should be approached through a sufficiently large incision. A clamshell incision affords improved exposure to bulky tumors that obscure important mediastinal structures and renders access to bilateral pleural spaces. Thoracoscopic and robotic approaches have been developed and can facilitate complete resection of early-stage thymomas. However, it is very important to not violate the primary

TABLE 2: Masaoka staging system and survival

Stage	Definition	Frequency at presentation	5-year survival rate	10-year survival rate
I	Macroscopically encapsulated, no microscopic invasion of the capsule	40%	92%	88%
II	IIa: Macroscopic invasion into mediastinal fat or pleura IIb: Microscopic invasion of the capsule	25%	82%	70%
III	Invasion into neighboring organs	25%	68%	57%
IVa	Pleural or pericardial metastasis	10%	61%	38%
IVb	Lymphatic or hematogenous metastasis	1%-2%	0%	0%

Data summarizing the results from multiple large studies from Detterbeck FC, Parsons AM: Thymic tumors, Ann Thorac Surg *77:1860–1869, 2004.*

principles of surgical resection in the enthusiasm to perform a minimally invasive procedure. Excessive tumor manipulation or disruption of the tumor capsule may result in spread of tumor into the mediastinum or pleural space. Minimally invasive approaches are not appropriate for larger thymomas (>4 cm) or outside of centers without substantial experience in robotic or thoracoscopic thymectomy. Transcervical thymectomy in the presence or suspicion of a thymoma should be avoided because of concern for incomplete mediastinal resection.

Transsternal Thymectomy

The chief goal of every surgical approach is to achieve a complete resection of all thymic tissue and the tumor, which is crucial for a good outcome. After sternotomy, the mediastinum and bilateral pleural spaces are evaluated for unanticipated metastatic disease. The tumor is evaluated to ensure that it can be completely resected and to see what, if any, structures need to be removed en bloc. In cases of myasthenia gravis, all anterior pericardial fat should be resected because it can contain ectopic thymic tissue.

Dissection can begin at the inferior poles of the thymus to clear it of the pericardium cranially until the left innominate vein is encountered. Invasion of the pericardium necessitates anterior pericardiectomy. This procedure can be performed without any consequences. The thymic venous branches draining into the innominate vein are then divided after ligation. The dissection should extend laterally to the phrenic nerves on both sides. The arterial blood supply from the internal mammary arteries can usually be divided with electrocautery. The superior horns of the thymus are then dissected, and division of the thyrothymic ligament liberates the gland.

Transsternal thymectomy remains the "gold standard" in surgical treatment of both myasthenia gravis and thymoma. The ability to achieve direct tumor visualization, palpation, and delicate direct handling suggests that transsternal thymectomy remains the sole approach for advanced-stage thymomas and thymic carcinomas. The limitation of this approach is increased hospital stay and outpatient postoperative recovery in comparison with approaches that do not require sternal division.

Video-Assisted Thoracic Surgery: Thymectomy

The use of minimally invasive thoracoscopic and robotic approaches for resecting small thymomas has increased. Thoracoscopic thymectomy can be approached via either the right or left side, depending on surgeon's preference and lateral dominance of the thymus. After intubation with a double-lumen tube, the patient is then placed in the lateral decubitus position, as for a conventional thoracotomy. A port is introduced along the midaxillary line between the sixth and eighth intercostal spaces according to the site of the tumor. In addition, two or, in rare cases, three other operative ports are positioned along the anterior and posterior axillary line to triangulate the working space around the lesion.

The dissection starts inferiorly, on the ipsilateral side, at the pericardiophrenic angle until the inferior horn is dissected, and then it proceeds to the contralateral side until the contralateral inferior horn is reached. Subsequent dissection continues upward similarly to the transsternal approach until the left innominate vein is encountered.

The thymic veins are identified, clipped, and divided, and then the upper horns are dissected. This technique results in removal of all thymus and perithymic fat. The specimen is then liberated from the patient via a port incision and a protective pouch.

Robotic Thymectomy

Robotic thymectomy offers improved visualization and depth perception via a binocular thoracoscope and carbon dioxide insufflation, as well as improved dexterity from wristed instrumentation (EndoWrist; Intuitive Surgical, Sunnyvale, Calif). This method, however, lacks haptic feedback; thus insinuation of tissue tension must be performed visually.

Robotic thymectomy can also be performed via either the right or left side, depending on surgeon's preference and lateral dominance of the thymus. The advantage of a left-sided approach is improved visualization of the left brachiocephalic vein. The right-sided approach affords better protection of the right phrenic nerve, which courses more anteriorly than the left and hence tends to be more intimately involved with the thymus.

The patient is positioned at a 30-degree angle. The camera is then introduced in the fifth intercostal space at the midaxillary line, with two working ports introduced in the third intercostal space at the midaxillary region and the fifth intercostal space at the midclavicular line, so that all instruments are triangulated to be 8 to 10 cm apart. The right arm of the EndoWrist has a spatula with electric cautery function in order to perform dissection, and the left arm dominant instrument is a Cadière forceps, an instrument for grasping the thymus atraumatically.

The dissection follows the same principles as basic videoscopic thymectomy. Starting inferiorly, the inferior horns and perithymic epicardial fat are freed, and dissection proceeds upward until the left innominate vein is encountered. The dissection is completed by dividing the thymic veins and dissecting the upper horns. The specimen is then placed in a protective pouch and removed via a port incision.

Minimally invasive surgical approaches to thymic disease are becoming more common. Video-assisted thoracic surgery (VATS) thymectomy was reported to produce results equivalent to those of transsternal thymectomy in early-stage thymomas, with a 5-year overall survival rate of 100%. The advantage of decreased hospital stay and fewer analgesia requirements in comparison with transsternal thymectomy is especially important in patients with myasthenia gravis and impaired respiratory mechanics.

Robotic thymectomy can be considered a natural progression of VATS, offering high-definition binocular vision, and improved maneuverability of robotic instruments enabled by wrist articulation of the instruments inside the chest cavity. These features enable precise isolation of the anatomic structures and safe manipulation of the tissues. Since the early 2000s, the robotic system has facilitated extension of a minimally invasive approach to cases of malignant tumors. In cases of myasthenia gravis, improvement in symptoms is observed in more than 90% of cases, on par with a transsternal approach. Complete remission is achieved in up to 30% of patients after robotic thymectomy and has surpassed the results of VATS. This probably results because resection is more complete, involving all prepericardial fat that contains ectopic thymic tissues.

The main limitations of robotic thymectomy are lack of long-term data, pressure for inappropriate use, and cost. Initial investment in the robot itself, as well maintenance of the robotic instrumentarium, is high. Some hospitals attempt to overcome the high cost by multidisciplinary use of the robotic system.

The surgeon's experience and technical aptitude with both VATS and robotic thymectomies is correlated directly with decreased operative times and comfort with resection of larger tumors. Some authorities argue that adequate level of competence is not reached until after 70 minimally invasive thymectomies.

SUMMARY

Thymic pathologic processes range from benign gland disease associated with symptoms of myasthenia gravis to thymoma to thymic carcinoma. Surgical management of thymic disorders should be included in every case in which cure is the goal because chemotherapy alone is almost never curative.

The thymus gland lies in a precarious anatomic location; thus it is amenable to a variety of surgical approaches. Transsternal thymectomy remains the most oncologically sound approach in locally advanced thymomas and thymic carcinomas. Minimally invasive approaches are becoming options for early-stage thymomas in centers with substantial experience. A thoracic surgeon should possess technical equipoise with all approaches and tailor them as appropriate to individual clinical cases.

The Management of Tracheal Stenosis

Cameron D. Wright, MD

Tracheal stenosis is usually the result of endotracheal tube cuff ischemic necrosis of the underlying trachea. The ischemic area of trachea involves varying depths of injury that cause a spectrum of injury from mucosal to full thickness, including the cartilage. Cuff lesions are circumferential and usually become progressively stenosed until reepithelialization occurs. The site of a tracheostomy stoma may become stenosed, usually as a result of a combination of factors: excessive removal of anterior tracheal wall at the time of tracheostomy, peristomal infection, or excessive lateral pressure from the ventilator tubing. Stomal stenosis is usually triangular in shape with a collapse of the two lateral tracheal walls to the center, often with a relatively normal posterior membranous wall. The narrowest portion of the airway is the cricoid in the lower larynx. Selection of an endotracheal tube that is too large relative to the size of the cricoid can lead to circumferential injury to the cricoid mucosa, which may lead to subglottic (laryngeal) stenosis. Stenosis that involves the larynx is more complex to repair, and the results are less certain than with simple tracheal resection. Stenosis also may involve the glottis from endotracheal tube damage to the vocal cords and arytenoids. An abnormal glottis must be corrected before correction of any tracheal problem because the glottis must provide an adequate airway at the conclusion of a tracheal resection. Malacia may be present in the trachea around the stenotic area and if severe must be resected as well.

TIMING OF THERAPY

Resection should be deferred until the patient fully recovers from the original illness that precipitated mechanical ventilation. All necessary operations that require general anesthesia (e.g., burn cases that need multiple excisions and scar releases) should be completed before tracheal resection. Often steroids are mistakenly administered to treat new-onset "asthma" after prolonged intubation. Steroids should be rapidly weaned because they play no role in amelioration of postintubation stenosis and they interfere with healing of the tracheal anastomosis. Glottic pathology should be corrected before treatment of tracheal pathology. Mucosal inflammation identified with bronchoscopy should be allowed to resolve before resection to reduce the chance of an anastomotic problem. A simple stomal stenosis rarely progresses to life-threatening airway obstruction, so these patients usually can be safely observed while they recover from their critical illness. Tracheal cuff stenosis often gradually scars to the point of airway obstruction, leading to the need for urgent treatment. If the patient is in otherwise good shape, definitive treatment with resection may be performed. The airway can be temporarily improved with bronchoscopic dilation if only a short period of time (i.e., weeks) is needed before definitive treatment. Laser bronchoscopy often further injures the airway and should be avoided when one wishes to temporize before proceeding to definitive resection. If months are needed before resection can be contemplated, tracheostomy should be strongly considered. Tracheostomy must be carefully planned and performed so as not to needlessly injure normal trachea, which could jeopardize the proposed tracheal resection. The stoma

should be constructed through the most severely damaged trachea, which eventually is resected so as not to waste good trachea. Self-expanding metallic stents should not be used for postintubation stenosis because they effectively lengthen the airway injury and often convert a simple short resection to a very long resection, which has a much greater failure rate. Silicone tracheal T tubes are useful in patients who need tracheostomy to maintain an airway because they allow for normal airflow through the mouth and nose. These tubes are relatively nonreactive with the tracheal mucosa and do not usually lead to extension of the injury to the airway.

INDICATIONS FOR RESECTION

In general, any patient with obstructive airway symptoms and tracheal stenosis after intubation should have definitive tracheal resection and reconstruction. Absolute contraindications are few and include a nonreconstructible airway (usually because of excessive length of the damaged airway), severe comorbidities, and a continued need for ventilation. Relative contraindications include a history of radiation to the trachea, continued mucosal inflammation beyond the area of resection, and active steroid use.

FACTORS TO CONSIDER FOR TRACHEAL RESECTION

Anatomic and demographic factors influence how much trachea can be safely resected and reconstructed. Probably the most important factor is body habitus; young, tall, thin patients with long necks have an abundance of trachea and are the most straightforward candidates for surgery. Alternatively, elderly kyphotic, short, obese patients with short necks and a cricoid that is at the sternal notch are the most challenging cases. Recent high-dose steroid use and insulin-dependent diabetes are risk factors for anastomotic problems, so special attention needs to be paid to the amount of tension on the anastomosis in these patients at higher risk. Pediatric patients tolerate anastomotic tension less well than adults; ideally resections only under 30% should be done in children, whereas some adults can tolerate resections up to 50% of the length of the trachea. Previous tracheal surgery causes relative fixation of the remaining trachea and thus limits any possible reresection to less than normal. Previous radiation therapy to the trachea also limits tracheal mobility and impairs microvascular blood supply, both of which place constraints on how much trachea can be safely removed.

AIRWAY MANAGEMENT

Patients who present with critical airway obstruction almost always can be managed with bronchoscopic dilation. A tracheostomy very rarely is needed to establish an airway acutely in postintubation tracheal stenosis. Patients should be promptly taken to the operating room for urgent bronchoscopic dilation. If the airway is judged to be critical, muscle relaxants are avoided and induction of anesthesia is done with an inhalational technique, which allows the patient to breathe spontaneously until the airway is secured with bronchoscopy. The surgeon must be present during induction of anesthesia with all equipment immediately available and absolute competence to establish an airway. When the patient's condition is deep enough to allow airway manipulation, rigid bronchoscopy is commenced with an adult #7 or #8 rigid bronchoscope to visualize the airway and stenosis. Dilation is begun with plastic small-diameter Jackson dilators through the bronchoscope until the maximal size is reached (about 6 mm). At this point, the airway is open enough to allow suctioning of retained distal secretions and to allow the anesthesiologist to ventilate the patient enough to return the end-tidal CO_2 to normal. The airway can be further dilated with passage of serial-sized rigid bronchoscopes from a pediatric #3 up to an adult #9. The surgeon can appreciate the degree of resistance with the passage of each size scope to decide exactly how far to dilate so as to avoid tearing the airway. The surgeon should select the proper sized bronchoscope that is just a little too big to fit through the stenosis to begin dilation with. This allows for a graded stretching of the stenosis. If too large a size is selected, the lip of the bronchoscope can instead tear the mucosa, leading to development of a flap that can occlude the end of the bronchoscope and lead to loss of the airway. Alternatively, the trachea can be dilated with balloon dilation. If dilation is planned as a temporizing measure, in general the dilation should be to the largest size possible so it lasts for as long as possible. If dilation is being done just before a resection, usually one dilates just enough to accept a #6 or #7 endotracheal tube.

TRACHEAL RESECTION AND RECONSTRUCTION

The patient is placed supine with an inflatable bag under the shoulders and the head placed in a soft gel ring that provides stability. At the beginning of the operation, the inflatable bag is inflated to extend the neck almost to the point of causing the head to float. An inflatable bag is used as when the trachea is to be reapproximated the bag is deflated and the head is flexed forward to cause the larynx and trachea to devolve toward the carina, which reduces tension on the anastomosis. The neck and anterior chest are prepped and sterilely draped. Usually a low collar incision is made just above the clavicles (Figure 1). If a stoma is present and is close to the incision, it is incorporated into the incision and excised. If it is inconveniently far away, it is ignored in terms of incision placement and later excised and closed separately. Some elderly kyphotic cases require access to the upper mediastinum for adequate exposure to the trachea; in such cases, all that is needed is a partial upper sternotomy through the manubrium only for access. Access is achieved below the pretracheal plane; the innominate vein and artery are simply retracted away from the trachea for excellent exposure all the way to the carina. Full sternotomy or lateral thoracotomy is never needed to deal with postintubation stenoses. Once the collar incision is made, subplatysmal flaps are elevated from the top of the thyroid cartilage to the clavicles. The strap muscles are separated in the midline and retracted laterally. The thyroid isthmus is divided if it has not already been done. The fatty tissue below the thyroid covering the airway is divided in the midline to complete the exposure of the entire anterior aspect of the airway present in the neck. The pretracheal fascia is elevated off the trachea at the sternal notch, and dissection is carried down to the carina, staying directly on the trachea as if for mediastinoscopy. This pretracheal mobilization facilitates reapproximation of the trachea and reduces tension on the anastomosis.

The anterior surface of the trachea is exposed from about 3 o'clock to 9 o'clock, which still preserves the blood supply that comes directly to the tracheal rings in a low lateral fashion. The area of the stenosis is now dissected in a circumferential fashion, staying exactly on the wall of the trachea so as to avoid injury to the recurrent nerves. The recurrent nerve is never dissected out and exposed. Injury to the nerve is rare if dissection is kept close to the trachea. Sometimes subtle cuff stenoses are difficult to see externally to know where to dissect. In such cases, intraoperative flexible bronchoscopy with pulling the endotracheal tube back to the cricoid allows precise identification of the limits of the stenosis. The surgeon on the field can pierce the trachea with a fine 25-gauge needle, which can be seen by the bronchoscopist to precisely localize the lesion. The trachea should be dissected no more than 1 cm beyond the stenosis to limit ischemia to the two cut ends of the divided trachea, which survive by collateral submucosal vascular supply. With high lesions, transection is carried out below the lesion. The endotracheal tube cuff is deflated before

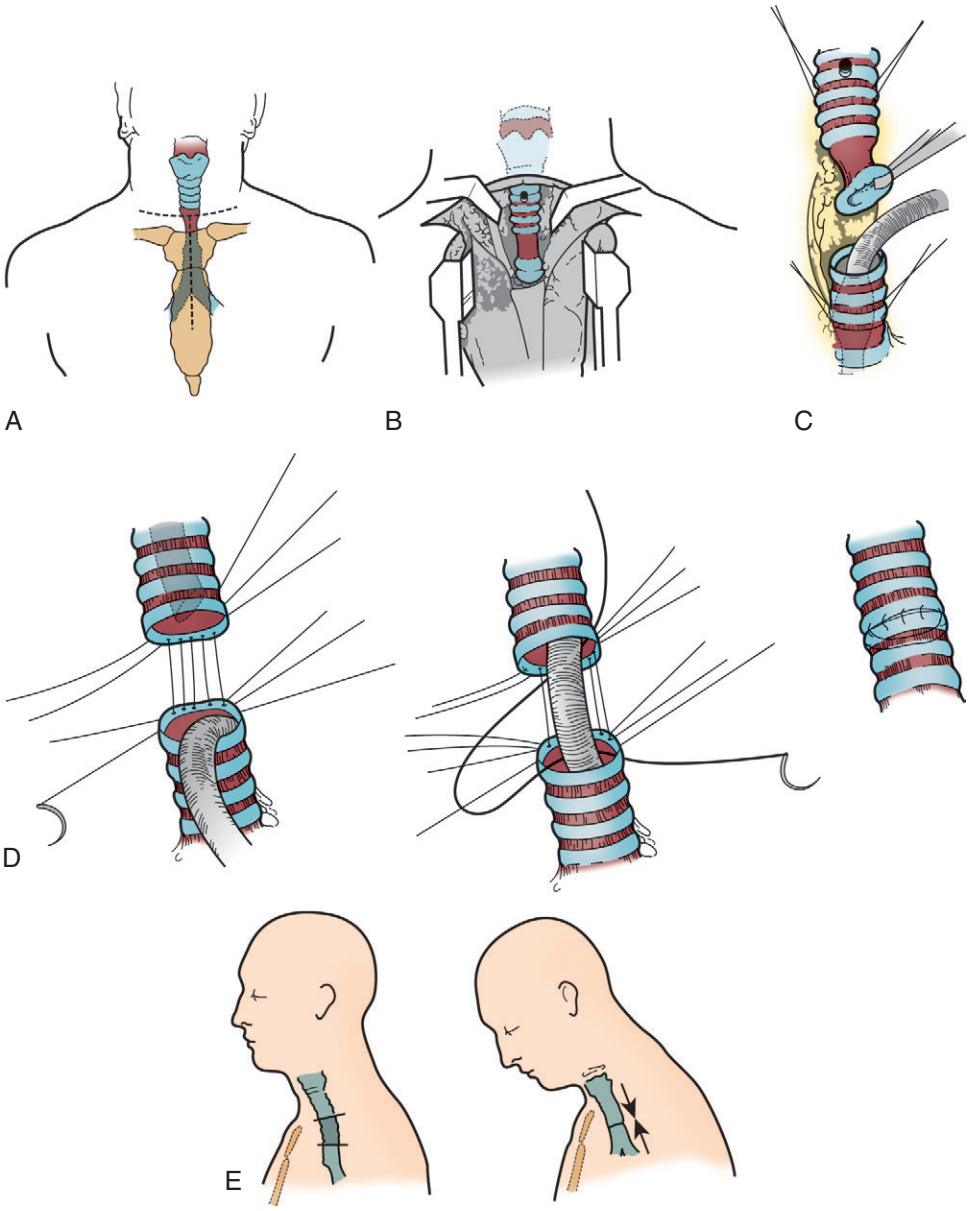

FIGURE 1 Tracheal resection and reconstruction for postintubation stenosis. **A,** A collar incision is used for most cases of postintubation stenosis. For very low lesions or for older patients with kyphosis, the upper sternum is split to provide better access. **B,** Access to the distal trachea is achieved by retracting the vessels forward and inferiorly. The innominate vein is never divided, and the innominate artery is left in its investing sheath to separate it from the eventual anastomosis. **C,** Once the trachea has been divided, ventilation is carried out with a sterile armored endotracheal tube on the field and is controlled by the assistant. **D,** The technique of anastomosis with fine 4-0 interrupted absorbable sutures. The native endotracheal tube can be faintly seen in the proximal trachea in the first drawing. After the posterior sutures are placed, the native endotracheal tube can be advanced into the distal trachea to allow placement of the anterior sutures. **E,** Cervical flexion reduces tension on the anastomosis by devolving the trachea toward the carina. *(From Grillo HC: Surgery of the trachea,* Curr Probl Surg *1970;7:2-59).*

the trachea is incised so the cuff inflates at the end. The tip of the endotracheal tube is pulled into the proximal airway out of the operative field. The stenotic trachea is elevated off the esophagus and dissected toward the larynx until relatively normal trachea is reached for the proximal tracheal transection. The distal airway is intubated with a separate sterile long armored endotracheal tube and is typically held in place and manipulated by the assistant. The distal airway must be kept clear of blood by the assistant to maintain good pulmonary hygiene. With a low lesion, the trachea is usually transected just above the stenosis and the stenotic trachea is dissected downward off the esophagus to the more normal distal trachea. In general, for all but the shortest lesions, it is better to remove less rather than more trachea and then rejudge both the quality of the remaining trachea against the degree of tension that will be required to perform the anastomosis. A balancing act is almost always necessary between the desire to achieve a normal trachea for anastomosis and the desire for an increased level of tension for the anastomosis. Sometimes mildly abnormal tracheal mucosa must be left behind to allow the anastomotic tension to be at an acceptable level. This judgment of how much to resect in all but the shortest stenoses is critical and takes experience to develop.

Lateral stay sutures of 2-0 Vicryl (Ethicon, Inc, Somerville, NJ) are placed at 3 o'clock and 9 o'clock about 2 tracheal rings from the cut edge, which will be tied outside the airway to loosely approximate the trachea and help reduce tension on the anastomotic sutures. If the resection is very short and thus the anastomotic tension minimal, the anastomotic sutures are placed next. If a fair amount of tension is expected, a trial approximation is usually done to decide whether additional release measures are needed. This judgment takes experience to develop and is critical to a successful result. If the tension is judged to be excessive, the distal trachea is mobilized to the maximal extent as a first step. If this is not enough, then usually a suprahyoid laryngeal release as described by Montgomery needs to be performed. A suprahyoid release usually translates to an additional 1 to 1.5 cm of tracheal length. Once the surgeon is assured the trachea can be safely reapproximated, the anastomosis is begun. Circumferential fine 4-0 Vicryl sutures are placed starting in the posterior midline and working out to the lateral stay sutures at 3 o'clock and 9 o'clock

on both sides. The sutures are placed so that the knots are on the outside and are about 3 to 4 mm deep from the cut edge and 3 mm apart from each other. Each suture is placed in a snap after the needle is cut off and then tagged to the drapes in successive order so that the more superficial sutures can be tied first followed by the deeper ones. Once the posterior sutures are placed, the remaining anterior sutures are placed again from one stay to another. Ventilation during the anastomosis is intermittent, with the assistant removing the endotracheal tube while the surgeon places a suture and then replacing the tube to allow ventilation while another suture is being readied. Once all the sutures are placed, the inflatable bag under the shoulders is deflated and the head elevated to reduce tension on the anastomosis. Ventilation is then switched back to the native endotracheal tube by carefully advancing the tube past the anastomosis into the distal trachea. Care must be taken to avoid entrapping or tangling the anastomotic sutures. The assistant then takes tension off the suture line by maintaining tension on the lateral stay suture and all the anterior sutures while the surgeon ties the lateral stay suture on the surgeon's side of the table. The opposite stay is then tied, followed by the anterior sutures and then finally the posterior sutures.

The endotracheal tube cuff is then deflated, and a large tidal volume breathe is given to an airway pressure of about 30 cm of water to test the anastomosis to ensure it is airtight. The author also pulls back the endotracheal tube and rebronchoscopes the patient to inspect the anastomosis from the inside as well. The anastomosis is covered with available vascularized tissue: the thyroid, a pedicled thymus flap, or a pedicled strap muscle. The wound is then irrigated, a suction drain placed, and the wound closed. A heavy guardian suture is placed between the chin and chest to prevent inadvertent neck extension by the patient. The suture is placed so that the neck is in a neutral position, not in a severe flexion position. The patient is awakened and extubated in the operating room and observed long enough to ensure a good airway. Patients are usually kept in the hospital 5 to 7 days for observation. A bronchoscopy is usually done on the anticipated day of discharge to carefully inspect the anastomosis and ensure there are no impending anastomotic complications. Recovery is usually quick and uneventful.

RESULTS

Results of tracheal resection have been quite satisfactory. From 1965 to 1992, 503 patients underwent tracheal resection and reconstruction for postintubation stenosis. This included the author's early experience before standardization of the operation was accomplished. Fifty-three of these patients had previous attempts at tracheal resection. A total of 521 resections were done, 13 for restenosis after initial repair. Lengths of resection averaged 3.5 cm and extended up to 7.5 cm. Results were good in 87.5% and satisfactory in 6%; failure occurred in 4%, and deaths in 2.4%. Failures were treated with tracheostomy in 11 patients, with T tubes in 7 patients, and with dilations in 2 patients. Prior resection increased the failure rate from 2.1% to 9.7% and the mortality rate from 2.1% to 3.8%. The level of the airway anastomosis is also a predictor. Trachea to trachea anastomoses faired best with a failure rate of 2.2%, trachea to cricoid anastomoses led to a 6% failure rate, and trachea to thyroid cartilage had a failure rate of 8.1%. Laryngeal releases were only performed in 46 patients. Dehiscence or restenosis occurred in 29 patients with 7 deaths. A subsequent publication from the author's group identified the risk factors for anastomotic failure: length, >4 cm; diabetes; age, <17 years; preoperative tracheostomy; reoperation; and laryngeal anastomosis.

The Management of Acquired Esophageal Respiratory Tract Fistula

Jahan Mohebali, MD, and
Christopher R. Morse, MD

OVERVIEW

Acquired esophageal respiratory tract fistulas present clinicians with significant diagnostic and management challenges. These fistulas result from myriad causes, both benign and malignant, and can involve the trachea or lower airways. Benign fistulas can be further separated into iatrogenic and noniatrogenic etiologies. In even the mildest circumstances, patients have chronic symptoms that include cough, aspiration, and recurrent bronchopulmonary infections. In severe cases, they may be in a clinical state of rapid and precipitous decline. Multiple approaches to treatment have been described in the literature and range from endoscopic stenting to surgical resection and reconstruction. Regardless of the underlying etiology, or chosen surgical approach, optimal management depends on early diagnosis and definitive repair. In cases in which definitive repair must be delayed, initial intervention should focus on fistula control and patient stabilization.

BENIGN ESOPHAGEAL RESPIRATORY FISTULAS

Benign acquired esophageal respiratory fistulas arise from both iatrogenic and noniatrogenic causes. The most common iatrogenic cause is tracheoesophageal fistula (TEF) formation in the setting of prolonged mechanical ventilation. This well-described clinical entity results from tissue pressure necrosis from the endotracheal tube cuff. The risk of fistula formation is increased when a concomitant

nasogastric tube is present, presumably from opposing pressure exerted on the esophageal wall. Patients prone to poor tissue healing (e.g., with diabetes or on high-dose steroid therapy) are particularly susceptible to this complication. High-volume, low-pressure endotracheal tube cuffs have mitigated, although not eliminated, these fistulas. Other patients at risk for iatrogenic fistulas are those who sustain injury to the airway or esophagus, including those undergoing esophageal dilation; surgery of the esophagus, airway, or cervical spine; and chronic stent placement.

Noniatrogenic causes are many and may affect any part of the esophagus and airway. Common etiologies include perforation of esophageal diverticula and mediastinal inflammatory processes, such as infectious and granulomatous disease. Fistula formation may also occur as a complication of caustic ingestion, foreign bodies, and trauma. Rare cases of fistula formation in patients with underlying immunodeficiency and esophageal Crohn's disease are also reported in the literature.

Timely diagnosis of benign esophageal respiratory tract fistulas requires a high index of suspicion. The cardinal symptoms of chronic cough, aspiration, and recurrent respiratory infection are nonspecific, and although fistulas are considered in the differential diagnosis in the setting of known esophageal or respiratory malignancy, benign fistulas are rarely considered as the underlying etiology in patients without neoplasm. As a result, many of these patients present after years of persistent symptoms that have been misdiagnosed as adult onset asthma or recurrent community-acquired pneumonia.

In patients on mechanical ventilation, signs of TEF include inability to achieve adequate tidal volumes, a persistently dilated stomach, or an unusually high level of air escaping from either a nasogastric or gastrostomy tube. In severe cases, patients may experience respiratory failure and sepsis that is refractory to standard therapy.

When suspicion for an underlying fistula is high, diagnosis is best achieved with barium swallow. Although this study requires patient cooperation, and thus precludes use in patients on ventilation, it remains the most highly sensitive diagnostic test. Bronchoscopy and esophagoscopy should always accompany a contrast study for direct visualization and characterization of the fistula in preparation for operative intervention.

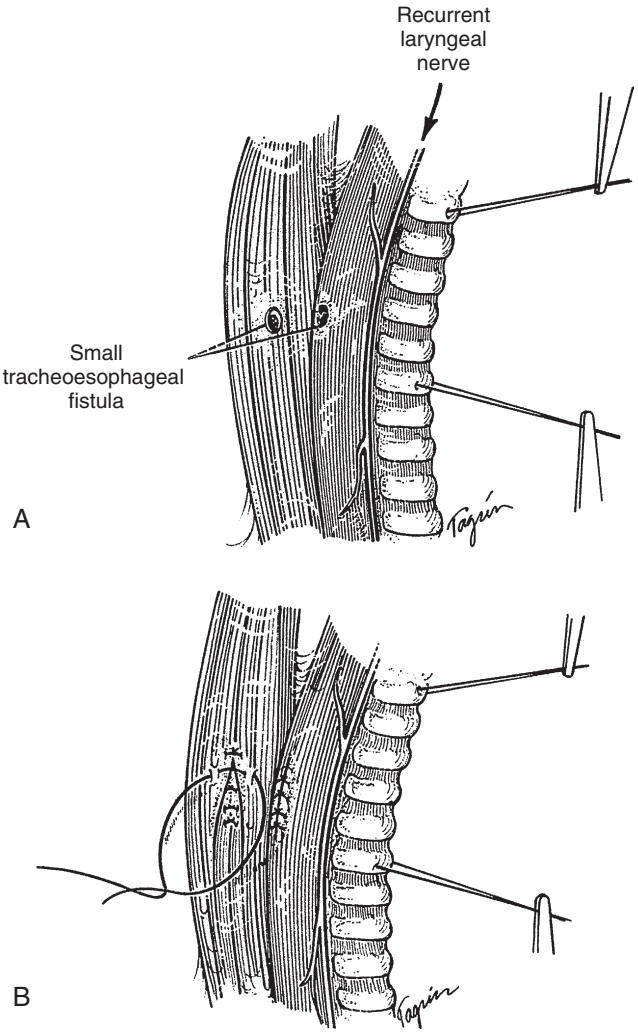

FIGURE 1 Small tracheoesophageal fistulas can be managed with division of the fistula and direct repair of the trachea and esophagus. **A,** The fistula is approached laterally, and the recurrent nerve is elevated with the trachea. **B,** The esophagus is closed in two layers. *(With permission from Mathisen DJ, Grillo HC, Wain JC, et al: Management of acquired nonmalignant tracheoesophageal fistula,* Ann Thorac Surg *52:759, 1991.)*

TREATMENT OF BENIGN FISTULAS

Successful repair depends on appropriate timing and preoperative planning. Historically, a multistep procedure was used for surgical repair; however, Grillo pioneered a one-step procedure that showed no difference in recurrence rates with simultaneous elimination of the morbidity of esophageal diversion. Patients on mechanical ventilation represent a significant challenge in that their rate of fistula recurrence is often higher after surgical repair. This is primarily the result of positive pressure on the airway suture line. Although it is not an absolute contraindication, repair in these patients should ideally be delayed until successful weaning from the ventilator has been accomplished.

Repair of Benign Tracheoesophageal Fistula

A variety of techniques have been described to surgically repair TEF. These include direct closure of the tracheal and esophageal defects (Figure 1), segmental tracheal resection and primary anastomosis with direct esophageal closure, tracheal closure with an esophageal patch, and as previously mentioned, a two-stage approach with esophageal diversion and primary closure of the tracheal defect. Regardless of the approach used, repair must take into account any underlying tracheal stenosis or tracheomalacia. If a stoma is present, the decision to include it in the repair depends on the distance between the stoma and the fistula. In the case of TEF resulting from prolonged endotracheal intubation, the surgeon must understand that there is often circumferential tracheal necrosis from the cuff that is best addressed with concomitant tracheal resection and reconstruction. Toward this end, Grillo's anterior cervical approach allows for adequate survey of the tracheal defect and is ideal if resection and reconstruction become necessary. Furthermore, transection of the trachea regardless of whether resection is planned facilitates assessment and repair of the esophageal defect. If no tracheal tissue is resected, the ends of the trachea can simply be primarily reanastomosed after esophageal repair.

The operation begins with the patient placed supine with the neck extended. A low cervical collar incision should incorporate any stoma and provides excellent exposure for proximal fistulas (Figure 2). If the fistula lies lower, a partial sternotomy improves exposures. Subplatysmal flaps are then raised, strap muscles are separated, and the thyroid isthmus is ligated and divided. The boundaries of the involved tracheal segment are confirmed with introduction of a 25-gauge needle through the anterior trachea with direct bronchoscopic vision. Circumferential tracheal dissection is then carried out in the area of anticipated transection, typically at the distal boundary of the fistula orifice. Direct dissection on the trachea minimizes nerve palsy.

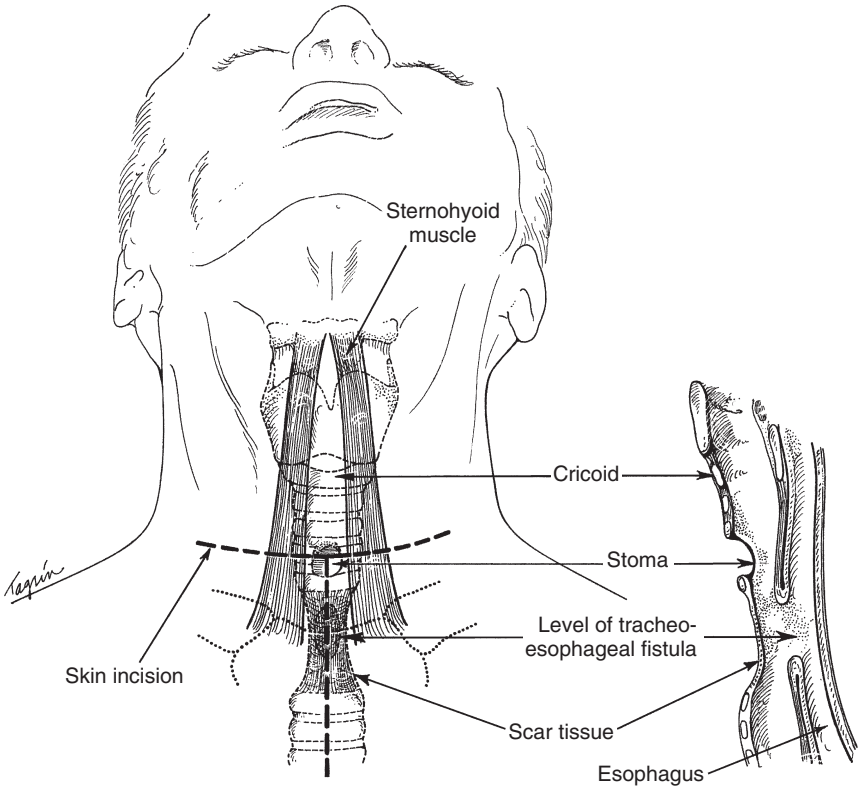

FIGURE 2 Exposure for most tracheoesophageal fistulas is through a low cervical collar incision. Splitting the manubrium might facilitate distal tracheal exposure. *(With permission from Mathisen DJ, Grillo HC, Wain JC, et al: Management of acquired nonmalignant tracheoesophageal fistula,* Ann Thorac Surg *52:759, 1991.)*

When dissection is complete, the trachea is divided (Figure 3). Cross-field ventilation is then achieved with intubation of the distal trachea. The orotracheal tube is pulled back, and a plane is developed between the esophagus and the membranous trachea. Once the esophageal defect is visualized, the mucosal edges are freshened and a two-layer longitudinal repair is carried out over a nasogastric tube. The inner layer is closed with inverting, interrupted 4-0 silk sutures through the full thickness of the mucosa. The knots should lie within the esophageal lumen. The outer layer consists of interrupted 4-0 silk sutures to reapproximate the esophageal muscle over the mucosal closure. A muscle flap, most often the sternohyoid, is used to cover the esophageal suture line to reduce the rate of fistula recurrence (Figure 4).

Next, attention is turned to the trachea. If circumferential tissue necrosis or concomitant tracheal stenosis or tracheomalacia is found, resection with reconstruction should be performed. If this is unnecessary, simple primary reanastomosis is performed. First, stay sutures are placed laterally to secure the proximal and distal trachea. Interrupted 4-0 vicryl sutures are then used to reanastomose the trachea, beginning with the membranous wall posteriorly and moving circumferentially forward (Figure 5). At this point, the endotracheal tube is advanced so that the cuff lies distal to the suture line and the neck is maintained in a flexed position to reduce tension. The stay sutures are tied first followed by the anastomotic sutures. An additional strap muscle flap is used to cover the anterior tracheal suture line. A drain is placed, and the cervical incision is closed in layers over it.

Occasionally, the length of the tracheal defect prohibits resection and reconstruction. In this case, the trachea is still divided to facilitate esophageal repair. No tracheal resection, however, is performed; the tracheal defect is instead closed over a T tube. A pediatric endotracheal tube can be passed through the side arm of the T tube to provide mechanical ventilation.

As mentioned, repair should ideally be delayed until the patient is weaned from mechanical ventilation. However, in some cases, the fistula itself may be responsible for ongoing respiratory failure and ventilator dependence. In these challenging circumstances, control of the fistula is critical to achieve extubation before definitive surgical repair. The patient's current endotracheal tube should be replaced with an extra long cuffed tube that allows the cuff to sit distal to the tracheal defect. This maneuver simultaneously minimizes additional tissue necrosis and excludes the fistula from both positive airway pressure and the lower respiratory tract. A nasogastric tube should be pulled back so that the tip sits just proximal to the esophageal orifice of the fistula to control oropharyngeal secretions. A gastrostomy tube and jejunostomy tube should be placed for drainage of gastric secretions and nutritional support, respectively. In cases in which these measures are insufficient to control the fistula, tracheal or esophageal stents have been described as temporizing methods. Although stents typically deliver unacceptably high rates of recurrence and complications when used as definitive therapy for benign fistulas, recent studies support their use as adjuncts in the particularly challenging scenario of patients on mechanical ventilation. These stents can often be removed later at the time of definitive surgical repair. It should be emphasized, however, that in the case of benign TEF, the esophagus and trachea should typically not be stented simultaneously because the two opposing stents are likely to contact one another, thereby introducing a foreign body into the fistula tract and subsequently impeding healing and closure.

Repair of Benign Bronchoesophageal Fistulas

In the case of lower esophageal airway fistulas, successful operative repair begins with the accurate definition of fistula anatomy. This requires examination with barium swallow, coupled with direct visualization with bronchoscopy and esophagoscopy in the operating room. Bronchoscopy often shows an area of inflammatory change with heaped up granulation tissue at the fistula orifice. Esophagoscopy, in turn, typically reveals a papilla or dimple at the esophageal defect. Literature reviews have shown that the vast majority of noniatrogenic, benign bronchoesophageal fistulas, which usually arise

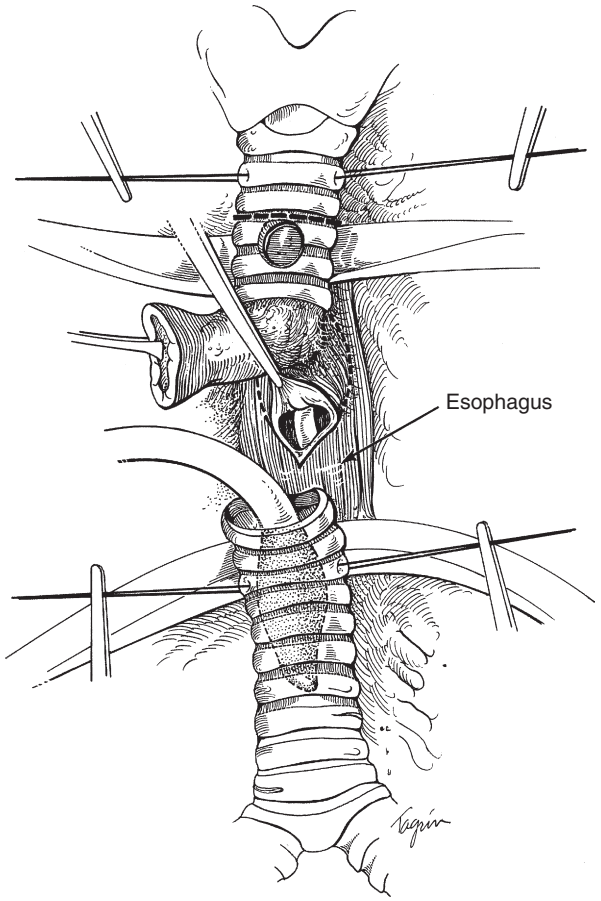

FIGURE 3 Circumferential dissection of the trachea allows the recurrent laryngeal nerves to fall laterally away from the trachea. Transection of the trachea exposes the esophagus. Ventilation is achieved across the operative field with placement of a sterile Tovell tube into the distal trachea. *(With permission from Mathisen DJ, Grillo HC, Wain JC, et al: Management of acquired nonmalignant tracheoesophageal fistula,* Ann Thorac Surg *52:759, 1991.)*

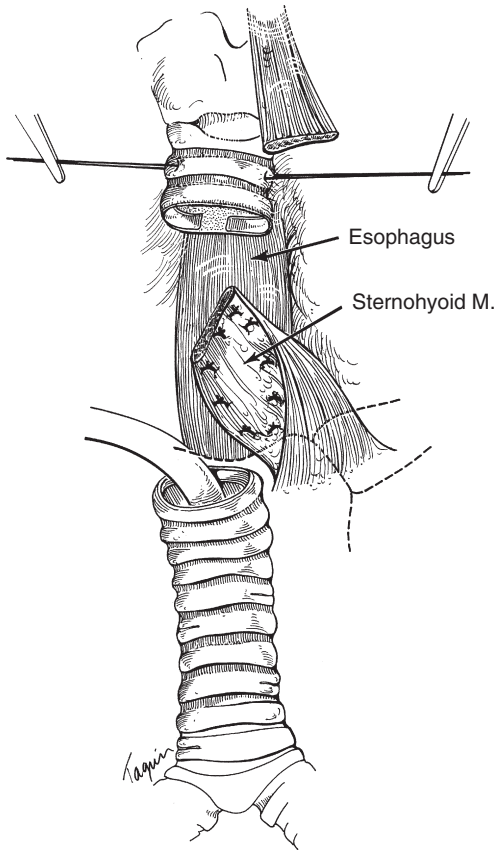

FIGURE 4 A pedicled strap muscle is used to buttress the esophageal repair and separate the esophageal suture line from the tracheal anastomosis. *(With permission from Mathisen DJ, Grillo HC, Wain JC, et al: Management of acquired nonmalignant tracheoesophageal fistula,* Ann Thorac Surg *52:759, 1991.)*

from mediastinal granulomatous or infectious processes, involve the right bronchial tree and distal esophagus. The more obtuse angle of the right mainstem bronchus, with its subsequent proximity to inflamed mediastinal nodes and the esophagus, may explain this pattern. Conversely, fistulas that result from intrinsic esophageal disease, or iatrogenic esophageal injury, are more likely to involve the left bronchial tree. These rules are not concrete, however, and fistulas can adopt unusual or tortuous paths.

After fistula characterization, repair begins with a right posterolateral thoracotomy. The fistula is then exposed and divided. Primary repair of the esophagus and bronchus can typically be achieved; however, it is of utmost importance to address any underlying esophageal or airway disease with resection if indicated. A pedicled tissue flap consisting of intercostal muscle, omentum, pericardial fat, or thickened pleura should be interposed between the esophageal and airway suture lines to prevent dehiscence and recurrence.

MALIGNANT ESOPHAGEAL RESPIRATORY TRACT FISTULA

The most common cause of malignant esophageal airway fistulas is esophageal malignancy, closely followed by lung cancer, although other intrathoracic neoplasia may result in the development of fistulas. By definition, fistula formation implies metastatic disease, and therefore, prognosis is exceedingly poor. As opposed to the case of benign disease, malignant fistula treatment focuses on palliation rather than cure. Historically, esophageal diversion or exclusion was the mainstay of treatment; however, the modern cornerstone of management is endoscopic stent placement. Use of stents to definitively manage benign fistulas is typically discouraged because of high rates of recurrence and complications related to stent migration. As previously mentioned, the exception is in the case of patients on mechanical ventilation with failed traditional techniques of fistula control. Stent use in the setting of malignant fistulas, however, relieves obstruction and becomes fixed in the malignant stricture that is often present to seal the fistula and prevent stent migration.

Esophageal Stents

Esophageal stents have evolved significantly from early models that consisted of rigid plastic to self-expanding metal stents (SEMS), to covered SEMS, and most recently, to hybrid self-expanding plastic stents. Each model has distinct advantages and shortcomings. Rigid plastic stents required significant dilation and often led to subsequent complications. SEMS have largely replaced plastic precursors; however, they are associated with significant tumor ingrowth and a subsequent decreased rate of retrievability. A newer generation of covered SEMS has higher retrieval rates but is also associated with an increased incidence of stent migration. Other complications reported in the literature include hemorrhage, obstruction, and perforation, with the complication rate rising with increasing stent dwell

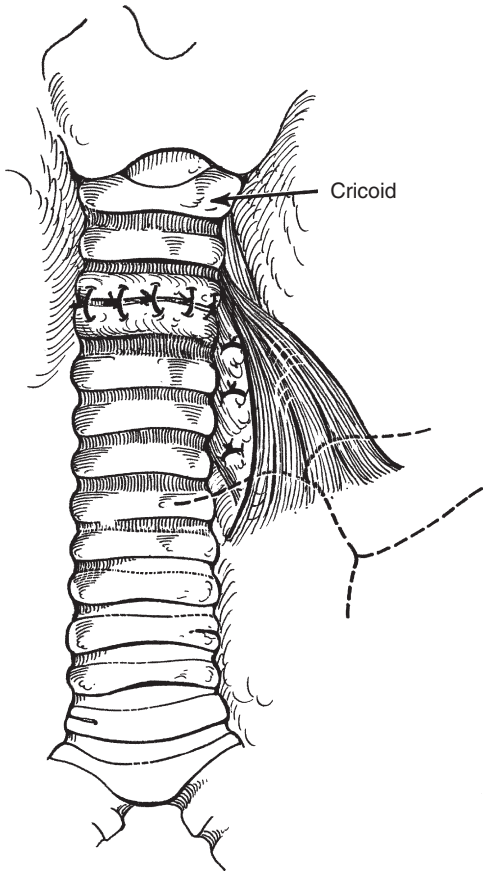

FIGURE 5 Tracheal anastomosis is performed with interrupted fine absorbable sutures (4-0 polyglactin). Four later traction sutures (2-0 polyglactin) are not shown. *(With permission from Mathisen DJ, Grillo HC, Wain JC, et al: Management of acquired nonmalignant tracheoesophageal fistula,* Ann Thorac Surg *52:759, 1991.)*

time. Each manufacturer provides a variety of stents with different lengths, diameters, and expansile forces that can be tailored to the clinical situation.

Although esophageal stent deployment can be performed with monitored anesthesia care, general anesthesia with endotracheal intubation ensures patient comfort and optimizes safety. The first step is to perform esophagoscopy to define the extent of esophageal involvement, locate the fistula orifice, and mark the boundaries of the associated malignant stricture. This is typically done in combination with fluoroscopy, whereby external clips are placed on the thorax to coincide with the proximal and distal ends of the stricture. Because many patients have underlying dysphagia, some degree of concurrent stricture dilation is also performed. In doing this, the surgeon should be cautious against overdilation of the stricture, which can decrease the possibility of achieving an adequate seal and increase the stent migration rate. After dilation, a guidewire is passed across the stricture and a stent expected to overlap the ends of the stricture by 1 to 2 cm is selected. The stent is then deployed into position with fluoroscopy using the external thoracic clips as markers. After recovery from anesthesia, barium swallow confirms sealing of the fistula tract before initiation of oral intake.

Airway Stents

Comparable to their esophageal counterparts, fistulas that arise from primary lung or respiratory tract neoplasms often require stenting for fistula occlusion. These fistulas, however, are optimally addressed by stenting of the airway rather than the esophagus because an obstructing airway stricture is likely. Concomitant esophageal stenting is occasionally required to ensure complete fistula occlusion.

A variety of airway stents that are similar to esophageal stents can be tailored to each clinical situation, and methods of deployment are analogous. Stent placement begins with evaluation of the airway and fistula orifice with bronchoscopy. Any necessary dilation is performed, and the stent is slowly deployed with direct bronchoscopic visualization. A baseline postoperative chest x-ray is useful to document stent position and to assess lung volumes. Barium swallow should confirm successful exclusion of the airway from the fistula tract.

SUMMARY

Acquired esophageal respiratory tract fistulas represent an uncommon and challenging clinical scenario. The presentation and pathophysiology of this disease entity is variable; however, treatment is based on fundamental principles: defining fistula anatomy, early intervention when feasible, and concomitantly addressing any underlying esophageal or airway pathology at the time of surgery. In patients who are ventilator dependent, initial interventions should focus on controlling the fistula and its consequent morbidity to facilitate extubation before definitive surgery. Although benign fistulas are primarily treated with operative repair, endoscopic stenting has become the palliative treatment of choice for fistulas that arise in the setting of neoplastic processes.

Repair of Pectus Excavatum

Kimberly M. Lumpkins, MD,
Paul Colombani, MD, MBA, FACS, FAAP, and
Fizan Abdullah, MD, PhD

Pectus excavatum (PE), historically known as funnel chest, is the most common chest wall deformity. It occurs in approximately 1 in 500 live births, with a male predominance of 2:1 to 9:1 in various series. The sternum is depressed towards the vertebral column with the greatest depression typically at the level of the xiphoid process. The implications of PE may range from cosmetic deformity with psychologic distress to significant cardiopulmonary impairment from decreased thoracic cavity capacity and compression of the heart. Although the exact etiology of PE is unclear, the condition is believed to result from abnormal development of the costal cartilages. Overgrowth of the costal cartilages, especially cartilages 4 through 7, leads to progressive dorsal displacement of the sternum. PE is associated with connective tissue disorders such as Marfan disease. PE often runs in families, but no specific genetic etiology has been identified.

EVALUATION OF THE PATIENT WITH PECTUS EXCAVATUM

Initial evaluation of the patient with PE requires a careful history and physical examination. One third of patients with PE have a defect evident from early childhood, and the remainder first appreciates the problem during the adolescent growth spurt. A history of worsening deformity around this time is often elicited. Symptoms at rest are rare, but the patient may report impaired exercise tolerance with shortness of breath. On physical examination, the chest should be examined for symmetry and location of the deepest point of the pectus. Asymmetry is not uncommon, and the defect is often slightly skewed to the right side. Patients with PE have a typical kyphotic posture with a protuberant abdomen. Calipers can be used to measure the chest diameter at both the deepest point of the deformity and the lateral chest wall to get an approximate indication of the severity of the pectus. Stigmata of collagen vascular disease, such as long fingers and toes, myopia, and easy bruising, may be observed. Patients who have clinical stigmata of Marfan disease but do not carry this diagnosis may benefit from referral for diagnostic evaluation.

Further diagnostic examination including chest computed tomographic (CT) scan, pulmonary function tests, and transthoracic echocardiogram is indicated to assess the degree of cardiopulmonary impairment caused by the PE. A chest CT scan without intravenous contrast allows the calculation of the Haller index, a quantification of the severity of the PE defect. For determination of the Haller index, the anteroposterior (AP) diameter of the chest is measured from the inner ribcage to the spine at the greatest point of the defect. The transverse diameter of the chest is measured from the inside of the ribs at the same location. The index is the ratio of the transverse to the AP diameters of the chest. PE repair is generally recommended at a Haller index of 3.5 or greater. An exercise pulmonary function test (PFT) is performed for assessment of lung volumes at rest and exercise. Typically, a mild to moderate restrictive defect is seen in these patients. Finally, an echocardiogram may show right ventricular compression or mitral valve prolapse. A subset of patients with PE with narrow chests exists for whom the Haller index fails; an improved corrective index has been developed to help grade the severity of their disease.

The extent of cardiopulmonary involvement in PE remains a subject of debate. Increasing Haller index has been associated with worse impairments in pulmonary function, but many patients with PE have spirometry values within the normal range. Many patients report subjective improvement in exercise tolerance after repair despite having normal PFT values both before and after surgery. In many cases, insurance requires documentation of objective measures of cardiopulmonary impairment or significant PE-related symptoms before authorization of repair. The operation is otherwise considered cosmetic in nature and is not covered.

OPEN REPAIR

The first widely adopted technique for repair of PE was the Ravitch operation. In this procedure, a midline sternal (in males) or fourth interspace transverse incision (in females) is performed and skin flaps are elevated to expose the sternum and the costal cartilages. The abnormal costal cartilages are resected in the subperichondrial plane. An anterior sternal osteotomy is performed to flatten the sternum. A metal strut is often placed retrosternally to provide more secure fixation. Historically, the Ravitch procedure was performed as early as age 4 years. However, a very small but significant subset of patients who underwent repair at such an early age subsequently had acquired Jeune's syndrome (asphyxiating thoracic dystrophy) develop as they progressed through puberty. These patients' thoracic cavities failed to expand with growth, presumably as a result of abnormal fixation of the growth plates in the costochondral joints. Correction of acquired Jeune's syndrome is complex and often unsatisfying. Most authors recommend delay of open PE repair until puberty to avoid this complication (Figure 1).

MINIMALLY INVASIVE PECTUS EXCAVATUM REPAIR (NUSS PROCEDURE)

In 1997, Nuss introduced a minimally invasive approach to PE repair. This approach relies on the natural flexibility of the costal cartilages to enable repair from the inside of the chest. Advantages include a shorter operative time and less disfiguring scar. The patient is placed supine with arms extended. The site of deepest depression of the sternum is identified and traced laterally. Incisions of 4 cm in length are made bilaterally along this line at its intersection with the anterior axillary line and are deepened until the pleura are entered with direct vision. In the original description, an introducer is then passed with thoracoscopic guidance from the left chest just retrosternally into the right chest. The thoracoscope is transferred to the right chest to observe passage of the introducer. Remaining strictly in the immediate retrosternal plane and using thoracoscopic guidance minimizes the chance of cardiac perforation or other mediastinal injury. However, in the authors' practice, thoracoscopy is no longer used during passage of the introducer. With use of slightly medial incisions, the pericardium is seen and bar passed without difficulty. In difficult cases, sternal elevation can be used to facilitate transmediastinal passage of the introducer. An umbilical tape is tied to the introducer as the tip exits the right-sided skin incision. The introducer is then withdrawn back through the left chest so that the umbilical tape traces its transthoracic passage. A pectus bar is selected based on the patient's body habitus. Ideally the bar should extend just beyond the edge of the rib cage on each side without protruding

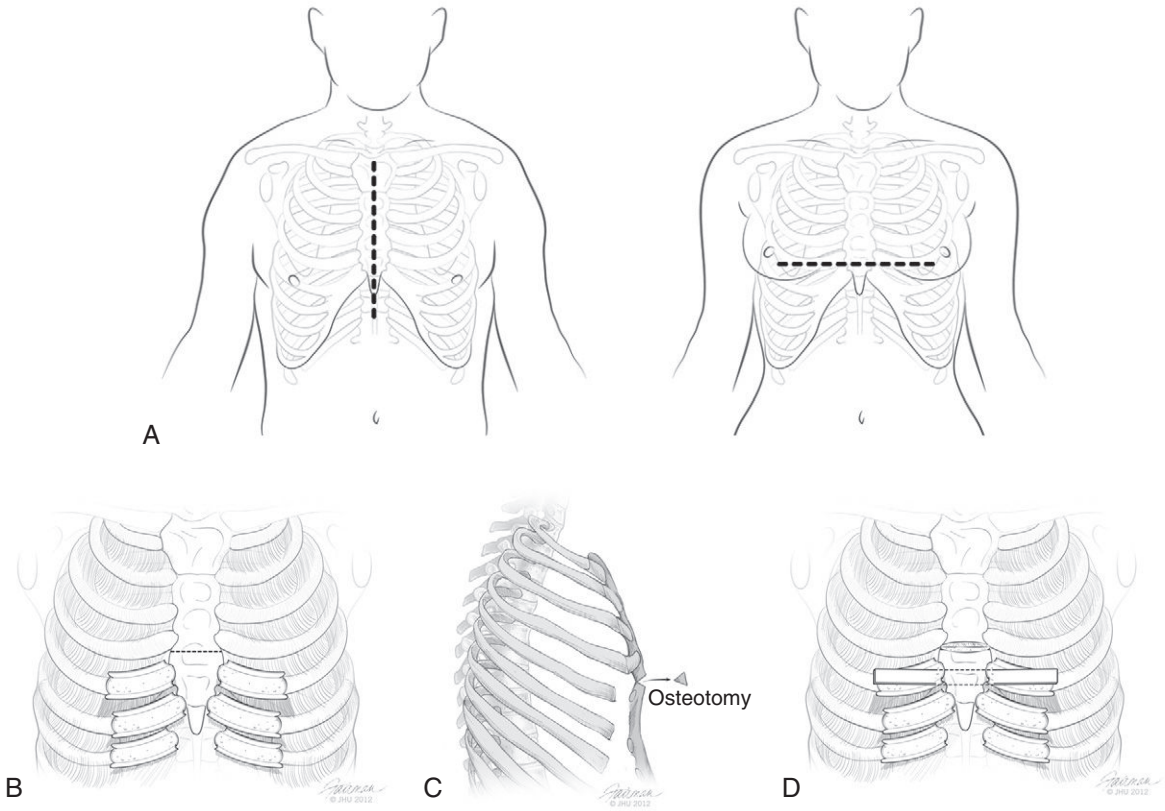

FIGURE 1 Open repair of pectus excavatum. **A,** *Left,* midline incision; *right,* submammary incision for cosmetic use in females. **B,** The costal cartilages are freed circumferentially from the perichondrium and divided at the junctions with the sternum and with the ribs. **C,** The sternal osteotomy allows the sternum to rise to a level position. **D,** Rehbein strut in place behind sternum. *(John Hopkins University Illustrations courtesy of Jennifer E. Fairman, CMI, FAMI.)*

too far beyond the ribcage, typically 2.5 cm shorter than the distance between the midaxillary lines. The exact degree of bend that must be applied to each side of the bar is a matter of judgment, but the goal is to slightly overcorrect the sternum rather than undercorrect it. The umbilical tape is tied to one end of the bar and is then withdrawn through the chest with the bar upside down (concave side up). After the bar is grasped exiting the right chest, it is flipped 180 degrees so that the convex side is elevating the sternum. Bar stabilizers are placed over the ribs on both sides to secure the bar above the ribcage. Wire or heavy polydioxanone (PDS) suture fixation of the stabilizers around the ribs is used bilaterally to avoid bar displacement. Patients with complex asymmetric defects, patients with Marfan's disease, and patients with suboptimal elevation of the sternum after placement of a single bar may benefit from placement of a second bar to improve sternal elevation. Placement of a second bar follows the principles of placement of the initial bar. A chest x-ray is obtained routinely in the recovery room. Small bilateral pneumothoraces are commonly observed as a result of air introduced during bar placement and in general may be managed expectantly without further imaging as long as the patient is clinically well (Figure 2).

Preoperative counseling is essential before repair. Postoperative pain can be considerable during the first few postoperative weeks, and some patients continue to experience pain for the entire period while the bar is in place. In severe cases, this can require removal of the bar with likely recurrence of the PE defect. Postoperative use of ketorolac and gabapentin can limit the use of narcotic analgesics. In general, the authors limit physical activity for the first 6 weeks after bar placement. After this point, there are no specific activity restrictions.

The ideal age for minimally invasive PE repair continues to be debated. A shift has been seen over the years towards repair at an older age, especially late adolescence into early adulthood. The authors typically perform the repair at 14 years of age. Recent reports suggest that patients over 30 years of age are more likely to require placement of two bars.

The correct length of time for the bar to remain in place remains debated. At least 2 years is recommended to allow adequate time for the costal cartilages to remodel in their new position. The authors have had rare immediate recurrences with bar removal at 2 years that have led them to favor leaving the bar in position for 3 years. At this point, the bar may be removed as an outpatient procedure. With general anesthetic, the previous incisions are reopened and the wires and stabilizers are exposed. The wires are cut and removed, followed by the stabilizers. The bends at either end of the bar are removed, and the bar can then be pulled out one side of the chest. The deep layers of the incision are closed with 2-0 vicryl suture and tied while a Valsalva's maneuver is performed to evacuate any introduced air. After routine subcuticular skin closure, the patient is returned to the recovery room. A postoperative chest x-ray is obtained. Small bilateral pneumothoraces may be seen and do not require intervention in the absence of clinical symptoms. The patient is discharged home with narcotic analgesia after a suitable observation period in recovery.

COMPLICATIONS OF MINIMALLY INVASIVE REPAIR

Although asymptomatic pneumothorax is commonly observed after PE repair, symptomatic pneumothorax may rarely result from inadvertent injury to lung parenchyma during bar placement. Enlarging

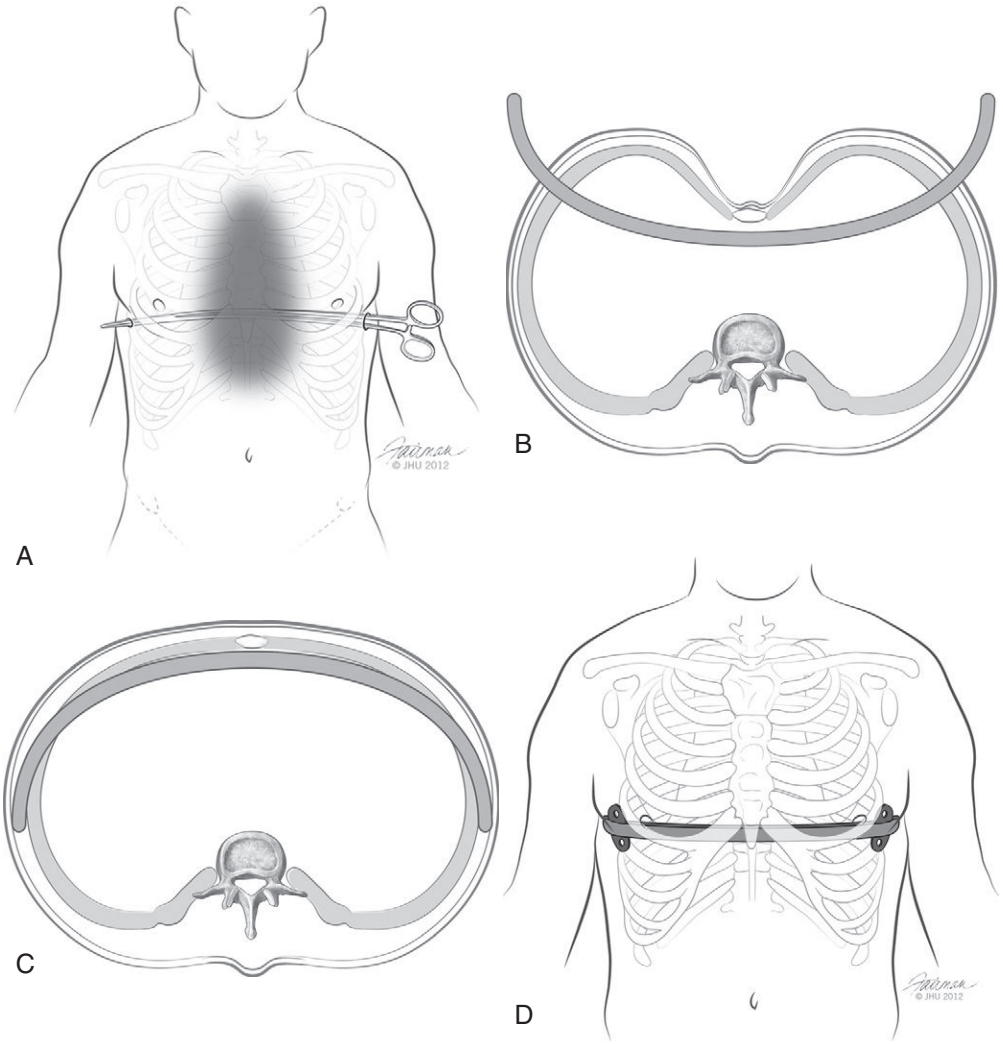

FIGURE 2 Minimally invasive pectus excavatum repair. **A,** Schematic of long clamp passing posterior to the sternum through bilateral intercostal incisions. **B,** Initial orientation of bar after passage through chest. **C,** Position of bar after flipping. **D,** Bar stabilizers in position. *(John Hopkins University, Illustrations courtesy of Jennifer E. Fairman, CMI, FAMI.)*

pneumothorax in the setting of clinical deterioration requires placement of chest tubes, often bilaterally. Urinary retention is frequently noted after surgery at a rate that exceeds that seen with other operations. The cause of this finding is uncertain, but this generally resolves within several days.

Intraoperative cardiac perforation is the most dreaded complication of minimally invasive repair. Although this is exceptionally rare, it is highly lethal. Immediate median sternotomy and cardiac repair are indicated in this setting.

Displacement of the bar can occur in as many as 5% of patients, often leading to immediate recurrence. Reoperation is required to flip the bar back into the appropriate position and resecure the bar to the rib cage. Additional wires may be necessary to adequately secure the bar in position. Wound infection is rare, occurring in less than 2% of patients, and can often be treated with antibiotics. Surgical drainage is sometimes necessary for more extensive infections.

Most pectus bars are composed of stainless steel, although titanium bars are available by special order. Unsuspected allergy to nickel may lead to localized skin reaction at the incisions or pericarditis. Symptoms may not occur for many months after placement, and these patients can often be treated medically with corticosteroids until it is time to remove the bar. Metal salt patch testing can be used before surgery to identify patients with allergies. A titanium bar is used in these individuals; however, it cannot be bent to shape as with a stainless steel bar. It must be molded to the correct shape by the manufacturer with guidance from the preoperative CT scan.

OUTCOME OF PECTUS EXCAVATUM REPAIR

Neither open nor minimally invasive repair of PE has been shown to be clearly superior in the repair of PE. Both have a higher than 94% success rate in improving psychologic perceptions and subjective assessment of exercise tolerance. No difference is seen in length of stay, although the rate of pneumothorax and reoperation is higher in the minimally invasive repair. Since its introduction, the minimally invasive repair has far surpassed the open repair in popularity and is used for the majority of PE repairs. However, the open repair may still be preferable in patients with severely asymmetric defects and in patients with mixed carinatum/excavatum phenotype. Failures of open repair have been successfully corrected with the minimally invasive approach, as have previous failures of minimally invasive repairs.

OPEN REPAIR OF ABDOMINAL AORTIC ANEURYSMS

Babak J. Orandi, MD, MSc, and James H. Black III, MD

OVERVIEW

Abdominal aortic aneurysm (AAA) affects as many as 8% of people over 60 years of age, and AAA rupture accounts for 15,000 deaths annually in the United States. Given that the natural history of AAA is progressive growth and eventual rupture and that the survival of rupture is rather dismal, the clinical aim is to detect AAAs and repair them when the risk of rupture begins to outweigh the risk of repair. The advent of the endovascular era has drastically changed AAA management. Many patients are willing to accept the increased risk of secondary interventions associated with endovascular aneurysm repair (EVAR) because of the minimally invasive nature of EVAR; however, a number of situations exist in which open surgical repair (OSR) is preferred. Unsuitable anatomy, lack of available endovascular capabilities, and uncertainty about long-term endograft durability in young patients are situations in which OSR may be the preferred approach (Box 1).

A number of large studies have characterized the phenotype of the typical patient with AAA. Risk factors include increased age, male gender, family history of AAA, increased height, hypertension, hyperlipidemia, coronary artery disease, peripheral arterial disease, cerebrovascular disease, and smoking history. The factors associated with an increased likelihood of rupture are female gender, increased mean arterial blood pressure, current smoking, diminished forced expiratory volume in 1 second, and aneurysm size.

The vast majority of patients with AAA are asymptomatic, and disease is detected incidentally or with screening. However, patients may present with thromboembolic symptoms, particularly lower extremity digital ischemia. Occasionally, patients report a pulsatile sensation in the chest, abdomen, or back. Large aneurysms can lead to compressive symptoms. Compression of the ureter results in hydronephrosis, and compression of the bowel or stomach leads to obstructive symptoms or early satiety. Although a rare presentation, aortic dissection in the setting of AAA can cause severe abdominal or back pain and mandates expedient repair because of the exceptionally high risk of rupture. AAA rupture presents with severe abdominal or back pain and, if uncontained, hemodynamic instability.

INDICATIONS FOR REPAIR

AAA symptoms typically mandate repair; however, the clinical decision making can be more nuanced in the asymptomatic patient. Because of the inherent risks of aortic interventions, the risk of rupture must exceed the risk of the proposed treatment to be justified. Several large randomized controlled trials have helped to define the aneurysm size at which repair is beneficial for the asymptomatic patient.

The United Kingdom Small Aneurysm Trial (UKSAT) randomized 1090 patients 60 to 76 years old with AAAs between 4.0 and 5.5 cm to either early OSR or surveillance and repair if the AAA grew to exceed 5.5 cm. The early OSR group had a 5.8% 30-day mortality rate with no long-term overall survival benefit. Of note, 76% of the patients in the surveillance group ultimately needed aneurysm repair.

The results of the UKSAT were mirrored in the Aneurysm Detection and Management (ADAM) trial. Five hundred sixty-nine patients within the U.S. Veterans Affairs healthcare system ages 50 to 79 years with aneurysms 4.0 to 5.4 cm in size were randomized to early OSR or surveillance. The investigators had a lower 30-day mortality rate (2.7%) for patients with OSR than that seen in the UKSAT, but patients for early OSR did not obtain benefit compared with the surveillance group. In the surveillance group, nearly 62% of patients eventually underwent AAA repair.

The advent of EVAR, with its associated lower operative mortality rate, has not changed the 5.5-cm threshold. Cao and colleagues recently showed that this size cut point holds true for patients with small aneurysms (4.1 to 5.5 cm) randomized to surveillance versus early EVAR in the Comparison of Surveillance Versus Aortic Endografting for Small Aneurysm Repair (CAESAR) trial. Only 50% of the planned 740 patients were randomized, and the trial was terminated prematurely for low enrollment, although follow-up is ongoing. At 3 years after randomization, no difference was found in mortality between the two groups, although the study may be insufficiently powered because of poor enrollment. Recently, the Positive Impact of Endovascular Options for Treating Aneurysms Early (PIVOTAL) trial randomized 728 patients with 4.0-cm to 5.0-cm AAAs to surveillance or early EVAR. At interim analysis, no difference was found between the two groups in terms of survival at a mean follow-up time of 20 months. A recent Cochrane review of treatment for small AAAs confirmed the findings of these larger studies. Namely, patients with small asymptomatic AAAs who undergo treatment, whether OSR or EVAR, have a higher 30-day mortality rate than those who undergo surveillance, and no difference is seen in overall long-term survival. Of note, nearly all the patients in these trials have been male. Given the lack of study of AAAs in women and that female gender is a risk factor for rupture, a slightly lower threshold for intervention of 5.0 cm is generally accepted.

Briefly, it is appropriate to consider the preferred imaging modalities for surveillance. In general, ultrasound scan (US) is the preferred

method for AAA screening and surveillance because it is noninvasive, is relatively inexpensive, and obviates the need for intravenous contrast administration. It is nearly 100% sensitive and specific, although AAA visualization can be limited by bowel gas or truncal obesity. Despite these benefits, computed tomographic (CT) imaging is the mainstay for operative planning (Figure 1). It allows for better delineation of the vascular anatomy, including evaluation of a potential landing zone to determine suitability for EVAR, and the presence of aberrant vessels and renovascular and aortoiliac disease.

PREOPERATIVE PLANNING

Because of the high-risk nature of aortic surgery and the frequent existence of comorbid conditions in this patient population, a thorough preoperative workup with medical optimization is warranted, particularly in terms of cardiovascular risk. For patients with significant coronary artery disease, the definitive trial on the timing of coronary revascularization, if needed, is the Coronary Artery Revascularization Prophylaxis (CARP) trial. In this study, patients at high risk for perioperative cardiac complications who were undergoing major elective vascular surgery were randomized to undergo revascularization or no revascularization before their vascular surgery. Revascularization before vascular surgery did not alter long-term mortality, with close to 20% of patients in either group having development of a myocardial infarction or related cardiac morbidity. Of note, this study's results do not apply to patients with unstable angina, aortic stenosis, or severe dysfunction of the left ventricle; these patients may benefit from cardiac intervention before AAA repair.

For current smokers, smoking cessation at least 2 weeks before surgery is ideal to prevent respiratory complications such as pneumonia. Patients with chronic obstructive pulmonary disease or other baseline pulmonary disease may benefit from the institution of bronchodilator therapy.

For patients with AAA with baseline renal insufficiency, care must be taken during and after surgery to avoid hypotension. Accordingly, some patients may need preoperative admission for intravenous fluid hydration. In addition, the administration of intravenous contrast in obtaining imaging studies must proceed judiciously to avoid contrast-induced nephropathy.

Preoperative communication with the anesthesia team is critical to ensure that any concerns can be addressed in a timely fashion. Epidural anesthesia in conjunction with general anesthesia ought to be considered for better postoperative pain control and fewer respiratory complications. The possibility of intraoperative and postoperative bleeding mandates the availability of a robust supply of blood products and appropriate vascular access to administer them and arterial blood pressure monitoring. Cell saver is helpful to prevent hemodilution if significant blood loss is to be expected. Maintenance of normothermia throughout the case with the use of warmed fluids and external warming devices reduces coagulopathy.

For patients undergoing AAA surveillance rather than immediate repair, studies have examined the role of beta-blockers, statin therapy, and angiotensin-converting enzyme inhibitors in slowing aneurysm growth with mixed results. Because many of these patients are at significant risk of cardiovascular disease, these measures are frequently appropriate regardless of their possible beneficial effects on AAA growth. Studies of antimicrobial therapy with doxycycline or roxithromycin to eradicate *Chlamydophila pneumoniae*, which has been implicated in AAA pathogenesis, have yielded disappointing results to reduce AAA growth rate. The most effective measure to decrease aneurysm growth is smoking cessation for current smokers, as tobacco has been shown to accelerate AAA growth and is an independent risk factor for AAA rupture.

BOX 1: Factors to consider for the patient with an abdominal aortic aneurysm

Indications for Abdominal Aortic Aneurysm Repair
- Greater than 5.5 cm in males, 5.0 cm in females
- Growth more than 0.5 cm/6 months
- Symptomatic

Indications for Open Surgical Repair of Abdominal Aortic Aneurysm
- Hostile neck
- Neck less than 1.5 cm
- Significant angulation of the neck, typically more than 60 degrees
- Suprarenal aneurysm
- Young patient (relative)
- Endovascular capabilities unavailable

SURGICAL REPAIR

Surgical Approaches

Open surgical repair can be accomplished with a transperitoneal (TP) or left retroperitoneal (RP) incision. The TP approach is generally performed via a generous midline incision (Figure 2), although a transverse incision near the level of the umbilicus is infrequently

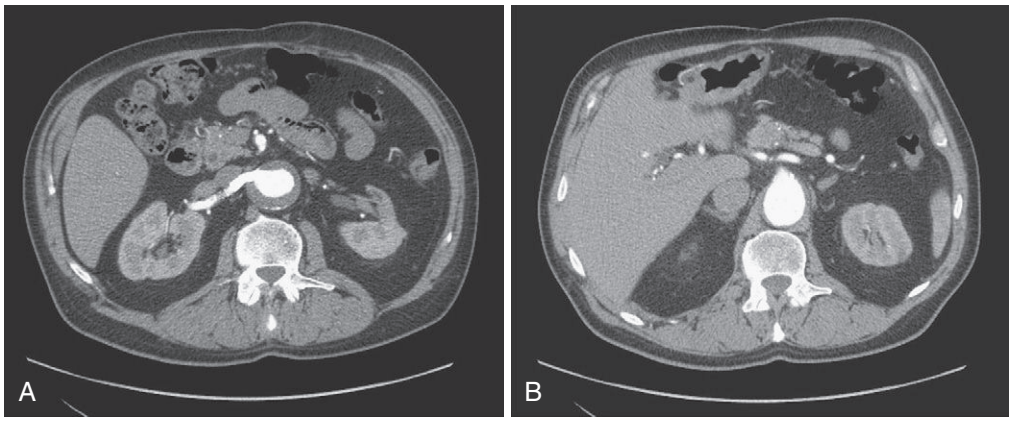

FIGURE 1 **A,** Extensive mural atheroma at the origin of the right renal artery can be fractured with aortic cross clamping, making an infrarenal cross-clamp location prone to produce renal interaction. **B,** The same patient shows a healthy aortic wall at the level of the celiac artery.

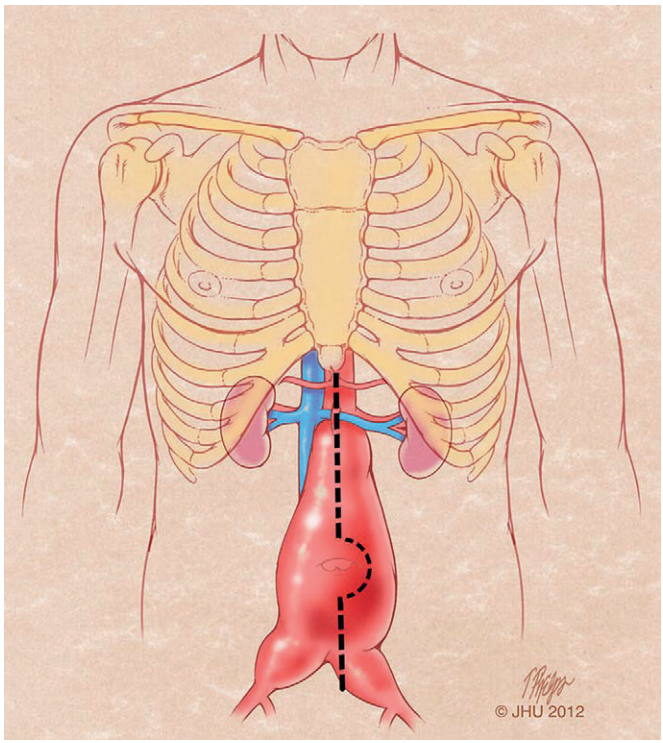

FIGURE 2 The transperitoneal approach provides wide access to the infrarenal aorta and allows inspection of the peritoneal contents.

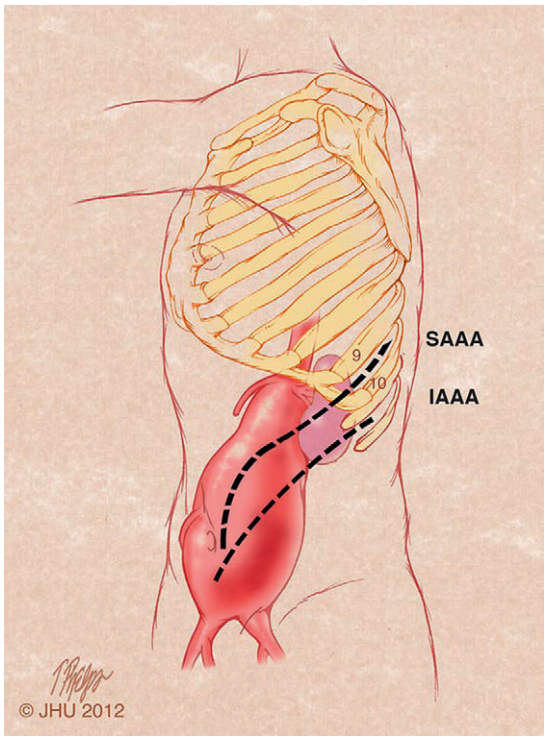

FIGURE 3 Incisions for exposure of infrarenal abdominal aortic aneurysm *(IAAA)* and suprarenal abdominal aortic aneurysm *(SAAA)* via left flank approach.

performed. Advocates of the latter approach claim that there is less postoperative pain and respiratory compromise, although the popularity of this approach has not caught on. The RP incision can be extended through the intercostal space between the ninth and tenth ribs to allow for a thoracoabdominal exposure (Figure 3). Extension of the incision between the 11th and 12th ribs allows for a purely retroperitoneal approach.

The TP approach has the advantages of wide access, the ability to offer full evaluation of the abdomen, and usually fairly rapid performance. In addition, it allows for easier access to the iliac arteries to treat occlusive or aneurysmal disease involving these vessels (Figure 4). These advantages must be tempered with the disadvantages of longer ileus, more insensible fluid losses, and more difficult access to proximal control for juxtarenal and suprarenal AAAs. On the other hand, the RP approach offers the advantages of avoiding a difficult dissection and lysis of adhesions for patients with multiple prior abdominal surgeries or other reasons to have a hostile abdomen, decreased insensible fluid losses, possibly shorter ileus duration than the TP approach, and enhanced access to proximal control of juxtarenal and suprarenal AAAs (Figure 5). Indeed, the latter is perhaps the most compelling reason to perform a RP approach; however, this approach makes access to the iliac and right renal arteries difficult, does not allow for exploration of the abdomen, takes longer to position the patient and gain access to the aorta, and may be associated with more chronic pain, wound problems, and incisional hernias.

Transperitoneal Approach

A longitudinal incision that uses the full length of the abdomen is performed. The colon is retracted in a cephalad direction, and the small bowel is retracted to the right and superiorly. Division of the ligament of Treitz enhances the rightward retraction of the small bowel. Blunt and sharp dissection along the anterior aspect of the aneurysm aids in identifying the left renal vein, which is gently

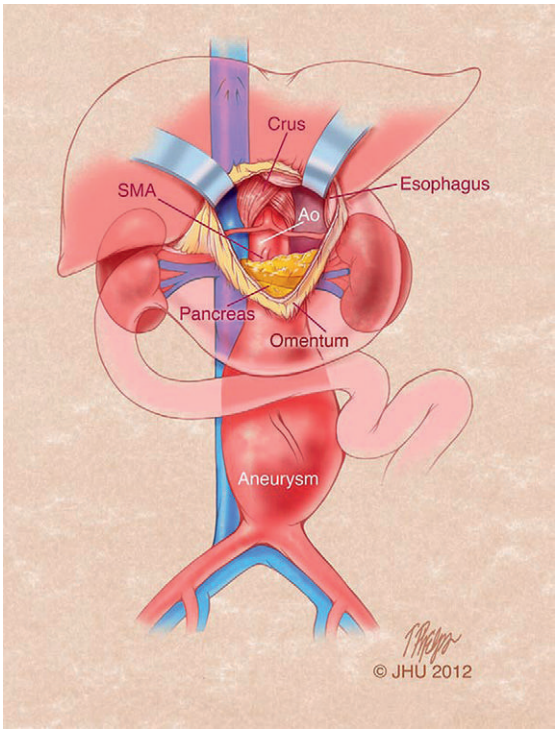

FIGURE 4 In a transperitoneal approach, the suprarenal aorta can be controlled through the gastrohepatic ligament and with division of the crus. This may be helpful in proximal aortic control during contained infrarenal aortic rupture when blood staining and hematoma obliterates the retroperitoneal anatomy. *SMA,* Superior mesenteric artery.

retracted cephalad. If necessary, ligation of the adrenal, gonadal, and lumbar arteries further mobilize the left renal vein. Avoid sacrificing the left renal vein because of the subsequent venous hypertension and increased bleeding and because of the risk of postoperative renal failure. Dissection of the aneurysm neck in anticipation of cross clamping is performed, with extension of the dissection in a caudad direction. Several variations and their indications of the transperitoneal approach are described in Table 1.

Retroperitoneal Approach

With the patient in the right lateral decubitus position, an incision is made at the level of the 11th rib from the posterior axillary line to the lateral rectus abdominis muscle. The retroperitoneum is entered laterally, and the peritoneal sac and posterior Gerota's fascia are retracted anteromedially to further open the retroperitoneal space and expose the aorta (Figure 6). If greater cephalad exposure is

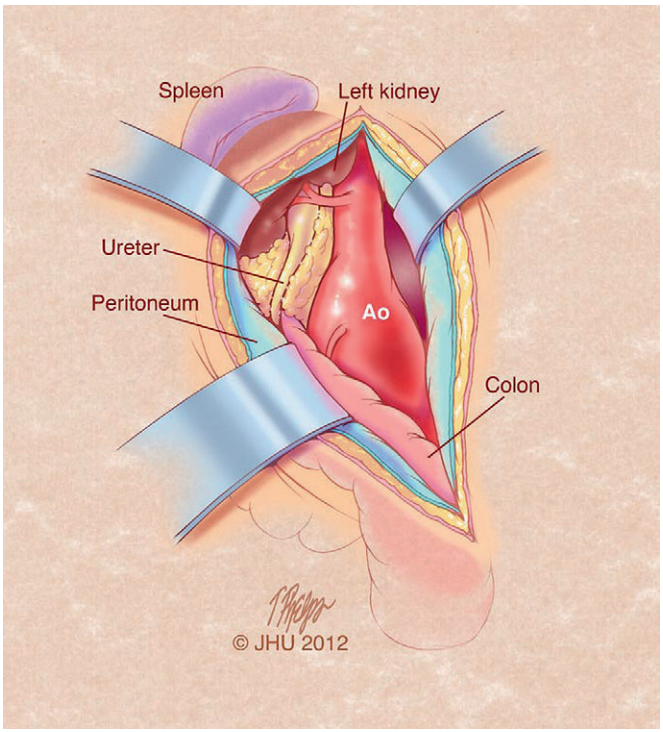

FIGURE 5 The abdominal aorta (Ao) is easily controlled in the retroperitoneal approach. The left kidney can be reflected anterior and the left lateral crus opened to expose the suprarenal region.

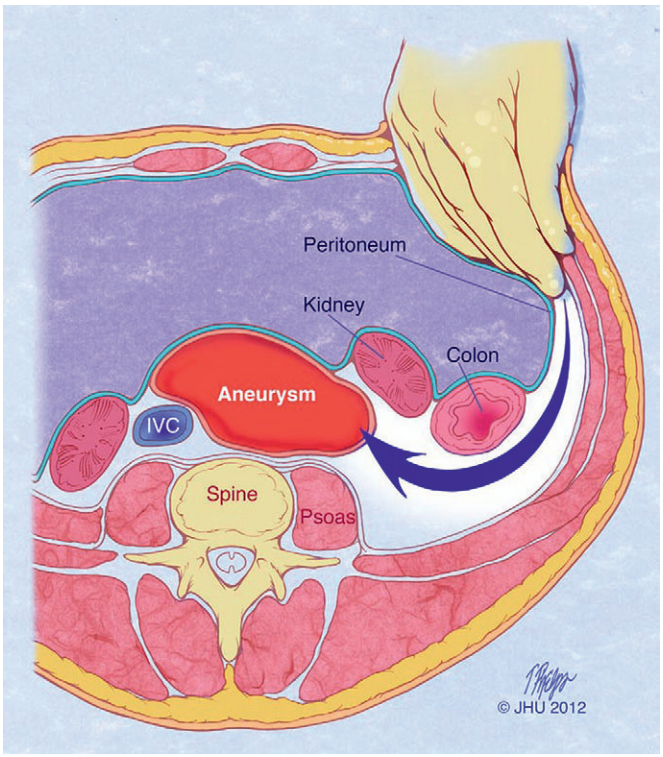

FIGURE 6 The plane of entry into the retroperitonal space is easily developed with manual blunt dissection behind the left kidney. *IVC,* Inferior vena cava.

TABLE 1: Transperitoneal approach variations

	Indications	Steps
Transperitoneal approach with supraceliac clamping	Rupture Juxtarenal AAA Heavy atherosclerotic disease in neck of the aorta precluding infrarenal/suprarenal clamping	Extend incision superiorly, with lower sternal split if needed Retract left hemiliver Divide gastrohepatic ligament Mobilize esophagus to the left Divide the right crus of the diaphragm
Transperitoneal approach with right medial visceral rotation	Juxtarenal AAA Concomitant right renal artery bypass or transaortic renal endarterectomy	Divide the hepatic flexure Mobilize the right colon by dividing the peritoneal reflection Retract right-sided viscera medially and superiorly Superior mesenteric artery is perpendicular to the aorta Divide the posterior crus of the diaphragm
Transperitoneal approach with left medial visceral rotation	Need for continuous exposure of the abdominal aorta and retroperitoneal approach is contraindicated	Divide the splenorenal and phrenocolic ligaments Mobilize the left colon by dividing the peritoneal reflection Left-sided viscera, with or without the kidney, are mobilized toward the right

AAA, Abdominal aortic aneurysm.

needed for suprarenal pathology, division of the median arcuate ligament and the crural fibers of the left hemidiaphragm can be performed.

Operative Conduct

Once the continuously diseased segment of the aorta is exposed and just before cross clamping, the patient undergoes systemic anticoagulation with intravenous heparin, except in the case of AAA rupture. Minimally diseased segments of the aorta are identified proximal and distal to the aneurysm as clamp sites using the knowledge of the preoperative CT scan, and the visceral and iliac vessels are clamped before clamping of the nonaneurysmal proximal aorta to prevent atheromatous embolization. After the clamps have been placed, the aneurysm sac is opened via a longitudinal arteriotomy. Mural thrombus is carefully removed, and lumbar vessel back bleeding is controlled with suture ligatures. At this point, the interior of the AAA should be inspected for delineation of healthier aortic wall for suture placement. Oftentimes the less diseased pararenal and suprarenal intimal surface is apparent as uninvolved by the mural thrombus burden (Figure 7).

The aortic reconstruction proceeds with a graft, typically composed of Dacron or polytetrafluoroethylene, which may be bifurcated in the event that aneurysmal disease extends to the iliac or femoral vessels. The graft is sized to fit the defect, and in the case of a bifurcated graft, care is taken to keep the main body of the graft short to prevent limb kinking and subsequent outflow obstruction. The proximal anastomosis is then performed with a double-armed 3-0 nonabsorbable continuous suture. In the situation of a suprarenal AAA, the aortotomy should be taken posterior to the left renal artery. Thereafter, a bevel is taken across the Dacron graft to allow the lateral wall of the graft more length to reconstruct the suprarenal region (Figure 8).

The distal anastomoses are performed in a similar fashion. Just before finishing the distal anastomosis, release the proximal clamp temporarily to flush out any clots that might otherwise embolize distally. The proximal clamp is closed, and the anastomosis is completed. This step is performed near the completion of the first distal anastomosis in the case of a bifurcated graft. Flow can now be reestablished to the just-completed limb, and with the other outflow limb occluded by a clamp, the final anastomosis can be performed and the final clamp removed. After hemostasis is ensured, the aneurysm sac is reapproximated over the graft if a TP exposure was used. This measure, in addition to flap coverage with omentum, helps minimize the risk of graft erosion and fistulization with surrounding structures, particularly small bowel.

Several points are worth noting regarding visceral vessel reimplantation. When reimplantation is anticipated, grafts with side arms for vessel reimplantation can be used to minimize clamp time and expedite visceral reperfusion. Usually the inferior mesenteric artery (IMA) can be sacrificed without consequence because it is often occluded; occasionally, however, it is the major source of flow to the left colon, particularly in the setting of significant occlusive disease of the iliac and mesenteric vessels and in patients with history of colon surgery. Poor back bleeding of the IMA should prompt reimplantation to prevent life-threatening ischemia of the colon.

At this point in the operation, a thorough evaluation for hemostasis to prevent postoperative hemorrhage is mandatory. The usual culprits are lumbar and intercostal vessels and undetected intraoperative iatrogenic splenic injury. The reconstructed vessels are palpated for a pulse, the viscera are inspected for perfusion, the wound is closed, and the patient is transferred to the intensive care unit for postoperative care.

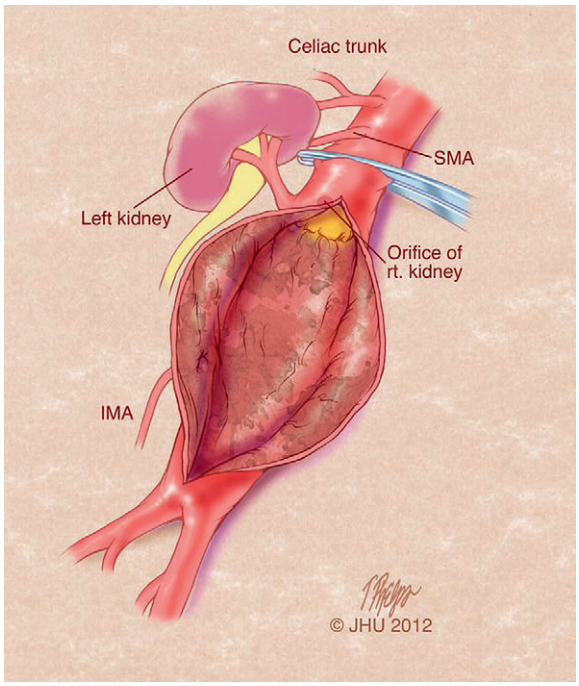

FIGURE 7 Juxtarenal abdominal aortic aneurysm after aortotomy. The aortic cross clamp is placed suprarenal to avoid embolizing material off the thrombus-laden infrarenal segment. *IMA,* Inferior mesenteric artery; *SMA,* superior mesenteric artery.

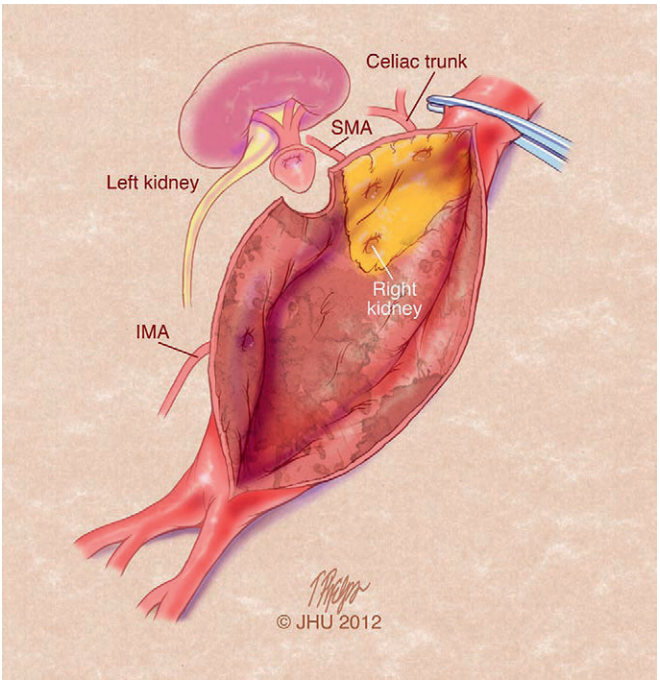

FIGURE 8 The aortotomy after suprarenal abdominal aortic aneurysm opening is taken posterior to the left renal artery. If the left renal origin cannot be directly reimplanted onto the surgical graft, an interposition 6-mm to 8-mm diameter graft can be used. *IMA,* Inferior mesenteric artery; *SMA,* superior mesenteric artery.

COMPLICATIONS

On the basis of the large randomized controlled studies mentioned previously, the 30-day operative mortality rate associated with OSR of 2.0% to 5.8% is generally favorable. In a study with a large administrative database, surgeon volume, hospital volume, and vascular surgery specialty were all found to be independently associated with a lower in-hospital mortality rate. Approximately one third of patients undergoing elective OSR have some sort of complication develop. Because of the magnitude of the operation and the baseline comorbidities of this patient population, there are a number of major complications specific to AAA repair to be aware of when caring for these patients in the perioperative period.

Ischemic colitis is a relatively rare but highly lethal complication after AAA repair; it most commonly involves the sigmoid colon and may be seen in 20% to 40% of patients after surgery for ruptured AAA. As mentioned previously, ligation of the IMA is usually safe but can be problematic for patients with insufficient collateral flow. For this reason, some surgeons advocate routine IMA reimplantation. Occasionally, patients with IMA borderline blood flow become symptomatic after surgery (Figure 9, *A,B*) after diuresis or an episode of hypotension. Patients can present in the postoperative period with hemoccult-positive or grossly bloody diarrhea. Other signs may be nonspecific, and symptoms include abdominal pain and distension, leukocytosis, metabolic acidosis, and fever. The diagnosis is made with flexible sigmoidoscopy. Treatment includes supportive care with intravenous fluid resuscitation, broad-spectrum antibiotics, bowel rest, total parenteral nutrition, and in the case of transmural ischemia or lack of improvement in patients with only mucosal involvement, colon resection with end colostomy. Primary anastomosis is not recommended because a leak may lead to fecal contamination of the aortic graft. Patients with spontaneously resolving ischemic colitis are at risk for colonic strictures.

Lower extremity complications can be either paralytic or ischemic in nature. Paraplegia, although dreaded and often irreversible, is thankfully a very rare occurrence. In elective cases, it occurs approximately in 1 of 100 to 2500 patients. The incidence rate is much higher in the case of AAA rupture—1.4%. It is thought that the underlying mechanism is spinal artery thrombosis, embolization, loss of forward flow through the iliac arteries, or disruption of an aberrantly low spinal artery. Ischemia of the lower extremities is a much more common complication than paraplegia. Debris inside the aneurysm sac may embolize distally during the course of the operation, necessitating cautious handling of the aorta during dissection, careful clamping of the distal vessels, flushing of the vessels, and sequential clamp removal. Large debris may need to be mechanically extracted; however, smaller emboli lodge distally, and little can be done to ameliorate this problem after the fact, underscoring the importance of prevention with careful operative technique. Thrombosis occasionally is the etiology of lower extremity ischemia and may be secondary to inadequate intraoperative anticoagulation, a preexisting hypercoagulable state, or technical error. Thrombectomy, anticoagulation, or revision of the distal anastomosis may be necessary.

Sexual dysfunction is a relatively common complication after AAA repair and occurs in 10% to 20% of patients. During surgery, care must be taken to avoid injury to the autonomic nerves that course along the lateral side of the distal aorta and cross into the pelvis near the left common iliac artery to minimize disruption of pelvic parasympathetic control of the bladder neck during orgasm. Loss of such nerve innervations produces retrograde ejaculation. The possibility of retrograde ejaculation, reduced male fertility, and difficulty achieving orgasm should be discussed with patients as part of the informed consent process.

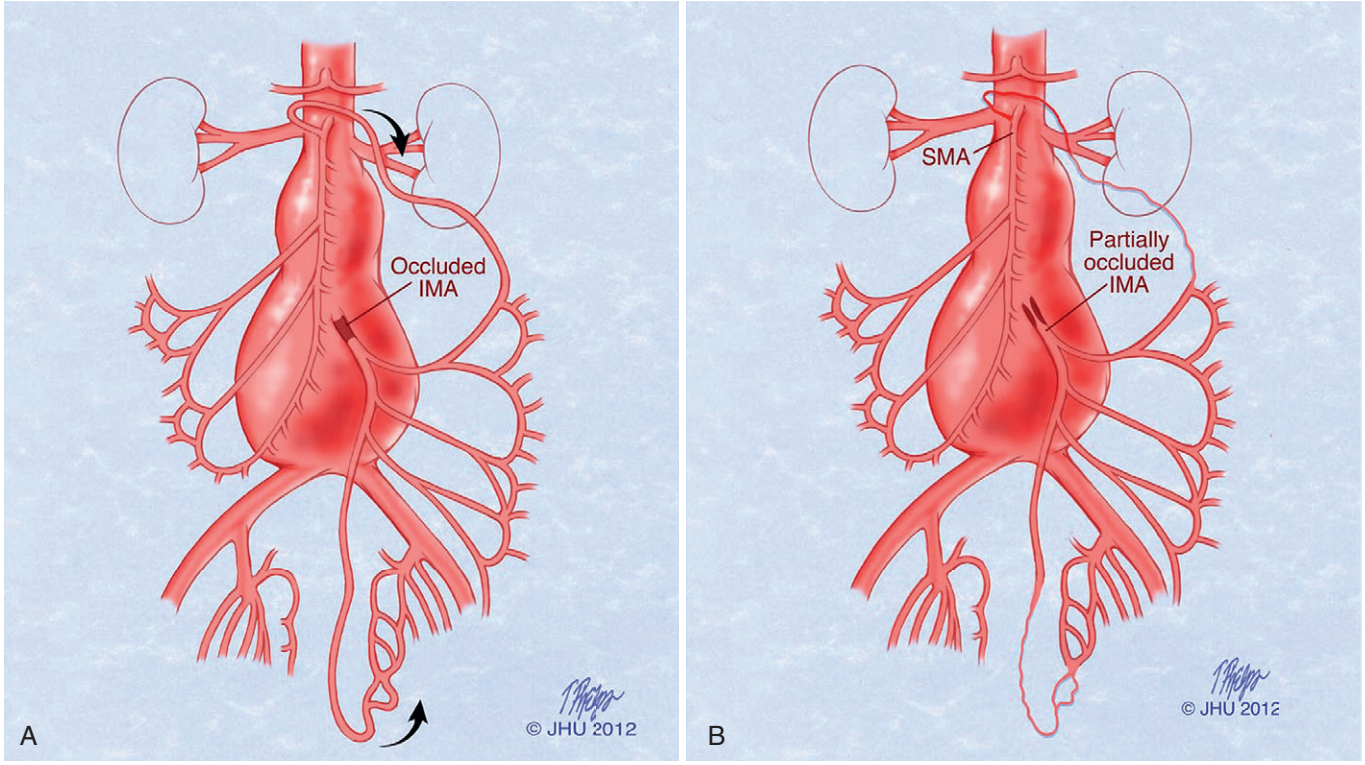

FIGURE 9 **A,** When the inferior mesenteric artery *(IMA)* is chronically occluded, collateral flow from the superior mesenteric artery *(SMA)* via the marginal artery or from internal iliac artery via the rectal and sigmoid arcade preserves colon viability during open surgical repair. **B,** In cases of preserved IMAs, the collateral network may be insufficient to maintain viability of the colon after surgery.

CONCLUSION

The advent of EVAR and the increasing expansion of its indications have forever altered the treatment of AAA. Even so, OSR is frequently necessary, particularly for patients with anatomy not amenable to endovascular repair. In addition, a number of questions remain as to the long-term durability and cost effectiveness of EVAR, rendering OSR perhaps a less commonly used operation yet still an important modality in the treatment of AAA.

Endovascular Treatment of Abdominal Aortic Aneurysm

Fahad Shuja, MD, and Christopher J. Kwolek, MD

INTRODUCTION

An abdominal aortic aneurysm (AAA) is defined as a focal dilatation of 50% or greater than the adjacent nonaneurysmal aorta. This disease affects primarily patients in the sixth to eighth decades of life. Other risk factors include smoking, male gender, Caucasian race, chronic obstructive pulmonary disease, and a positive family history. Increased use of modern imaging modalities may contribute to the increase in the diagnosis of AAAs since the diagnosis is often made incidentally when the patient is being evaluated for other problems. In a Veterans Affairs screening study of more than 73,000 patients 50 to 79 years old, the prevalence of AAAs greater than 3 cm was 4.6% and the incidence of those 4 cm or greater in size was 1.4%.

The primary determinant of rupture risk is maximum aneurysm diameter. Despite minor differences in estimated risks, there is general consensus that the rupture risk increases substantially with a AAA diameter between 5 and 6 cm. Surgical repair is indicated when the risk of aneurysm rupture outweighs operative risks, and therefore a size of 5.5 cm is considered appropriate for repair in most circumstances. Other indications for repair include symptomatic aneurysms and aneurysms that grow more than 0.5 cm within a 6-month interval. Two recent prospective randomized trials have shown no difference in outcomes between early endovascular treatment and delayed treatment of asymptomatic aneurysms between 4 and 4.9 cm (Pivotal Trial, Medtronic, Minneapolis, Minn) and between 4 and 5.4 cm (Caesar Trial, Cook, Bloomington, Ind).

PREOPERATIVE CONSIDERATIONS

The long-term success of aortic endografts depends heavily on appropriate patient selection. Different devices vary in their specific anatomic requirements, but the basic principles remain the same. These include an appropriate aortic neck, a distal sealing zone, and a suitable path for the endograft to be placed through. Computed tomographic angiography with reformatted three-dimensional reconstructions is the most widely used preoperative imaging assessment tool for this purpose.

Aortic Neck Anatomy

The aortic neck is defined as the area of the aorta cephalad to the aneurysm, below the level of the renal arteries, in which the endograft will be placed. This area serves as the site of proximal fixation that will prevent the device from distal migration. It is important to obtain a circumferential seal in this region to prevent blood leakage into the aneurysm sac. For this reason, the graft is typically oversized by 10% to 20% relative to the diameter of the aneurysm neck. The minimal length needed varies among devices, but it is typically 15 mm. The largest neck diameter that can be treated with a Food and Drug Administration (FDA)–approved device is 32 mm. The presence of circumferential thrombus or severe aortic wall calcification can negatively affect the ability to obtain seal and fixation. Other factors that are important in determining whether a patient is a candidate for endovascular aneurysm repair (EVAR) include the angulation and shape of the aortic neck. Angulation is the angle formed between the vertical plane and a line that transects the long axis of the aneurysm. Angulation of greater than 60 degrees may lead to endoleaks, kinking, and stent migration and is therefore considered a contraindication for EVAR. A conical-shaped neck, defined as an increase in diameter of the neck by more than 10%, is also considered a contraindication to routine endografting.

Iliofemoral Access

The iliofemoral arterial system provides access for endograft placement. The presence of thrombus, calcifications, and tortuosity can

significantly hinder a distal seal. Most available endografts require at least a 15-mm segment of iliac artery to be of adequate caliber and free of significant disease. The largest iliac diameter currently treated by an FDA-approved device is 25 mm. A minimum common femoral artery diameter of 6 mm is required to accommodate the smallest delivery system available. The configurations of the most recently approved endografts in the United States are listed in Table 1.

TECHNICAL DETAILS OF THE PROCEDURE

1. Prep the patient's abdomen from xiphoid to mid thighs to allow for both femoral and retroperitoneal access for placement of an iliac conduit if necessary.
2. For open exposure of the femoral arteries, use bilateral oblique groin incisions halfway between the inguinal ligament and the groin crease just over the femoral pulse, to optimize wound healing in heavy patients. These can be extended inferiorly, if necessary, using a hockey stick incision. Only use a vertical incision if you are planning to perform an iliofemoral endarterectomy. Use a 19G entry needle and a 0.035-inch 3J guidewire to enter the common femoral artery.
3. For percutaneous access to the femoral arteries, use ultrasound to identify a noncalcified entry site for the micropuncture needle and guidewire. Upsize to a 5F sheath over a 0.035-inch guidewire. Then use two ProGlide closure devices (Abbott, Abbott Park, Ill) over a 0.035-inch 3J guidewire prior to inserting your working sheath.
4. Systemically heparinize the patient with 75 to 100 mg/kg of heparin.
5. Using a Kumpe catheter (Cook Medical, Bloomington, Ind) or a Berenstein catheter (Boston Scientific, Natick, Mass), direct the guidewire into the descending thoracic aorta and exchange for a 0.035-inch Lunderquist guidewire (Cook Medical, Bloomington, Ind) on the side for placement of the main body of the stent graft.
6. After gaining access on the contralateral side, advance an 8F sheath into the bottom of the aneurysm sac and place a marking pigtail catheter at the L1 vertebral level, checking the position of the renal arteries with a gentle hand injection of contrast.
7. If uncertain about your stent graft measurements and lengths, you can proceed to perform a power injection run with the marking pigtail catheter in place to obtain total length measurements. Otherwise, you can proceed to insert the main body of the graft over the Lunderquist wire on the ipsilateral side and perform the first power injection run at the level of the renal vessels. You can then proceed to adjust the image intensifier cranially to correct for parallax and repeat a power injection run at a rate of 20 mL/sec for a total of 10 mL of volume. This will allow you to position the fabric of the stent graft just at the level of the renal arteries. You must know the relationship of the graft to the proximal markers for the stent graft that you are using.
8. For Gore, Cook, and Medtronic grafts, you then proceed to deploy the proximal portion of the graft just above the renal arteries and pull down into the final position. Both Cook and Medtronic grafts also have a proximal bare spring that is deployed for fixation.
9. Do not forget to pull down the marking catheter into the aneurysm sac. This can also be performed over a 3J wire after the proximal graft has been deployed. You then proceed to cannulate the contralateral gate with a Kumpe catheter, Cobra-2 catheter (Cook Medical, Bloomington Ind), or a reversed curve catheter such as a visceral selective, depending on the position of the contralateral gate. Do not forget to rotate the image intensifier if necessary to get different orientations of the contralateral gate.
10. Once the wire and catheter are in the contralateral gate, advance both into the descending thoracic aorta and exchange for a 0.035-inch Lunderquist guidewire. Confirm that you are actually in the contralateral gate by advancing a sheath and performing an injection of contrast into the graft. Inflate a 12-mm balloon within the contralateral gate and rotate the

TABLE 1: FDA-approved devices for endovascular repair of abdominal aortic aneurysms

Device/type (Avg # pieces)	Manufacturer	Main body diameter (mm)	Aortic treatment diameter (mm)	Main body delivery size (F)	IFU neck length/angle (degrees)	Iliac treatment diameter (mm)	Material	Suprarenal stent
Zenith Flex/ modular (2-3)	Cook Inc. (Bloomington, Ind)	22-36	18-32 Outer to outer	18-22 ID 20-24 OD	15 mm ≦60	7.5-20	Stainless steel–polyester	Yes
AFX/Unibody (1-2)	Endologix (Irvine, Calif)	25-34	18-32 Inner to inner	19 OD	15 mm ≦60	10-23	Cobalt-chromium-PTFE	Optional
Excluder/ modular (2-3)	WL Gore (Flagstaff, Ariz)	23-35	19-32 Inner to inner	18 ID 20 OD	15 mm ≦60	8-25	Nitinol-PTFE	No

image intensifier laterally in both directions to make sure that the balloon remains within the iliac limb. Then, rotate a pigtail catheter in the main body of the graft and advance cranially to prove that the catheter is not trapped between the stent graft and the aortic wall.

11. Reinsert the marking catheter to measure the distance from the contralateral gate limb to the hypogastric artery. Perform a hand injection of contrast via the ipsilateral sheath, which has been pulled back into the external iliac artery. For the left internal iliac artery, rotate the image intensifier to the right and caudally. For the right internal iliac artery, rotate the image intensifier to the left and caudally.
12. Choose the appropriate length and diameter iliac graft limb, making sure that the proximal portion lands between the minimal and maximal overlap zones.
13. Deploy the ipsilateral iliac graft limb for Gore, Cook, and Medtronic grafts.
14. If extending to the external iliac artery is necessary, an additional iliac extension limb will often be used. If the common iliac aneurysm extends down to the iliac bifurcation, then embolization of the internal iliac artery will also be necessary to prevent an endoleak from occurring.
15. Using a compliant CODA (Cook Medical, Bloomington, Ind) or Reliant (Medtronic, Santa Rosa, Calif) balloon, you should perform balloon angioplasty of the proximal attachment zone, the graft overlap sites, and the distal attachment zones.
16. Completion angiogram should be performed using the marking pigtail catheter and a power injection with a rate of 20 to 25 mL/sec for a total volume of 25 or 30 mL. Delayed views will also be necessary to evaluate for late endoleaks. Other things to evaluate include the following:
 a. Filling of the renal and visceral vessels
 b. The position of the proximal endograft with the distance to the renal arteries and the presence of a type I endoleak
 c. Blood flow through the main body and the iliac limbs
 d. Distal flow into the iliac vessels and runoff vessels, including the presence of a type IB endoleak and status of the internal iliac artery.
 e. Delayed flow into the aneurysm sac via lumbar collaterals and the inferior mesenteric artery, leading to a type II endoleak
17. Hints for improved angiography. (A) Remove all stiff guidewires and replace them with softer catheters or wires that will not straighten the vessels. (B) Pull back the sheaths into the external iliac arteries and draw back on them with a 30-mL syringe while performing a power injection to simulate flow in the native external iliac arteries.
18. Remove the sheaths over a stiff wire if the access was difficult. Watch for a drop in pressure, potentially signifying a tear in the iliac artery. If this occurs, place an occlusion balloon across the iliac artery on the affected side. If this is unsuccessful, you can also place an aortic occlusion balloon via the contralateral side.
19. Perform repair of the femoral artery using primary closure with either two running 5-0 Prolene sutures (Ethicon, Somerville, NJ) or multiple interrupted Prolene sutures, or using femoral endarterectomy with bovine pericardium angioplasty closure.

A selection of endograft bodies, iliac limbs, proximal aortic cuffs, and distal extensions will be critical to safely performing these procedures. In addition, a selection of large compliant aortic angioplasty balloons (e.g., CODA, Reliant) and noncompliant aortic balloons (Z-MED, B. Braun, Bethlehem, Pa) and bare metal 3010 or 4010 Palmaz stents (Cordis, Bridgewater, NJ) will be helpful to address proximal or distal endoleaks.

Of the currently available endografts on the market, all perform well when used within the parameters of the instructions for use (IFU) of the device. We performed a device-specific analysis within and outside the IFU on three endografts in commercial use at the time: Cook Zenith, Gore Excluder, and Medtronic AneuRx. There was no difference between the devices in intraoperative technical factors, perioperative mortality, graft failure, and aneurysm-related mortality within the IFU. However, EVAR procedures performed outside of IFU had higher rates of aneurysm-related mortality, reintervention, and graft thrombosis.

POSTOPERATIVE CARE AND FOLLOW-UP

Intraoperative anesthesia management involves a regional anesthetic in over 90% of cases in our institution with general anesthetic reserved for those patients with airway problems who cannot lie flat for several hours. In some instances, the procedure can be performed under local anesthesia, particularly in patients with good access vessels, which may be amenable to percutaneous closure. This trend will increase as the diameter of delivery systems continues to decrease to less than 14F.

Patients no longer require a stay in the intensive care unit or even a prolonged stay in the recovery room. After patients are transferred to the floor, the epidural catheter is removed and the patients are encouraged to ambulate. Ice bags can be used for control of local swelling over the groin incisions, and oral pain medications are used. Patients are provided with preoperative teaching information with plans for discharge on postoperative day (POD) 1. Visiting nurses check on their status at home. No routine postoperative imaging is obtained.

Patients are seen in follow-up evaluation at 30 days with an abdominal/pelvis computed tomographic angiogram with intravenous contrast. This will be used as the new baseline exam for assessing aneurysm sac size and volume as well as the presence of an endoleak. Patients are routinely seen at 6 and 12 months with similar studies done to evaluate sac size and the presence or absence of an endoleak. If the sac is stable or shrinking with stable anatomy, we will often switch to surveillance using a graft duplex to assess for flow in the stent graft, measure aneurysm sac size, and determine the presence of flow outside the graft signifying an endoleak. Plain films of the stent graft can also be obtained to assess for stent graft position and the presence of stent fractures. Follow-up will continue on an annual basis. If the aneurysm sac is obliterated after 5 years, then we will often switch to a follow-up regimen of every 2 years.

COMPLICATIONS

A number of complications can be seen following EVAR. These are often related to issues with access at the time of the procedure or longer term issues with the exclusion of the aneurysm sac.

The primary route of insertion for most endografts is the iliofemoral arterial system. In cases of iliac artery atherosclerosis, the lumen may not permit the passage of the delivery system. Advancement of the device despite resistance can cause dissection, thrombosis, or even vessel rupture in 1% to 2% of cases. The iliac artery can be treated with balloon angioplasty or dilatation prior to advancement of an endograft. An alternative is to place an endovascular or open iliac conduit. The final solution is to use a hybrid of these two techniques by using the SoloPath balloon-expandable sheath (Terumo, Ann Arbor, Mich) to simultaneously dilate the vessel and provide a pathway to the aorta.

An endoleak is the persistence of blood flow outside of the endograft within the aneurysm sac. Endoleaks result when there is incomplete isolation of the aneurysm sac from systemic circulation resulting in aneurysm sac expansion and potential rupture. Endoleaks are the most common cause of secondary interventions and aneurysm-related morbidity following EVAR. They are classified according to

their etiology. Five different types of endoleaks have been described (Table 2).

Type I

Type I endoleaks result from inadequate seal at either the proximal aortic or distal iliac attachment sites. This can result from a size mismatch between the graft and the vessel, severe aortic neck angulation, or applying the graft to a vessel wall with heavy calcification or thrombus. Type I endoleaks are usually visualized on angiography immediately after deployment. Delayed type I endoleaks are thought to be secondary to aneurysm sac reconfiguration, as the sac diameter decreases over time. Type I endoleaks rarely close spontaneously and are therefore repaired as soon as they are discovered. Treatment may involve reballooning the attachment site, using proximal or distal extension grafts, or placing a balloon-expandable Palmaz stent to obtain better graft expansion and wall apposition.

Type II

These are the most common type of endoleaks, occurring in up to 25% of EVAR patients. They occur from retrograde filling of the aneurysm sac from a patent aortic branch vessel, such as the inferior mesenteric artery or a lumbar artery. Patients are often asymptomatic and diagnosed on postoperative surveillance imaging. The endoleaks may not be visible during the arterial phase since the sac fills retrograde through a collateral network; therefore, delayed images are often necessary. These will show pooling of contrast outside of the endograft wall and within the aneurysm sac. Management of a type II endoleak may consist of close observation, and spontaneous resolution is reported in 30% to 90% of cases. However, in patients where the aneurysm sac increases in size, we have had success treating these patients with embolization using Onyx Glue (EV3, Covidien, Mansfield, Mass) via a direct translumbar approach.

Type III and Type IV

Type III endoleaks are caused by defects in the fabric of the graft or at the junction of modular components. Treatment consists of placing covered stents to exclude the aneurysm sac from systemic pressure. Type IV endoleaks are due to leaking of blood between the interstices of the fabric or where the graft is sutured to the stent. When seen at the time of initial implantation, these usually resolve with reversal of anticoagulation. However, relining of the endograft may also be necessary if this persists.

TABLE 2: Types of endoleaks

Type of endoleak	Definition
I	Inadequate sealing at either proximal or distal attachment sites
II	Flow into the aneurysm sac from patent branch vessels (e.g., inferior mesenteric artery or lumbar artery)
III	Defect in the fabric of the graft or failure of seal between graft components
IV	Leaking of blood between the interstices of the graft fabric
V	The aneurysm sac remains pressurized in the absence of a visible endoleak, also termed *endotension*

Endotension

Endotension, or type V endoleak, is defined as elevated aneurysm sac pressure resulting in sac expansion in the absence of a radiographically demonstrable endoleak. The exact etiology is unknown, and treatment is largely undefined. Secondary conversion to open repair is sometimes necessary but carries a significant mortality rate in some series.

Limb Thrombosis

Thrombosis of an iliac limb occurs in up to 11% of cases. The lack of stent support within an iliac limb increases the risk of thrombosis by eightfold, compared with intrinsically supported limbs. Most patients experience ipsilateral buttock and/or limb claudication within the first 6 months following their EVAR. Management is dictated by patient symptoms. Asymptomatic patients can be observed while symptomatic patients might require attempts at thrombolysis or a femoral-femoral bypass.

Migration

Migration of stent grafts is a known risk factor for development of a delayed type I endoleak and subsequent aneurysm rupture. Conrad published our 10-year results with EVAR in 2009. The overall incidence of graft migration in more than 800 EVAR patients was 1.7%. Neck angulation and neck diameter have been cited as important risk factors for device migration. Treatment usually involves placement of a proximal extension graft or conversion to open repair.

SUMMARY

Parodi and colleagues reported the first repair of an aortic aneurysm with a stent graft in 1991. Since then, EVAR has emerged as the procedure of choice for 70% to 80% of patients with AAA treated in the United States. While the elective mortality rate for open repair has remained consistent at 4% to 5% when based on data from large administrative databases, the perioperative morbidity and mortality rates of EVAR have continued to decrease. These differences are even more pronounced in patients over the age of 80.

There are three widely quoted randomized trials comparing endovascular repair to open repair of AAA. The EVAR 1 trial compared 543 EVAR patients with 539 open repair patients. There was a significant increase in the 30-day mortality rate for open repair versus EVAR (4.7% compared with 1.7%). The EVAR group had a significantly higher rate of secondary intervention (9.8% compared to 5.8%); however, procedures related to the original open operation, such as bowel obstruction and hernia repair, were not included in the analysis. After 8 years of follow-up, the aneurysm-related survival rate was 93% in both groups. The DREAM trial comprised 351 patients with aneurysms larger than 5 cm randomized to EVAR versus open repair. The rates of aneurysm-related deaths were 5.7% and 2.1% for open and endovascular repair, respectively. However, there was no survival advantage after the first postoperative year. The largest of the three trials, OVER, followed 881 patients for a mean of 5.2 years within the Veterans Affairs hospital system. The trial had similar conclusions: an upfront survival advantage with EVAR with "mortality catch-up" later. Another important similarity among all three trials is the remarkably low aneurysm-related mortality rate (<5%) up to 6 years of follow-up.

A trial comparing EVAR to medical management in 338 patients unfit for open surgical repair (EVAR 2 trial) showed a similar 30-day mortality rate (9%) as well as a 4-year AAA-related mortality rate (14%) between the two groups. The study was criticized for a 25% crossover rate from nonoperative to EVAR arm. Furthermore, 52% of the perioperative deaths in the EVAR group occurred preoperatively. The Society for Vascular Surgery published their own data on patients at high risk in 2006. A total of 565 EVARs and 61 open repairs were compared in patients at high risk. The definition of "high risk" was the same as that in EVAR 2 (age > 60, aneurysm > 5.5, and one of the following: symptomatic congestive heart failure, valvular heart disease, cardiac arrhythmia, chronic obstructive pulmonary disease, chronic renal failure, or serum creatinine value > 2.6 mg/dL). The 30-day mortality rate for EVAR was 2.1% compared with 5.1% for open repair. This difference was not statistically significant. There was no difference in rates of AAA-related death at 4 years (4% vs 5%). This study helped alleviate the initial concerns that had emerged after EVAR 2 about the safety of EVAR in patients at high risk.

NEW DEVICES ON THE HORIZON

Key limitations to successful EVAR relate to patient's anatomy and device design. Short/angulated necks, occlusive/tortuous iliofemoral arterial system, preservation of hypogastric inflow, endograft migration, and endoleaks pose major challenges for future progress in the area of EVAR.

Several companies have developed lower profile devices to allow treatment of patients with smaller and more tortuous iliac access vessels. The Trivascular Ovation (Trivascular, Santa Rosa, Calif) device has a 14F outer diameter (OD) delivery system and was recently approved for use in the United States. The Cook low-profile device (LP) (Cook, Bloomington, Ind) has an 18F OD introducer system while the Cordis Incraft device (Cordis, Bridgewater, NJ) also has a 14F OD delivery profile. Both are currently in clinical trial within the United States.

The Terumo Anaconda stent graft (Terumo, Ann Arbor, Mich) has a retrievable proximal delivery system that allows for repositioning of the stent graft in the proximal seal zone. Both the Anaconda graft and the Lombard Aorfix graft (Lombard Medical, Oxfordshire, UK) are designed to accommodate more severe angulation in the proximal aortic neck. Both have completed clinical trials in the United States.

Fenestrated stent graft technology is now available to address juxtarenal aneurysms with neck lengths of less than 10 mm. The Cook Zenith fenestrated stent graft (Cook Inc, Australia) is now approved for use in the United States, and the Endologix Ventana endograft is currently being evaluated as part of an FDA-approved Investigational Device Exemption trial (Endologix, Irvine, Calif).

Two new stent grafts currently being evaluated outside of the United States have the potential to revolutionize the management of AAAs. The Cardiatis multilayer stent (Cardiatis, Isnes, Belgium) is designed to divert flow away from the aneurysm sac while allowing for persistent patency of critical side branches without the need for any branched grafts or fenestrations. This stent has been approved for use in Europe where further data are being accumulated on the treatment of AAA. The Nellix stent graft system (Endologix, Irvine, Calif) relies on the use of two balloon-expandable stents to maintain a flow channel through the aneurysm sac to the iliac arteries. Two attached endobags are then filled with a polymer, which completely obliterates the aneurysm sac, theoretically eliminating the risk of endoleaks since the aneurysm cavity is filled. This device is commercially available in Europe and will soon enter clinical trial in the United States.

Current endograft technology has allowed between 70% and 80% of current AAAs in the United States to be treated with stent graft technology. Although initial results are excellent, long-term follow-up remains critical since up to 25% of patients may require a secondary intervention. The majority of these interventions can be performed with a catheter-based procedure, and the need for open conversion with graft explantation remains low. Next-generation endografts are now being designed to address these shortcomings and may prove more durable than current devices.

The Management of Ruptured Abdominal Aortic Aneurysm

Natalia O. Glebova, MD, PhD, and
Mahmoud B. Malas, MD, MHS, FACS

INTRODUCTION

Ruptured abdominal aortic aneurysm (rAAA) is a lethal condition, with mortality rates estimated at 90% for all patients and at 40% to 70% for those patients who reach the hospital. rAAA is the 13th leading cause of death in the United States. The incidence of rupture has decreased over time, likely because of the implementation of screening and aggressive repair of asymptomatic enlarging abdominal aortic aneurysms (AAAs). The mortality rate of rAAA, on the other hand, has remained high, albeit with recent trends toward decline thought to result from the increase in endovascular repair of rAAA.

The risk factors for AAA rupture are aneurysm diameter, female gender, chronic obstructive pulmonary disease (COPD), cigarette smoking, and hypertension. Peak wall stress is a better predictor of rupture than aneurysm diameter but is more difficult to determine in clinical practice. Rupture of an AAA, defined as bleeding outside the adventitia of the dilated aortic wall, may be free into the peritoneal cavity or contained in the retroperitoneal space. Retroperitoneal rupture is in general thought to result in better outcome than free intraabdominal ruptures because the retroperitoneum may tamponade the hemorrhage and thus allow patient survival to definitive care.

DIAGNOSIS AND EVALUATION

The classic symptoms of a patient presenting with a rAAA are severe back pain, hypotension, and a pulsatile abdominal mass. This combination is infrequent, and other symptoms, such as abdominal or chest pain or a syncopal episode, may constitute the presentation. Differential diagnoses of patients with rAAA often include perforated viscus or ulcer, renal stones, or myocardial infarction. The nonspecific nature of the symptoms, coupled with the dire prognosis should diagnosis of a rAAA be delayed or missed, underscore the need for high suspicion of rAAA as the etiology for any patient presenting with severe abdominal or back pain.

Patient evaluation is concomitant with resuscitation, further diagnostic studies, and treatment planning. Physical examination should include not only the usual cardiac, respiratory, and abdominal examinations but also assessment of popliteal pulses to ascertain the presence of other aneurysms and of femoral and pedal pulses to evaluate distal perfusion and establish the patient's baseline values. Carotid arteries should be auscultated for bruits. An electrocardiogram (ECG) should be performed if the patient's condition is stable and time allows, and blood should be drawn for chemistries, blood counts, and crossmatch.

If the patient's condition is stable, imaging helps confirm the diagnosis and determine the treatment approach. If a plain abdominal or chest x-ray is obtained (likely in consideration of a perforated viscus), a calcified AAA may be visible. Ultrasound scan is useful for identification of an AAA but is not sensitive for detection of rupture. Computed tomographic (CT) scan is the best imaging modality for evaluation of rAAA. On the basis of several studies, patients with conditions that are stable enough on presentation to the emergency department with a rAAA are likely to survive 2 to 11 hours before intervention. Thus, if the patient's condition is stable, enough time is generally available to obtain a CT scan. This scan confirms the diagnosis and delineates anatomy (e.g., identification of a retroaortic left renal vein anomaly helps to avoid injury during cross clamping). If endovascular repair is a consideration, a CT scan with intravenous contrast should be performed (Figure 1). Alternatively, an angiogram may be performed once the patient is in the operating room.

When the patient is diagnosed with rAAA, preoperative resuscitation should be centered on permissive hypotension, with a systolic blood pressure goal of 50 to 70 mm Hg concomitant with an appropriate level of consciousness. Aggressive resuscitation may raise the blood pressure enough to overcome the existing tamponade and result in profuse bleeding, with the ensuing instability and increased use of blood products contributing to the cycle of coagulopathy.

TREATMENT

In the operating room, if the patient's condition is unstable, further bleeding from the rAAA should be halted with the selective percutaneous placement of an occlusive balloon in the suprarenal aorta proximal to the rupture. This is done with local analgesia to avoid the hemodynamic instability that is likely to take place on induction of general anesthesia in a patient with a hypovolemic, and likely already hypotensive, condition. Access is obtained via the common femoral artery, and a sheath is introduced through which a compliant balloon is advanced and inflated with fluoroscopy (see subsequent discussion). This effectively establishes proximal control. An angiogram may be performed with temporary balloon deflation to delineate anatomy and evaluate for endovascular repair or rAAA.

Endovascular Repair

Although results are not uniform, some studies have found the endovascular repair of rAAA is associated with less morbidity and mortality (long-term follow-up of endovascular aneurysm repair [EVAR] for rAAA is lacking). A fine-cut CT scan with and without intravenous contrast is necessary to determine whether the patient is a candidate for endovascular repair on the basis of iliac artery diameter, calcification, and tortuosity, as well as aneurysm neck diameter, thrombus load, and angulation. Alternatively, angiography may be performed to evaluate for EVAR versus open repair. General contraindications for EVAR are infrarenal neck length of less than 10 mm, neck diameter greater than 32 mm, angulation greater than 60 degrees, external iliac artery diameter less than 6 mm, and extensive calcification or thrombus present at the landing zones.

If the patient's condition is stable, a standard EVAR may be performed. This procedure can be done entirely with local anesthesia with intravenous sedation as needed. Access is gained via puncture of the common femoral artery anterior to the femoral head. Ultrasound scan–guided puncture may be helpful in patients with weakly palpable femoral pulses. After sheath placement, a 180-cm Benston wire (Cook Medical, Bloomington, Ind) is advanced into the thoracic aorta with fluoroscopic guidance. Next, a glide catheter (Terumo Medical Corporation, Somerset, NJ) is advanced over the Benston wire with fluoroscopic guidance. Then, a 260-cm Amplatz super stiff wire (Cook Medical) is introduced through the glide catheter. Next, a 14F or 16F 35-cm sheath is placed in the femoral artery over the stiff wire, with the tip of the sheath kept in the suprarenal aorta. A compliant occlusion balloon is then placed through the sheath and inflated proximal to the rupture up to the contour of the aortic wall

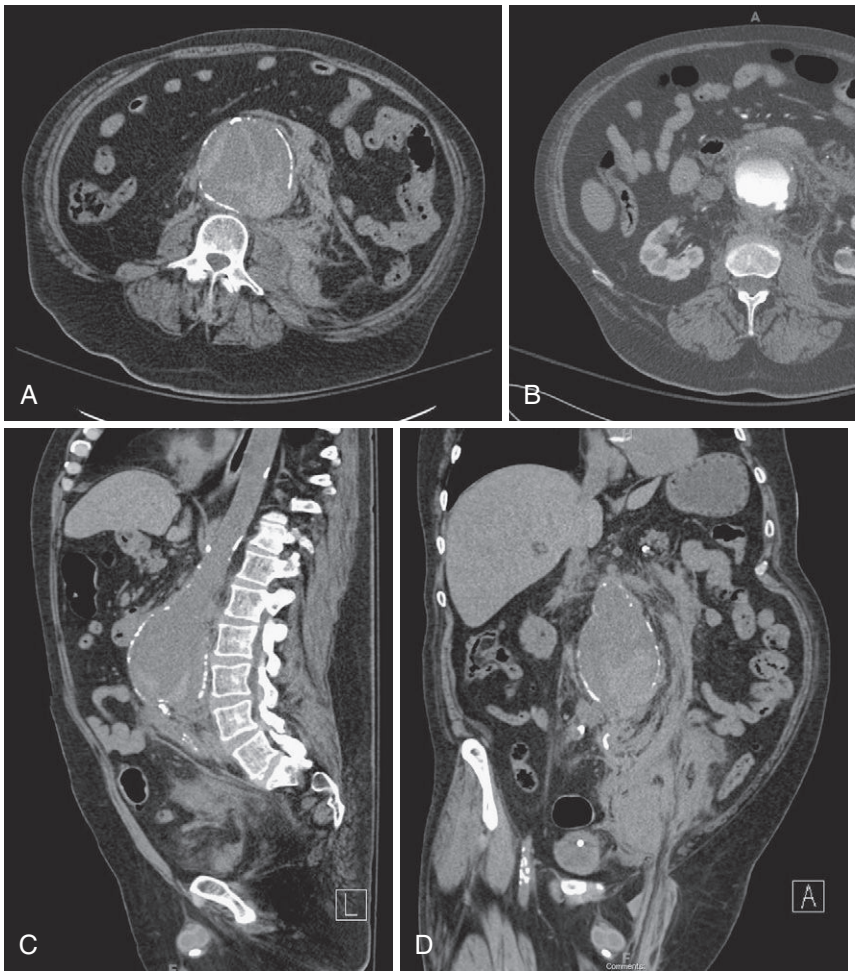

FIGURE 1 Computed tomographic (CT) scan of abdomen and pelvis shows ruptured infrarenal abdominal aortic aneurysm (AAA) with contained left retroperitoneal hematoma. **A,** CT scan without intravenous contrast shows rupture of the aneurysm. **B,** CT scan with intravenous contrast shows the area of rupture. **C,** Saggital views of same aneurysm. **D,** Coronal view of the ruptured AAA. *(Images courtesy of Dr. T. Reifsnyder; used with permission).*

to achieve complete occlusion and immediate hemodynamic improvement (Figure 2). The sheath tip should be placed under the balloon's shoulders and the sheath secured outside the patient to prevent distal migration of the balloon under the mounting proximal pressure.

A multihole catheter is inserted over a hydrophilic guidewire through the same sheath to perform an aortogram with bilateral iliac artery runoff to delineate the anatomy. This process may be difficult given the absence of aortic flow with a proximal occlusion balloon. Identification of the orifice of each renal artery is imperative to prevent coverage during endograft deployment. Either CO_2 angiography or temporary deflation of the occlusion balloon may be necessary to achieve this goal. Alternatively, aspiration off the sheath site port during contrast injection can simulate blood flow.

The stent graft is inserted via the contralateral common femoral artery after percutaneous access is obtained as described previously or via cut down approach. A stiff wire is then used to introduce the stent graft via an appropriate sheath. Of note, the tip of the ipsilateral sheath that supports the balloon should be above the stent graft to allow eventual withdrawal of the balloon into the sheath after stent deployment (see Figure 2). The stent graft is positioned based on angiography data. Once the endograft has been deployed, a second occlusion balloon may be inflated inside the graft main body and the proximal balloon deflated and withdrawn through its sheath, thus minimizing visceral ischemia time.

Usually, a bifurcated stent graft is used for EVAR of rAAA. At least one internal iliac artery needs to be preserved to minimize the risk of colon ischemia. In patients with unstable conditions, one may choose to rapidly place an aortouniiliac endograft with a contralateral iliac occluder followed by a femorofemoral crossover bypass graft. Once the aneurysm is excluded, the occlusion balloon is retrieved through its sheath. If the patient's condition becomes hemodynamically unstable with balloon deflation, one can inflate a smaller balloon in one of the endograft limbs to allow enough time for resuscitation with perfusion of at least one of the lower extremities.

Endoleaks are evaluated with angiography and treated expeditiously because their presence may result in ongoing hemorrhage. If hemodynamic instability is encountered despite aneurysm exclusion confirmed with angiography and the patient exhibits hypotension with difficulty in ventilation, peaked airway pressures, and decreased urine output, the cause of instability may be abdominal compartment syndrome from a large hematoma. The authors' experience is to create a small retroperitoneal incision to evacuate the hematoma, which successfully stabilizes the patient's condition during endovascular repair of rAAA after exclusion of the aneurysm.

Open Repair

If an open repair approach is chosen, the patient should be prepped and draped before the induction of general anesthesia. Large-bore peripheral intravenous catheters, an arterial line, a nasogastric tube, and a Foley catheter should all be placed. Every attempt should be made to keep the patient warm to minimize coagulopathy. One may choose between the transabdominal and the retroperitoneal approach, usually determined by the surgeon's typical approach to elective AAA repair.

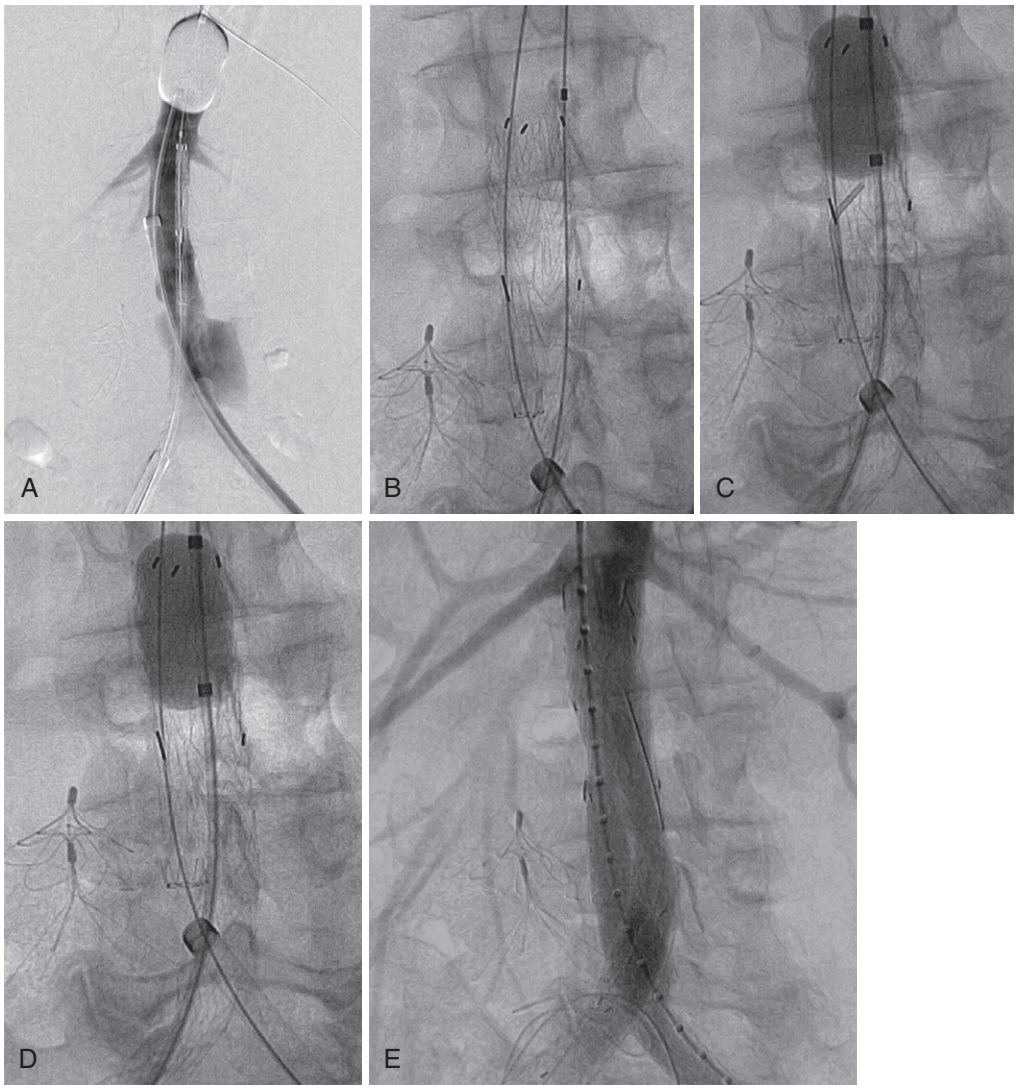

FIGURE 2 Endovascular repair of ruptured abdominal aortic aneurysm. **A,** Inflated suprarenal aortic occlusion balloon and stent graft shown before deployment, with angiogram revealing the area of rupture. **B,** Aortic occlusion balloon has been deflated and retracted, and the stent graft subsequently deployed. **C,** Reinflation of aortic occlusion balloon below the renal arteries in the endograft main body before contralateral gate cannulation. **D,** Contralateral gate cannulation with inflated aortic occlusion balloon. **E,** Completion angiogram with no evidence of endoleak and compete exclusion of the rupture. *(From Mehta M, Kreienberg PB, Roddy SP, et al Ruptured abdominal aortic aneurysm: endovascular program development and results,* Semin Vasc Surg *23(4):206-214, 2010, Fig. 4.)*

A transabdominal approach allows evaluation of intestinal ischemia. With a midline incision, the abdomen is entered, and the supraceliac aorta is exposed by dividing the left triangular ligament of the liver, retracting the left lobe of the liver to the right, and incising the gastrohepatic ligament. The stomach and esophagus (identified with the nasogastric tube) are reflected to the left. If the balloon occlusion technique described previously has not been used, the supraceliac aorta is identified at the diaphragmatic crus and clamped, or alternatively compressed against the spine with a sponge stick. The clamp should be moved to an infrarenal location as soon as possible to minimize visceral ischemia time. Care is taken to identify the left renal vein. After clamping, further resuscitation is allowed before the aneurysm sac is entered.

On opening of the aneurysm, retrograde bleeding from the lumbar arteries is controlled with suture ligation. Distal control is achieved by clamping the iliac arteries or distal aorta. Alternatively, 5F Fogarty occlusion balloons may be placed into each iliac artery through the aneurysm sac. The proximal anastomosis is then completed with a tube graft and 3-0 doubled armed polypropylene sutures. Pledget reinforcement may be necessary if the wall of the aorta is severely diseased. Once the proximal anastomosis is completed, the clamp should be moved distally to the graft. Good communication with the anesthesia team is imperative because hypotension may result from visceral reperfusion. A bifurcated graft should be used only if the iliac arteries are severely diseased. An aortobifemoral graft increases the risk of graft infection; thus, the authors prefer to perform the anastomosis to distal external iliac arteries and stay in the pelvis. For minimized risk of pelvic and colonic ischemia, at least one internal iliac artery should be reperfused. This may be achieved with retrograde perfusion from the distal external iliac artery or antegrade flow from the common iliac artery, depending on the aortic reconstruction configuration. If systemic heparinization is not used to minimize bleeding, the iliac arteries should be flushed copiously with heparinized saline solution to avoid distal thrombosis before completion of the distal anastomosis.

Care must be taken at the conclusion of open rAAA repair to examine the colon and evaluate the blood supply with Doppler scan at the antimesenteric border if intestinal viability is in doubt. Abdominal closure is then performed in the routine manner, although one may have to leave the abdomen open with a negative-pressure dressing if organ edema is concerning for development of abdominal compartment syndrome.

A retroperitoneal approach may be chosen for open repair of rAAA. This approach is thought to be associated with less morbidity and is helpful in patients with prior abdominal surgery and in those with a suprarenal AAA. A curvilinear incision is made from the umbilicus to the 12th rib. The anterior rectus sheath and muscle is divided, followed by the external oblique, and the retroperitoneum

is best entered at the 12th rib level. The peritoneum is then mobilized bluntly to the right, and the left ureter is identified and retracted medially. The operation proceeds similarly to the repair described previously.

Postoperative management after either open or endovascular repair of rAAA requires attention to possible complications. Bleeding, abdominal compartment syndrome, myocardial infarction, arrhythmias, congestive heart failure, respiratory failure, renal failure, liver dysfunction, and ischemia of multiple organs including colon, spinal cord, and extremities are some of the more severe complications encountered after these operations.

DISCUSSION

Ruptured AAA remains a highly morbid and lethal condition. Those patients who survive to reach the hospital and undergo repair of rAAA have exceedingly high rates of morbidity and mortality. Several patient characteristics are known to be associated with death after rAAA: hypotension, advanced age, cardiac arrest, elevated serum creatinine, anemia, and ischemic heart disease.

The multiorgan failure (MOF) that not infrequently occurs in these patients is thought to result from the ischemia-reperfusion injury that occurs during rAAA repair. The "two-hit" hypothesis stipulates that two ischemic events, rupture that results in total body ischemia from hemorrhagic shock and aortic cross clamping that leads to lower torso ischemia, are followed by reperfusion, which leads to the release of inflammatory mediators and further tissue injury.

Several prospective randomized trials have shown dramatic decreases in operative mortality and morbidity rates after elective AAA repair with the endovascular approach but with higher long-term reintervention rates compared with open repair. However, the most recent randomized trial in the United States, the Open Surgery versus Endovascular Repair of Abdominal Aortic Aneurysm (OVER) trial, has shown similar reintervention rates between open elective AAA repair and EVAR. Because rAAA is less common, no level I evidence is found regarding the role of EVAR in the repair of ruptured AAA. Nevertheless, endovascular repair of rAAA is associated with less blood loss, ischemia, and shock. Centers with high volumes of elective EVAR have published encouraging results that show a decrease in operative deaths from rAAA to 20% to 30% with the endovascular approach described previously. An important note is that those patients who undergo EVAR may have a higher rate of reintervention, which requires close follow-up.

SUMMARY

Ruptured AAA is a morbid and lethal condition characterized by patient presentation with back or abdominal pain, hypotension, and sometimes a palpable pulsatile abdominal mass. Evaluation should be concomitant with treatment. A key feature of resuscitation is permissive hypotension, with a systolic blood pressure goal of 50 to 70 mm Hg concomitant with an appropriate level of consciousness. Repair may be approached in the open fashion or with endovascular means. CT scan with intravenous contrast or an angiogram is necessary if endovascular repair is planned. With either approach, if the patient's condition is unstable, a suprarenal occlusive balloon percutaneously placed in the aorta before the induction of anesthesia helps decrease bleeding and stabilizes the patient. Whether endovascular or open repair is the best approach in rAAA is not entirely clear at this point. Further research will help determine which approach is preferable in which patients.

Abdominal Aortic Aneurysm and Unexpected Abdominal Pathology

Junaid Malek, MD, and Michael T. Watkins, MD

OVERVIEW

Abdominal aortic aneurysm (AAA) is a common, typically asymptomatic, potentially life-threatening condition. In the elective operative setting, management revolves around excluding the dilated segment of aorta from pressurized blood flow to prevent further growth and eliminate the risk of rupture. Currently, two major approaches exist for treating AAA: open surgical repair via either anterior or retroperitoneal approaches and minimally invasive endovascular aneurysm repair (EVAR).

Prior to the advent of endografting, open repair remained the long-standing gold standard for treating AAA, with proven long-term efficacy. However, EVAR has quickly replaced open AAA as a first-line treatment in suitable candidates because of the significantly decreased risk of perioperative morbidity and mortality. Continued evolution of stent grafts and delivery systems has made endovascular repair feasible in progressively more unfavorable aneurysm anatomy. As EVAR grows in popularity, fewer patients are undergoing laparotomy for repair of their aneurysms; thus, the discovery of unexpected, coincident intraabdominal pathology at the time of operation has become less common. Furthermore, the frequent preoperative use of noninvasive imaging modalities—including computed

tomographic (CT) scan, Doppler ultrasound, and magnetic resonance imaging (MRI)—has increased the likelihood of discovering coexisting conditions well before the patient ever sees the operating room. Nevertheless, indications for open AAA repair still exist, and surgeons who encounter unexpected conditions at the time of repair must prioritize their findings and develop an operative strategy that minimizes the overall risk to the patient.

Clinical scenarios involving aortic aneurysms and coincident intraabdominal pathology may be generally separated into four distinct categories: elective operation for aortic pathology with incidental finding of asymptomatic nonvascular pathology; emergent operation for presumed symptomatic aortic pathology with incidental findings of nonvascular pathology; emergent operation for abdominal pathology with incidental finding of an aortic aneurysm; and elective operation for abdominal pathology with incidental finding of an aortic aneurysm. This chapter describes each of these scenarios, focusing on those clinical entities most commonly encountered.

ELECTIVE ABDOMINAL AORTIC ANEURYSM REPAIR AND ASYMPTOMATIC ABDOMINAL DISEASE

Virtually every patient undergoing an elective aneurysm repair, either EVAR or open, has undergone a preoperative CT scan. When asymptomatic intraabdominal disease is discovered on CT scan prior to EVAR, the surgeon is generally able to choose whether to proceed with EVAR or to treat the concomitant pathology first. Because EVAR is so well tolerated and causes minimal physiologic derangement, the aneurysm can typically be repaired without significantly delaying the subsequent treatment of other time-sensitive pathology, such as cancer. Furthermore, the peritoneal cavity is left untouched by EVAR, permitting a clean laparotomy for other intraabdominal interventions. Even in an era of extensive preoperative imaging prior to elective open AAA repairs, unrecognized pathology is occasionally discovered. Frequently this identified pathology will have either been too small to appear on CT scan or will have been of a nature making it unlikely to appear. At this point the surgeon has three options: continue the open AAA without any other concomitant surgical procedure, abandon the AAA and treat the concomitant condition first, or attempt simultaneous treatment of both AAA and the unexpected pathology. The decision depends on the type and severity of abnormality found. If the surgeon elects to continue the AAA repair without synchronous treatment of concomitant disease, it must be recognized that the patient may not have another opportunity for the secondary disease process to be safely addressed for quite some time because of the need for the patient to recover from the physiologic insult of a major open vascular procedure in the immediate postoperative period and the well-recognized risk of reoperative laparotomy because of adhesion formation in the intermediate term. If the surgeon elects to treat only the concomitant pathology without treating the AAA, the increased risk of aneurysm rupture caused by delay in repair must be considered. Because open AAA repair is almost always reserved only for those aneurysms large enough to exhibit an elevated risk of rupture, this risk should not be considered insignificant. If the surgeon chooses to address both problems simultaneously, he or she must be willing to accept the potentially increased morbidity of putting a patient through two procedures instead of one, lengthening anesthetic time and increasing blood loss. Furthermore, resection of the concomitant pathology may require opening the gastrointestinal or biliary tracts, thereby potentially increasing the risk of an aortic prosthetic graft infection, a devastating complication. The most commonly encountered abnormalities include cholelithiasis, appendix and Meckel's diverticulum, gastrointestinal malignancies, genitourinary malignancies, and solid organ tumors.

Cholelithiasis

Cholelithiasis is found in up to 20% of AAA laparotomies. When noted, the surgeon must choose whether to leave the gallstones alone because simultaneous treatment may increase the chances of graft infection or perform a cholecystectomy to avoid the risk of postoperative cholecystitis or choledocholithiasis. Because cholecystectomy can generally be performed quickly with a minimum of blood loss, the greatest factor at play is the elevated risk of graft infection associated with opening the biliary tract.

This topic was once a subject of much debate in the literature, with some citing an elevated risk of cholecystitis in the postoperative period. However, as advances in minimally invasive and interventional radiologic techniques have improved our ability to treat gallbladder disease, the weight of opinion has shifted away from synchronous cholecystectomy. Laparoscopic cholecystectomy, transhepatic biliary stenting, and endoscopic retrograde cholangiopancreatography (ERCP) have permitted symptomatic cholelithiasis and choledocholithiasis to be safely treated almost always without the need for second laparotomy.

Because any AAA repair, open or endovascular, requires close postoperative follow-up, the patient may be screened in the postoperative period for any signs or symptoms suggestive of symptomatic cholelithiasis and referred for elective laparoscopic cholecystectomy when indicated. Patients with recognized gallstone disease should be educated in dietary modification and should be considered for treatment with ursodiol.

Appendix and Meckel's Diverticulum

Because of the significant risk of aortic prosthetic infection associated with opening the gastrointestinal tract, asymptomatic appendices and Meckel's diverticula should unequivocally be left alone during an open AAA repair. Incidental discovery of acute appendicitis during an open AAA repair would be a rare occurrence indeed, but if discovered, it would certainly need to be resected. A more challenging dilemma arises if evidence of a chronically inflamed appendix or Meckel's diverticulum is discovered. The risk-benefit ratio would still argue against synchronous resection, *unless the inflammation indeed appears to be acute.* Advances in laparoscopic management of appendix and Meckel's diverticula have made resection following AAA repair, even in the immediate postoperative period, quite feasible, with a low likelihood of need for repeat laparotomy. In the setting of acute appendicitis with gross purulence, appendectomy followed by interval aneurysms repair is the preferred approach.

GASTROINTESTINAL MALIGNANCIES

Gastrointestinal (GI) malignancies are notoriously difficult to identify on CT scans. Furthermore, aortic aneurysms and GI malignancies tend to occur in the same patient populations: in smokers and in those older than age 50 years. Thus, the discovery of previously unrecognized colorectal or small bowel malignancies at the time of laparotomy for AAA repair is a relatively common occurrence. Colorectal cancers (CRCs) are most common, with an estimated frequency of concurrence with AAA of between 0.49% and 2.1%. Therefore, the occasional discovery of synchronous GI malignancies would most certainly be encountered in high-volume vascular centers.

Concomitant surgical correction of both CRC and AAA is considered controversial because of the magnitude of a combined operation. Generally, a staged procedure is recommended, with the order of treatment depending on the judged severity of each condition; a 4- to 6-week period of convalescence between open operations is

usually required to maximize the patient's physiologic reserve. However, intervention for CRC can often be accelerated by employing less invasive laparoscopic and endovascular methods. Unfortunately, during this period, the untreated pathology may worsen or become symptomatic. Repairing the AAA first postpones colectomy and risks metastasis of colorectal cancer, whereas starting with colectomy leaves the patient at risk of death from rupture of the aneurysm. Synchronous treatment, on the other hand, avoids the need for a second operation, which may not be well tolerated in the frail vascular surgical population; postoperative recovery may be faster from a psychological point of view as well.

Lin and colleagues (Lin P, et al., 2008) published a multicenter retrospective review of 108 patients with concomitant CRC and AAA. Among the 35 cases in which CRC was treated first followed by staged open aneurysm repair, Lin observed that two patients (6%) died after their initial CRC resection with autopsy results of both patients confirming aortic aneurysm rupture as the cause of death. Among the 11 patients who underwent CRC resection first followed by staged EVAR, two (18%) developed sigmoid ischemia after EVAR, requiring immediate laparotomy and sigmoidectomy. Among the 26 patients who underwent AAA repair first, the time to subsequent colectomy was significantly delayed when compared to other cohorts and averaged 115 days. Finally, those patients who underwent EVAR as either the primary or staged operation required a significantly shorter cumulative hospital length of stay. While no graft infections were identified during the study period in the eight patients undergoing combined open AAA repair and CRC resection, the authors argued that the possibility of such infections is a substantial enough concern to prompt avoidance of a combined approach. Lastly, because of the increased risk of aortic rupture after abdominal operations, Lin recommended that patients with asymptomatic synchronous CRC and AAA of greater than 5 cm undergo aneurysm repair first to reduce the risk of perioperative aneurysm rupture.

Shalhoub and colleagues (Shalhoub J, et al., 2009) published a review of 24 cases from prospectively maintained databases of patients with concurrent colorectal malignancy and abdominal aortic aneurysms. In patients undergoing staged management with colectomy first, they documented no interval aneurysm ruptures. However, in their series, patients with large aneurysms underwent EVAR prior to colectomy. The authors concluded that staged management is a reasonable approach with a low risk of aneurysm rupture, though simultaneous repair may be performed in patients with obstructing CRC with an aneurysm that is less than 6 cm, where the risk of interval AAA rupture is significant. They also stressed the usefulness of EVAR in preventing delay of CRC management. It may be preferable to perform EVAR first for a large aneurysm; the patient is discharged home within 24 hours and is able to undergo colectomy, usually via laparoscopic approach, in the next 2 to 4 weeks. In one case, an 8-cm AAA was discovered incidentally on preoperative CT scan for colon adenocarcinoma in a 72-year-old man. He underwent EVAR followed by laparoscopic hemicolectomy 3 weeks later and was cancer free with a stable aneurysm at his 2-year follow-up.

Should the surgeon opt to proceed with synchronous resection, excellent surgical technique with control of peritoneal contamination is a must if graft infection is to be avoided. Preoperative administration of antibiotics and aggressive bowel preparation should also be performed if the cancer was recognized preoperatively. If EVAR is not an option in the setting of a nearly obstructing left-sided colorectal lesion, a temporary transverse colostomy can be performed at the conclusion of open AAA repair.

Discoveries of small bowel and gastric tumors have also been reported, with patients undergoing simultaneous enterectomies or gastrectomies. In such cases, a management algorithm similar to that described above for colorectal malignancies is best followed. Patients should be staged when possible, unless the acuity of each condition individually is felt to be so high as to mandate synchronous intervention.

Genitourinary Malignancies

Renal carcinoma, unless large or invasive, may go unrecognized if aneurysms are approached via midline laparotomy. The chance of discovering a synchronous renal mass is increased with the retroperitoneal approach.

Synchronous repair of AAA and nephrectomy have been described, with a low risk of bacterial graft contamination. Although synchronous treatment avoids necessitating a second retroperitoneal exploration, a staged approach should be used if the AAA repair is particularly difficult or if intraoperative blood loss is significant. Additionally, patients with known reduced preoperative kidney function may benefit from a staged approach with more meticulous operative planning. In Figure 1, a frail vasculopath presented with a tender abdominal aneurysm, right flank pain, and a right renal mass on CT scan. He underwent endovascular AAA repair, followed by catheter-directed radiofrequency ablation of the renal tumor.

In cases of bladder or prostate cancer, the risk of urinary bacterial contamination is higher. Although there are reports of simultaneous resection of aggressive bladder cancer and aneurysm repair, a staged approach would be considered most prudent to minimize the risk of bacterial graft contamination.

A prospective study by Grego (Grego F, 2003) compared simultaneous aneurysmectomy and radical cystoprostatectomy with a staged procedure and found no statistically significant difference in the outcome and morbidity. Preoperative renal function must be assessed before a concomitant operation, as an early trend toward increased mortality was found by Grego in those patients with preoperative moderate renal insufficiency. Again, aneurysm size matters here: an AAA greater than 5 cm may undergo a simultaneous operation, and smaller AAAs may be staged, also considering EVAR if possible.

Solid Organ Tumors

Solid tumors of the spleen, liver, and adrenal gland have also been documented and successfully resected at the time of AAA repair.

FIGURE 1 Abdominal aortic aneurysm (computed tomographic scan).

Given the typically sterile nature of these organs, simultaneous resection appears reasonable as long as the patient can physiologically tolerate the blood loss and additional anesthetic time associated with the second procedure.

EMERGENT ABDOMINAL AORTIC ANEURYSM REPAIR AND CONCOMITANT DISEASE

Emergent AAA repair is indicated in two situations: with symptomatic AAA and ruptured AAA (rAAA). Imaging studies are usually available in the first case but not necessarily in the latter because of the extreme urgency of the condition and need for prompt transport to the operating room. In either case, the first priority is aneurysm repair, after which the major goal should be for prompt and aggressive resuscitation in the intensive care unit. Pursuing other intraabdominal findings at this time would be ill advised unless they were deemed to be life threatening in nature.

Among patients with a symptomatic but unruptured AAA and a synchronous intraabdominal lesion, the prioritization of conditions should depend on the severity and related mortality risk of each. Symptomatic AAAs are believed to represent aneurysms in the initial stages of rupture, suggesting that the risk of leaving them untreated would be significant. However, if a concomitant intraabdominal condition is considered life threatening or extremely urgent, aneurysm repair could conceivably be temporarily delayed. If the AAA is massive or is demonstrating early signs of rupture on visual inspection, synchronous open repair would be necessary. Thankfully, the concurrence of two such unrelated yet life-threatening conditions is a rare event.

The treatment of ruptured AAAs is shifting away from open repair toward EVAR when technically possible, with studies indicating a 30% mortality rate reduction in EVAR cohorts. Unexpected concomitant disease may be evident on preoperative imaging conducted for EVAR planning but is otherwise unlikely to be discovered. Even if other pathology is noted preoperatively, treatment of the aneurysm always takes first priority. However, if suspicion develops during EVAR of a synchronous intraabdominal catastrophe, aneurysm repair may need to be followed by diagnostic laparoscopy or exploratory laparotomy prior to transport to the ICU.

Unfortunately, patients in whom control of aneurysmal bleeding has been achieved and aortic continuity restored may nevertheless have suffered enough visceral ischemia during the procedure to develop bowel necrosis. In such cases, clearly nonviable bowel should be resected prior to returning the patient to the ICU for resuscitation, and the abdomen should be left open for marginal bowel to be inspected 24 to 48 hours later.

EMERGENT LAPAROTOMY FOR SYMPTOMATIC ABDOMINAL PATHOLOGY WITH INCIDENTAL ASYMPTOMATIC ABDOMINAL AORTIC ANEURYSM

A broad spectrum of emergent intraabdominal pathologies may bring a patient to the operating room without prior CT imaging. Possible scenarios include blunt or penetrating abdominal trauma, severe lactic acidosis of suspected intraabdominal origin, obvious bowel obstruction in a virgin abdomen, or clear perforation with peritonitis, to name only a few.

Clearly, acute intraabdominal pathology must be prioritized and treated first, and any life-threatening conditions should be addressed promptly. If the aneurysm is found to be exceedingly large or at imminent risk for rupture, either an intraoperative or prompt postoperative vascular surgical consult should be sought.

Operations for intraabdominal infectious conditions, such as perforated viscus or infected necrotizing pancreatitis, make open aneurysm repair in the near-term time frame prohibitively dangerous given the high likelihood of graft infection. If at all possible, the patient should be considered for endovascular repair, as this prevents infected peritoneal contents from ever coming into contact with prosthetic material.

If the patient did not undergo preoperative imaging or was taken for laparotomy based solely upon clinical impression, it is important to ascertain whether the patient's acute presentation (e.g., abdominal pain) was actually a result of the anticipated nonvascular pathology or was rather stemming from the aneurysm. If laparotomy is otherwise negative for findings explaining severe abdominal pain, a symptomatic aneurysm in the early stages of rupture should be added to the differential diagnosis, and a vascular surgeon should be consulted intraoperatively for prompt assessment. Consideration for abdominal closure and prompt CT imaging for possible EVAR should be made in the absence of a ruptured AAA.

Necrotic small bowel with superior mesenteric artery (SMA) compromise in the setting of AAA should also prompt an urgent vascular surgical consultation. Aneurysmal thrombus or dissection could account for a sudden SMA ostial thrombosis. This life-threatening condition would require emergent revascularization, with or without concomitant aneurysm repair.

ELECTIVE LAPAROTOMY FOR ABDOMINAL PATHOLOGY WITH INCIDENTAL ASYMPTOMATIC ABDOMINAL AORTIC ANEURYSM

With the frequent use of preoperative imaging studies in preparation for elective intraabdominal surgeries, the unexpected discovery of AAA at laparotomy is rare. The discovery of an unexpected aneurysm may be alarming, especially to an operating surgeon who in all likelihood is not a vascular specialist. Unless the aneurysm is exceedingly large or appears to be at imminent risk for rupture, it is probably reasonable for the surgeon to proceed with the planned abdominal operation. A vascular surgeon should be consulted either intraoperatively or promptly following the conclusion of the operation to assess the aneurysm and the patient's suitability for repair. Given the need for high-quality preoperative CT angiography, as well as specialized equipment including fluoroscopy, synchronous EVAR in such a situation is generally not feasible. However, patients with aneurysms larger than 5 cm may be considered for prompt endovascular repair in the perioperative period. Patients with unfavorable anatomy for EVAR may do better with a more extended convalescent interval provided they are followed closely and warned about the signs and symptoms associated with AAA expansion or rupture.

SUMMARY

Although several case series and theoretical models do exist in the literature addressing the topic of AAA repair and synchronous disease management, much of the decision making depends on basic surgical principles of infection control, relative risk of the underlying pathologies encountered, and minimization of patient morbidity. Several general recommendations may be followed:

1. Emergent AAA repair takes priority over any concomitant disease.
2. Any nonlethal, nonvascular pathology discovered during elective AAA repair may be left alone at that time.
3. Incidental AAA found during emergent or elective laparotomy should be promptly evaluated by a vascular surgeon in the

immediate perioperative period; if large enough to represent a rupture risk, it should be addressed soon thereafter, preferably via EVAR.

4. Meticulous surgical technique must be followed if the gastrointestinal or biliary tracts are to be violated during a synchronous aneurysmectomy, as aortic graft infection is a highly lethal complication.

The Management of Thoracic and Thoracoabdominal Aortic Aneurysms

R. Todd Lancaster, MD, MPH, and Richard P. Cambria, MD

INTRODUCTION

Descending thoracic aortic aneurysms (DTAAs) involve the segment of the aorta bounded by the origin of the left subclavian artery and the diaphragm. Thoracoabdominal aortic aneurysms (TAAAs) involve the visceral aortic segment and varying degrees of the thoracic and abdominal aortas in accordance with the anatomic classification devised by Crawford (Figure 1). These aneurysms are uncommon when compared with isolated infrarenal aneurysms, comprising no more than 2% to 5% of the spectrum of aortic aneurysms.

In contrast to degenerative aneurysms associated with the abdominal aorta, the thoracic aorta is involved in a broader spectrum of pathologies, which are potentially etiologic in the formation of aneurysms. Examples of these include dissection, connective tissue disorders, aortitis, and trauma. Open surgical management of diseases of the thoracic aorta is accompanied by significant morbidity and mortality rates compared with repair of abdominal aortic aneurysms (AAAs). The emergence of stent-graft repair of the thoracic aorta, however, has substantially diminished the morbidity of surgical repair for many patients; although its role in certain pathologies such as degenerative aneurysm of the descending thoracic aorta and acute traumatic tear is well established, its ultimate utility in acute and chronic dissection remains the subject of ongoing study.

Patients with aneurysms in these locations are often diagnosed incidentally on radiographic imaging; however, up to 40% of patients will present with symptoms. These symptoms are related to compression or erosion of nearby structures or to inflammation of the mediastinal pleura. When symptomatic, patients with aneurysmal dilation of the thoracic aorta may manifest back pain, hoarseness, dysphagia, cough, and, of course, rupture. The final point to be made in this regard is that such back pain mediated by large thoracic aneurysms can be chronic in nature, somewhat different from the paradigm typically associated with symptomatic AAA. In particular, large aneurysms involving the visceral aortic segment can lead to a syndrome of both epigastric and back pain; the latter can be severe when vertebral body erosion occurs. As would be intuitively expected, such symptoms have been correlated in natural history studies with increased rupture risk.

INDICATIONS FOR SURGERY

Longitudinal studies have found that the mean rate of growth for all thoracic aneurysms is 0.1 cm per year. Not surprisingly, increasing aneurysm size is associated with higher rupture risk. Rupture, which carries a 90% mortality rate, accounts for 30% of all deaths in patients with thoracic aneurysms, occurring with an incidence rate of 3.5 per 100,000 patient-years. Risk factors for rupture include increasing patient age, pain (including atypical pain), other symptoms attributable to the aneurysm, a history of chronic obstructive pulmonary disease (COPD), and dissection developing within a degenerative aneurysm. Population-based studies have indicated an overall 5-year rupture risk of 20%, with 80% of ruptures occurring in women. In fact, female gender has been identified as an independent variable predicting aneurysm rupture (relative risk [RR] 6.8; 95% confidence interval [CI], 2.3-19.9; $P = 0.01$).

DTAAs appear to expand at more rapid rates as they become larger, and several investigators have correlated increased expansion rates with rupture. Furthermore, studies have indicated that rupture risk is negligible in aneurysms less than 5 cm, equivalent to the risk of surgical morbidity in the 5-cm to 6-cm range, and increases substantially at aneurysm diameters larger than 6 cm and/or growth rates of 10 mm or more per year. These natural history observations have led to the acceptance of 6 cm as a generally appropriate size threshold for recommendation of surgical intervention in patients with degenerative DTAAs and TAAAs. Increasing expansion rate is used as an indicator of heightened rupture risk, as is the presence of symptoms, and in such cases, consideration is given to earlier operation. In the cases of chronic dissection and Marfan's syndrome, a 5-cm size threshold is maintained because of rupture proclivity at

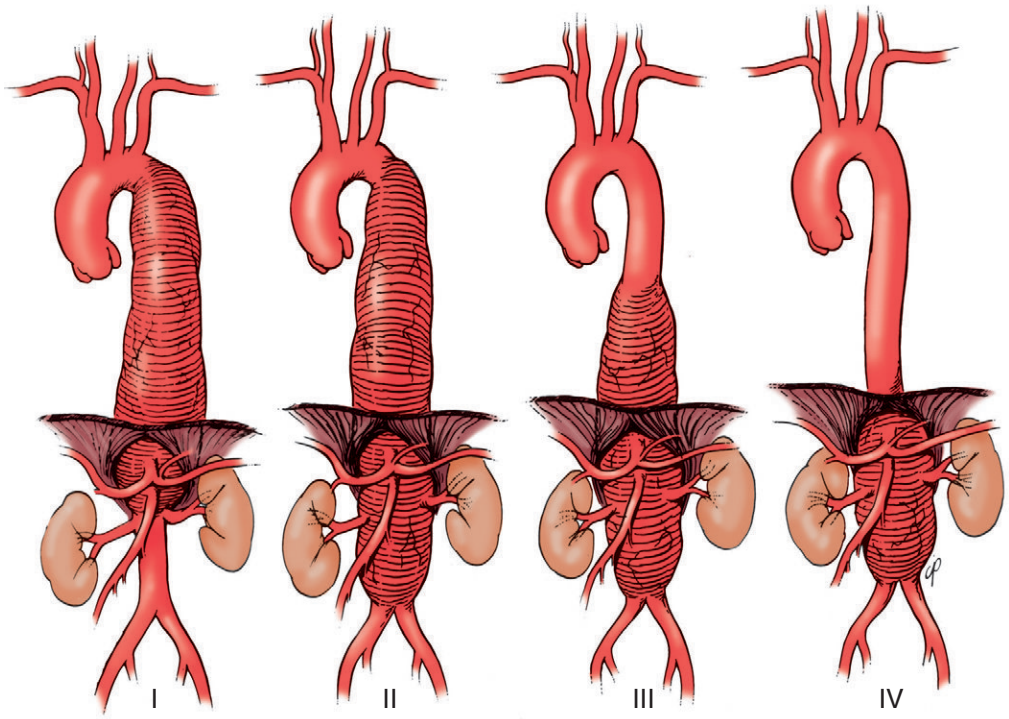

FIGURE 1 Crawford classification scheme for thoracoabdominal aortic aneurysm.

smaller sizes; in addition, many such patients are considerably younger than the typical patient with a degenerative lesion.

PREOPERATIVE RISK ASSESSMENT

The Crawford classification describes TAAA based on the extent of aortic resection and, in many cases, can be considered caudal extension of a descending thoracic aortic (DTA) lesion (e.g., extent I TAAA) or cephalad extension of a total abdominal aneurysm (e.g., extent IV TAAA). This classification is useful clinically since it has direct implications for both the technical conduct of operation and the incidence of operative complications, especially ischemic spinal cord injury (SCI).

An accurate assessment of associated comorbid conditions (especially cardiac, pulmonary, and renal comorbidities) is mandatory to guide appropriate decision making with respect to recommending open surgical repair. All patients should be evaluated with dipyridamole thallium scanning, or the equivalent thereof, to assess perioperative myocardial ischemic potential. In addition, patients with a history of symptoms suggestive of heart failure should have an assessment of left ventricular function. Cardiac catheterization may be appropriate for patients with evidence of coronary ischemic potential on physiologic testing, or with an ejection fraction of less than 30%. However, ischemic cardiomyopathy in this range generally precludes open operation. Patients who have severe coronary disease and asymptomatic aneurysms may undergo myocardial revascularization prior to aneurysm repair, as the clinical scenario dictates.

While patients with significant impairments of pulmonary reserve can usually be detected on the basis of history alone, we have a low threshold for obtaining preoperative pulmonary function studies in patients with extent I-III TAAA. Limited pulmonary reserve is a common consideration in deciding to forego formal open repair. Yet COPD itself is a well-documented risk factor for aneurysm expansion and rupture. Advanced age is an important component only inasmuch as it is accompanied by overall fragility and impaired functional status.

The coexistence of renovascular disease and some degree of renal insufficiency is especially commonplace in patients with TAAA and has important implications for accurate assessment of perioperative risk and long-term preservation of renal function. In our experience, 15% of patients had significant renal insufficiency as manifested by a preoperative serum creatinine of 1.8 mg/dL or higher. In many series, the presence of an abnormal preoperative serum creatinine is at least a univariate correlate of perioperative mortality, largely related to an increased risk of perioperative renal failure. Although the potential for restoration of renal function by correction of renovascular lesions exists in some patients, advanced renal dysfunction constitutes a relative contraindication to elective operations.

Associated vascular diseases and comorbid conditions are commonplace in patients presenting for treatment of thoracic aneurysms. Synchronous aneurysms typically involving the ascending aorta or arch have been observed in some 10% of patients being evaluated for DTAA or TAAA repair. Prior operation for aortic aneurysm disease is seen in one third of patients, and the most common of these is a previous infrarenal aneurysm repair. Additionally, up to one quarter of patients with thoracic aortic disease have concomitant AAA; therefore, all patients should undergo baseline imaging of the entire aorta at the time of initial diagnosis.

OPEN SURGICAL MANAGEMENT

The choice of surgical technique varies as a function of aneurysm extent and complexity. The two general approaches involve a clamp-and-sew technique (often supplemented by adjuncts to minimize complications related to spinal cord, renal and visceral ischemia) versus the use of distal aortic perfusion through an atriofemoral bypass (AFB) circuit. Although distal perfusion has been favored as a technique for repairing isolated thoracic aneurysms, some centers report comparable results using both clamp-and-sew and distal perfusion techniques. Variations in operative technique largely have been driven by the effort to minimize the major complications of SCI and renal failure. Sufficient experience and review of end results

support the selective application of adjuncts such as cerebrospinal fluid (CSF) drainage, distal aortic perfusion, intercostal reconstruction, and renal hypothermic perfusion.

Adjuncts for Organ Protection

Our institutional experience over the past quarter-century has evolved from a clamp-and-sew technique (with adjuncts such as epidural cooling) to one that favors distal aortic perfusion with motor evoked potential (MEP) monitoring for extent I-III TAAA. The clamp-and-sew technique, with emphasis on surgical simplicity and expediency, continues to be applied for extent IV TAAA with favorable results. Among spinal cord protective adjuncts, only CSF drainage is supported by a robust evidence base. The benefits of routine intercostal reconstruction have been questioned in the context of the "collateral network concept," which de-emphasizes the importance of individual intercostals arteries, since these vessels are generally interconnected in the paraspinous musculature and well collateralized via the hypogastric arteries, as demonstrated in magnetic resonance imaging studies. Based on these data, our approach to TAAA repair has evolved to emphasize intraoperative support of the collateral network through distal aortic perfusion and selective intercostal reconstruction based on MEP monitoring. The latter provides real-time assessment of spinal cord nutritive circulation during the conduct of operation.

Renal protection is achieved through the direct installation of renal preservation fluid (4° C lactated Ringer's with 25 g of mannitol per liter and 1 g methyl prednisolone per liter) into the renal artery ostia after the aorta is opened, thus causing a rapid decline of renal core temperature. This is important because of the significant impact of postoperative renal failure (defined as a doubling of baseline creatinine or absolute level >3.0 mg/dL) on operative mortality. Indeed, in our experience, patients who sustained significant postoperative renal failure had an eightfold increase in their mortality risk (OR 7.8; 95% CI, 3.4-17.9; P <0.0001). Equally important to renal protection is renal artery reconstruction, either secondary to their location with respect to the aneurysm or because of orificial stenosis. Whereas the left renal artery is generally managed with a side-arm bypass graft, treatment of right renal artery stenosis is more challenging through a left flank incision. Our practice is to use balloon-expandable stents placed directly into the ostia for right renal artery reconstruction during TAAA repair for either orificial stenosis or, if technical issues arise with inclusion, button reconstruction of the right renal artery (Figure 2). Review of our own experience shows that after a mean follow-up of 405 days, 98% of renal stents were patent, suggesting that placement of balloon-expandable stents is a durable form of renal artery reconstruction during TAAA repair.

The final adjunct in our overall approach involves in-line mesenteric shunting, again also selectively applied in accordance with aneurysm complexity, anticipated duration of mesenteric ischemia, or both. As displayed in Figure 3, immediately after performance of the proximal anastomosis, pro-grade pulsatile perfusion can be established into either the celiac axis or superior mesenteric artery (preferred) to minimize visceral ischemic time and its potential contribution to coagulopathic bleeding. When combined with distal aortic perfusion during performance of the proximal anastomosis, such in-line mesenteric shunting often results in 10 minutes or less of visceral ischemia. Obviously, the same concept can be achieved by creating a Y-circuit on the AFB cannulae setup, but this can be clumsy to position intraprocedurally.

Operative Technique

Irrespective of individual preferences concerning protective adjuncts, the key to operative success remains the provision of broad, continuous exposure of the entire left posterolateral aspect of the thoracoabdominal aorta (Figure 4). The patient is positioned on the table in the right lateral decubitus position. The location and extent of the thoracic portion of the incision is determined by the proximal extent of the aneurysm as the posterior portion of a standard posterolateral thoracotomy incision is only necessary for type I and type II aneurysms. We keep the thoracic portion of the incision low and have found that the fifth or sixth interspace with posterior division of the sixth or seventh ribs provides adequate exposure for even the more proximal aneurysms. The costal margin is divided at the level of the sixth interspace, and a self-retaining retractor system is placed to ensure continuous exposure of the entire operative field (Figure 5). A thoracoabdominal incision at the eighth interspace will usually provide adequate exposure for a type IV aneurysm, and a double

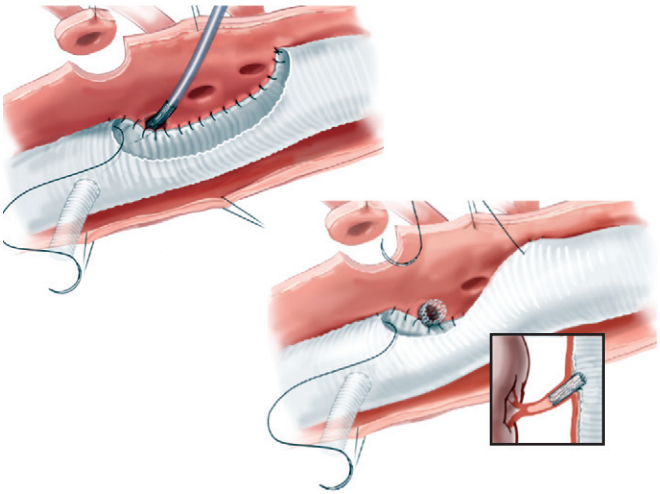

FIGURE 2 Treatment of right renal artery stenosis via a left flank incision. Placement of a balloon-expandable stent is favored over orificial endarterectomy.

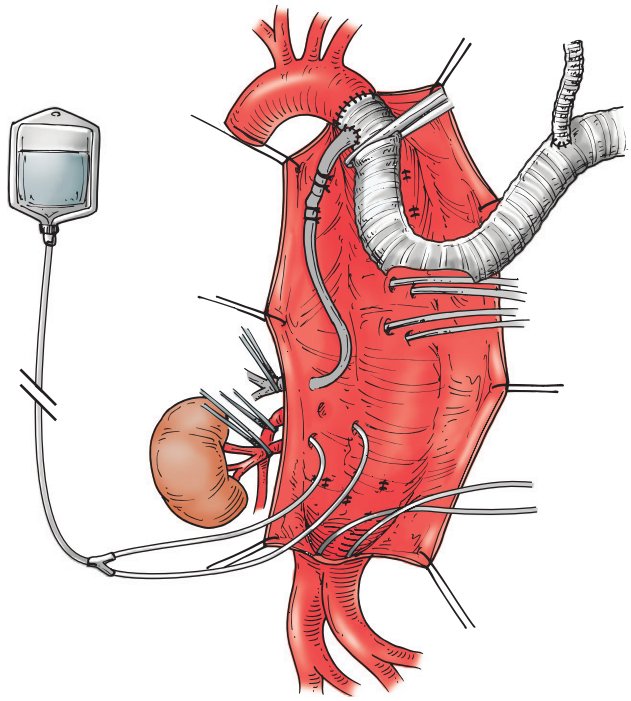

FIGURE 3 After completion of the proximal anastomosis, in select cases, a side-arm graft is used for in-line mesenteric shunting to the celiac or superior mesenteric artery.

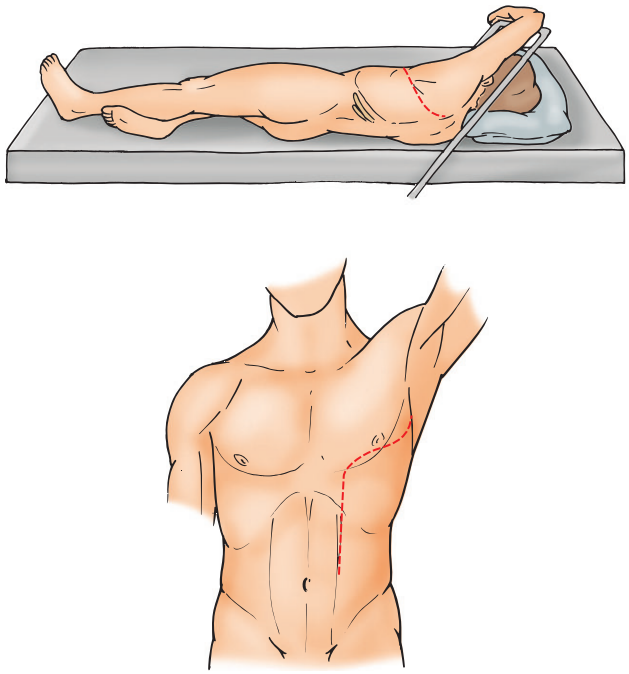

FIGURE 4 Thoracoabdominal incision. The patient is positioned in the right lateral decubitus condition. The interspace through which the incision is carried is determined by the proximal and distal extent of the aneurysm.

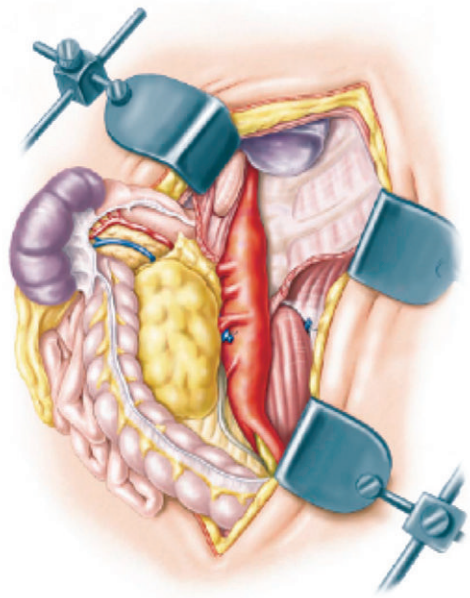

FIGURE 5 A self-retaining retractor is used to provide broad, continuous exposure of the left posterolateral aspect of the thoracoabdominal aorta.

lumen tube for deflation of the left lung is generally not necessary in these cases. The abdominal portion of the incision is not extended to the midline; rather, it is kept well lateral on the abdominal wall. The advantage of this approach is that it allows the visceral contents to lie within the abdominal cavity, thus decreasing evaporative fluid and heat losses. The abdominal portion of the incision is transperitoneal, thus allowing direct inspection and assessment of the visceral circulation when the case is completed. We have found no advantage,

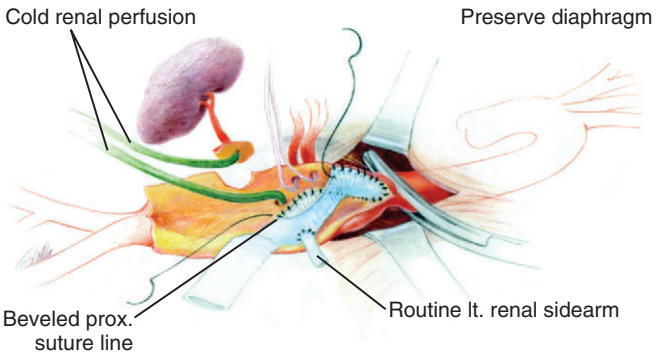

FIGURE 6 In the majority of extent IV TAAA repairs, the anatomy is suitable for a simplified reconstruction with a beveled proximal anastomosis with a left renal side-arm graft.

and indeed increased bleeding, when attempting to keep the abdominal portion of the incision extraperitoneal.

In the repair of extent IV TAAA, we use limited lateral division of the diaphragm, preserving its phrenic innervation. Subsequently, for the majority of these lesions, the operative field is set up in a totally infradiaphragmatic orientation. The repair is undertaken using a clamp-and-sew technique with routine renal hypothermic perfusion. We do not employ the use of a double-lumen endotracheal tube or that of CSF drainage. In the majority of our experience (93%), the patient's anatomy is suitable for a simplified reconstruction with a single-beveled proximal anastomosis (Figure 6).

For repair of extent I-IV TAAA, exposure of the left posterolateral aspect of the abdominal aorta is obtained by entering the plane posterior to the spleen, left kidney, and left colon (Figure 7). The abdominal contents are then reflected to the patient's right, and the left ureter is identified and preserved under laparotomy pads. The retroperitoneal fatty and lymphatic tissues overlying the aorta are transected with electrocautery, and the large posterior branch of the left renal vein that courses across the aorta is identified and divided. Located topographically close to this vein is the left renal artery (Figure 8). Once identified, the left renal artery is dissected back toward its origin on the aorta, which serves as a suitable point to initiate the cephalad and caudad division of the retroperitoneal tissues over the aorta inferiorly and division of the median arcuate ligament and diaphragmatic crura superiorly.

There are several methods by which the incision in the diaphragm may be managed (Figure 9). The quickest and simplest method that affords excellent exposure is direct radial division of the central tendon of the diaphragm from underneath the costal margin to the aortic hiatus. This approach, however, will irrevocably paralyze the left hemidiaphragm and ultimately contribute to postoperative respiratory embarrassment. A second approach involves the circumferential division of the diaphragm through its muscular portion, leaving a few centimeters attached laterally to the chest wall; this method is both time consuming and bloody. When the surgeon elects to preserve diaphragmatic innervation in an extent I-III lesion, a large Penrose drain can be passed around the diaphragm pedicle and used to retract superiorly and inferiorly as needed during the reconstruction. We have applied this method liberally, particularly in patients with evidence of preoperative pulmonary compromise.

After deflation of the left lung, the thoracic component of the dissection is typically straightforward. Electrocautery is used to divide the mediastinal pleura over the aneurysm and proximal aorta. For type I and type II aneurysms, proximal control of the aorta in the region of the left subclavian artery origin is necessary. Mobility of the vagus nerve is gained by dividing it distal to the origin of the left recurrent nerve, which should be identified and preserved. Should more proximal control be necessary, the ligamentum

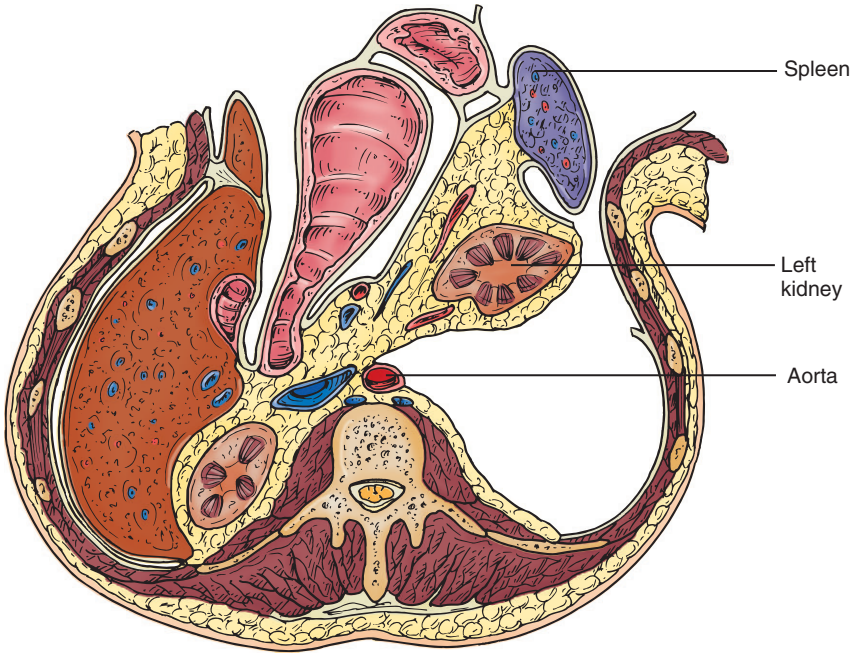

FIGURE 7 Exposure of the left posterolateral aspect of the thoracoabdominal aorta is obtained by entering the plane posterior to the spleen, left kidney, and left colon.

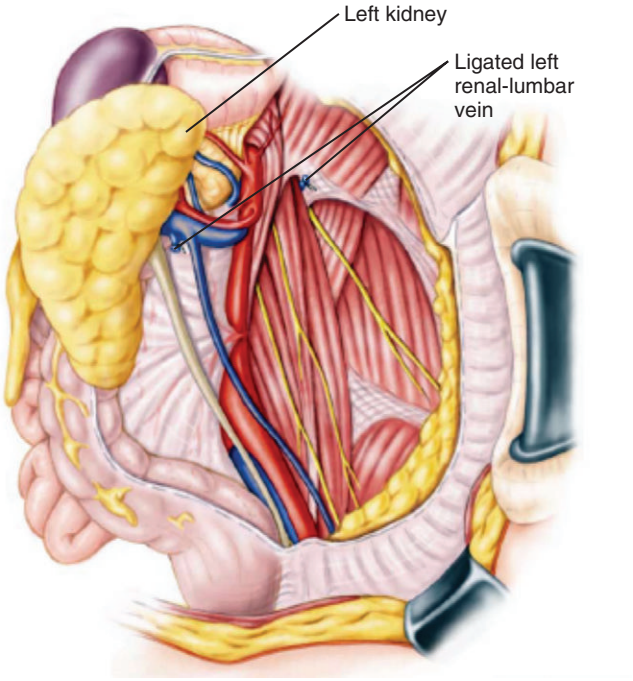

FIGURE 8 The posteriorly coursing left renal-lumbar vein is divided as it lies across the aorta. This vein is located topographically close to the left renal artery.

arteriosum is divided on the underside of the aortic arch. Care must be taken to keep the dissection directly on the aortic arch to avoid injuring the left main pulmonary artery. When degenerative aneurysm is the underlying pathology, exposure in this area is usually straightforward. However, in patients with chronic dissection, the prior inflammation from the dissecting process makes exposure more difficult. The aorta is surrounded with a vessel tape on either side of the left subclavian artery depending on the proximal extent of the aneurysm. Blunt dissection on the posterior aspect of the aorta is used to clear sufficient normal aorta to allow placement of the cross

clamp while maintaining adequate length of aorta for an accurate proximal aortic anastomosis. There are circumstances wherein proximal aortic cross clamp application is either not technically possible or is hazardous (e.g., in the case of a shaggy or highly calcified aorta). In such cases, deep hypothermic circulatory arrest (DHCA) can be used for the proximal reconstruction with resumption of brain perfusion after the anastomosis has been performed. Indeed a few champion this technique as "preferred" in TAAA surgery. However, the "majority" opinion, which we share, is that the consequences of DHCA (specifically, bleeding and lung dysfunction) are such that this method should be used only when no other technical option exists to repair the aneurysm. In fact, this has been rare in our experience. External control of the left subclavian artery is desirable but not mandatory, as intraluminal balloon control can be obtained if the aortic clamp is placed proximal to the left subclavian artery. The celiac artery and superior mesenteric artery (SMA) are controlled externally as this is required for in-line mesenteric shunting and facilitates subsequent visceral Doppler interrogation.

Next, the aortic prosthesis is prepared by attaching a 6-mm polytetrafluoroethylene (PTFE) side-arm graft that will serve as the conduit for left renal artery reconstruction. An additional side-arm graft of 10-mm Dacron (Atrium; Hudson, NH) is placed proximally to provide inflow for the in-line mesenteric shunt (Figure 10). For most aneurysms, a Dacron prosthesis is the preferred conduit. However, a PTFE conduit is used to repair mycotic aneurysms because of its decreased susceptibility to infection. At this point, the surgeon begins the clamping sequence in close cooperation with the anesthesiologist. It is important to avoid abrupt, severe increases in afterload coincident with proximal thoracic aortic cross-clamping, which can be accomplished with the judicious use of pharmacologic afterload reducing agents in anticipation of placement of the aortic clamp. Abrupt and severe increases in afterload that occur with proximal aortic cross-clamping can lead to left ventricular strain, myocardial ischemia, and an increase in CSF pressure.

If indicated, AFB is initiated by cannulation of the left atrium through a purse string suture in the left inferior pulmonary vein, and the arterial return is established via the left common femoral artery (Figure 11). Typically a single small dose of heparin is used. It is unnecessary to monitor activated clotting times, and heparin is redosed only if flow in the bypass circuit needs to be turned off for a period of time (e.g., to dissect out a prior aortic graft). Flow through the bypass circuit is such that distal mean perfusion pressures of at least 60 to 70 mm Hg are maintained; a gauge to the adequacy of the distal perfusion pressure is persistent urine output and the status of MEPs. MEPs are monitored by a dedicated neurologist who is able to address technical issues such as patient response to anesthetic agents and electrode failure. Any true deterioration in MEPs prompts either an increase in the stimulus intensity or an increase in distal perfusion pressures. If MEPs do not respond to the initial hemodynamic maneuvers, reconstruction of lumbar or intercostal vessels via an inclusion button is performed (Figure 12). Depending on TAAA extent and topography, multiple sequential clamp sites are often utilized; with "isolation" of the DTA between clamps, deterioration of MEP is rather rare. In cases using AFB, sequential clamping allows continuous renal and visceral perfusion during the creation of the proximal anastomosis.

After the establishment of AFB, the aneurysm is opened initially in the chest. When the entire descending thoracic aorta is resected,

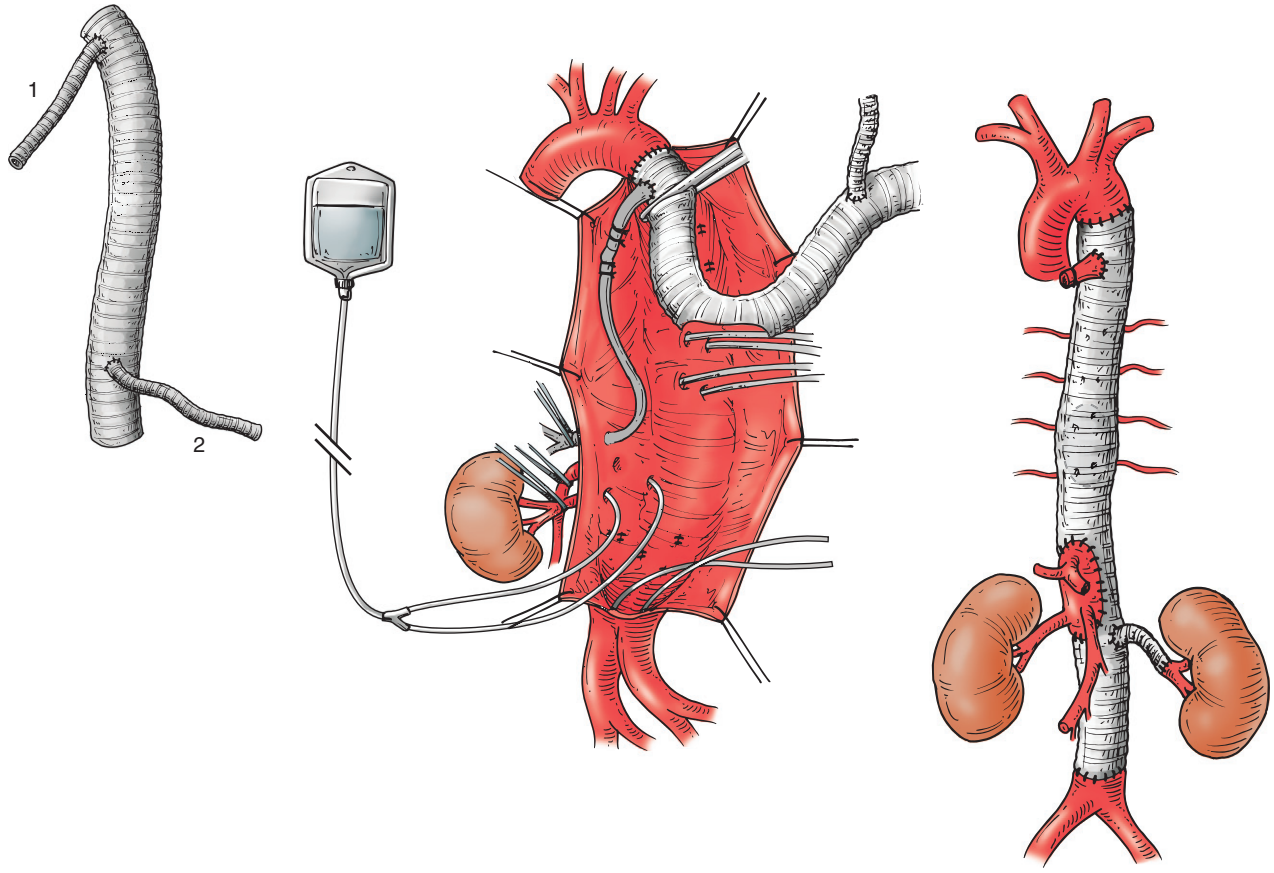

FIGURE 10 Preparation of the aortic prosthesis. A 10-mm Dacron graft *(1)* is attached proximally for in-line mesenteric shunting, and a 6-mm polytetrafluoroethylene (PTFE); *(2)* side-arm is attached for the left renal artery reconstruction. Sequential clamping allows for mesenteric perfusion during visceral reconstruction.

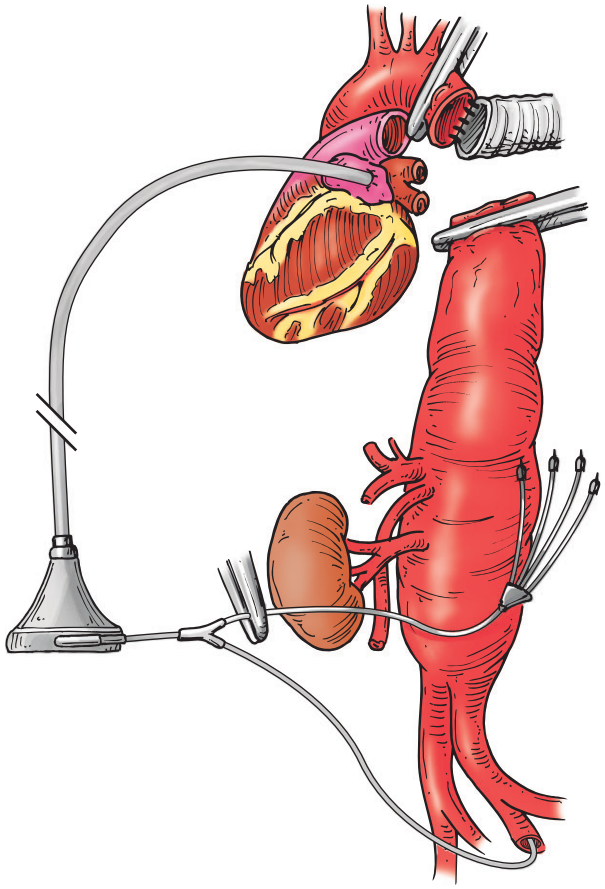

FIGURE 11 Atriofemoral bypass is initiated by cannulation of the left atrium (via the left inferior pulmonary vein), and arterial return is established vial the left common femoral artery. A Y-connector may be applied to the arterial return tubing for perfusion of visceral or intercostal arteries.

proximal intercostal vessel orifices between T_4 and T_8 are usually backbleeding profusely and are quickly oversewn. Intercostal arteries in the T_9 to L_1 aortic segment are evaluated for potential reimplantation into the main body of the graft. These vessels are controlled with intraluminal balloons to prevent backbleeding and the negative "sump" effect on net spinal cord perfusion caused by exposure of these orifices to atmospheric pressure (Figure 13). Even without deterioration in MEP, the decision to reconstruct or eventually oversew these vessels is deferred to later stages in the operation. The proximal aortic neck is prepared for reconstruction, and circumferential division of the aorta is generally preferred, and is mandatory in chronic dissection, to avoid the late complication of suture line esophageal erosion. Reinforcement of the suture line with an external Teflon felt (Bard; Murray Hill, N.J.) collar is a frequently applied adjunct.

A clamp is placed on the main aortic graft distal to the mesenteric shunt side-arm, flow is then established in the shunt, and mesenteric perfusion (typically into the SMA origin with a 20F arterial perfusion catheter) is confirmed by assessing arterial backbleeding from the other mesenteric vessel origin. The next step of the operation may be reconstruction of the intercostal vessels in the T_9 to L_1, if so indicated by deterioration of MEP, but in fact, this is uncommon. These can be reconstructed through an inclusion button anastomosis, or intercostal arteries in the region of a proximal or distal aortic anastomosis can be reconstructed using a long beveled suture line. Other methods of intercostal vessel reanastomosis include the attachment of additional short side-arm grafts to the main aortic graft, or, in cases where vessel origin is rotated superiorly and to the patient's left side, implantation to the main aortic graft using Carrel patches of aorta that contain the intercostal vessels may be feasible but can be technically clumsy (see Figure 12).

Visceral and renal artery reconstruction is carried out next. Orificial endarterectomy can be performed when significant occlusive lesions of the right renal and superior mesenteric arteries exist (Figure 14). This involves incising the diseased intima and media and developing a proper endarterectomy plane that can be verified by noting the pinkish color of the inner adventitia. While such orificial endarterectomy has been the standard method for clearing visceral vessel ostial stenoses, we have largely abandoned this in favor of direct orificial balloon-expandable stenting. This is particularly true with

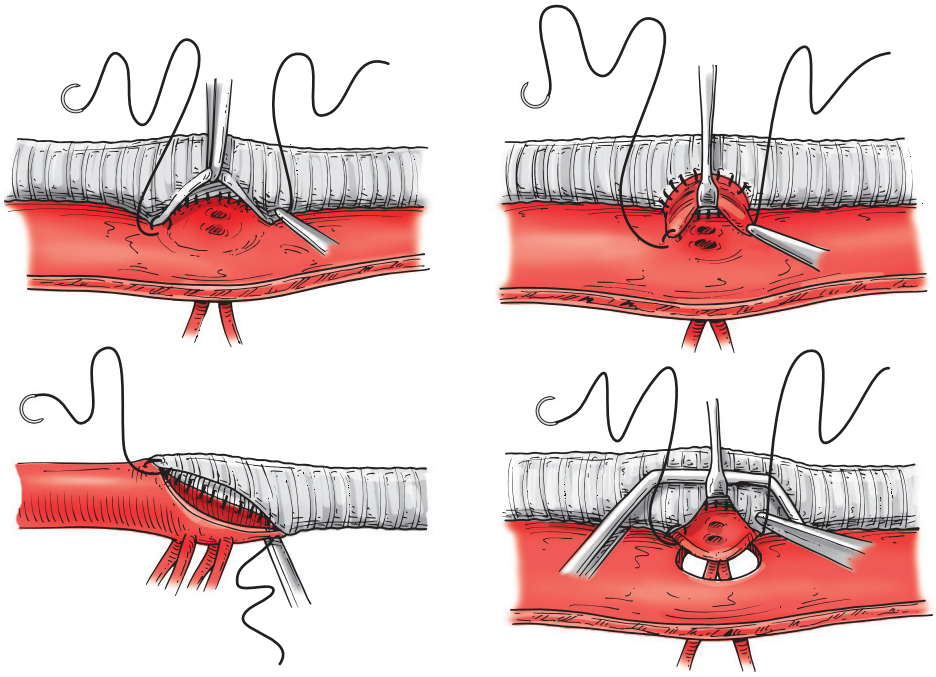

FIGURE 12 If indicated, reconstruction of lumbar or intercostal vessels may be performed via inclusion button, short side-arm graft, beveled anastomosis, or Carrel patch.

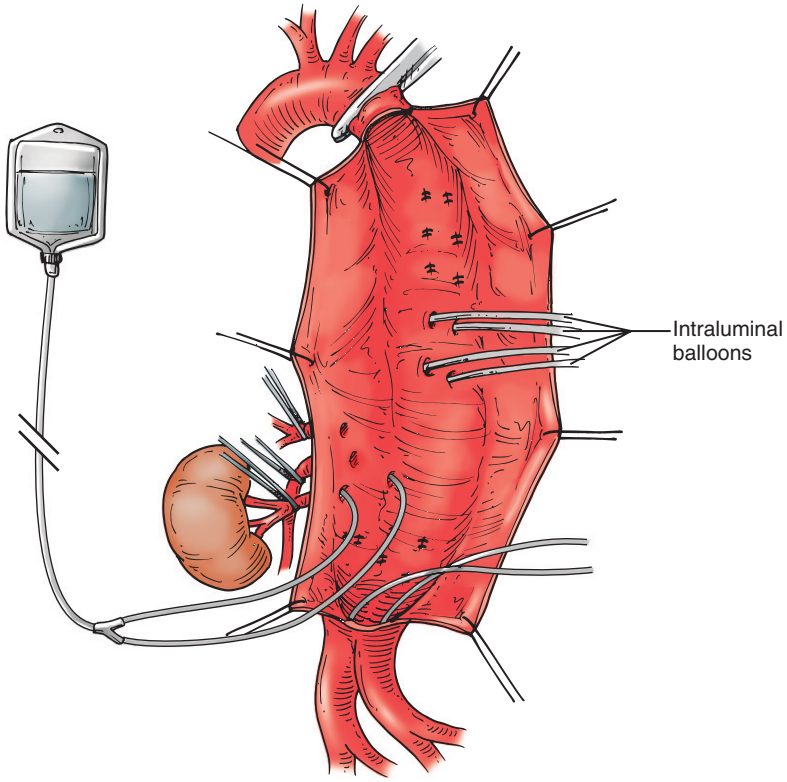

FIGURE 13 After the aneurysm is opened, back-bleeding intercostal arteries are controlled with Pruitt intraluminal balloons. *(LeMaitre Vascular, Burlington, Mass.)*

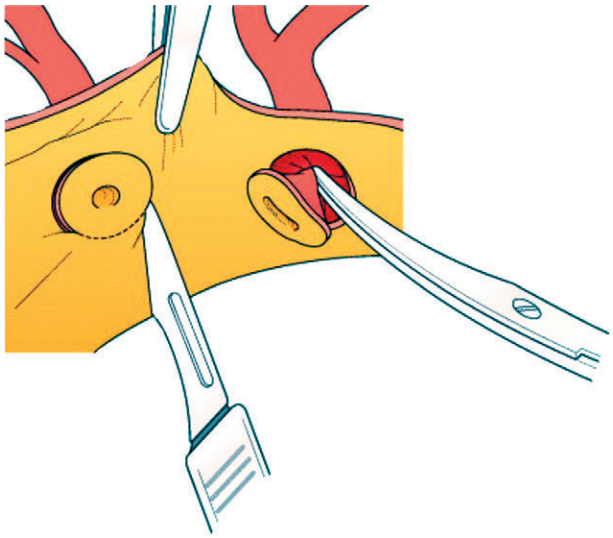

FIGURE 14 During visceral artery reconstruction, orificial endarterectomy may be performed in the setting of significant occlusive lesions.

respect to the right renal artery (see Figure 2). This method is simple, and certainly expeditious when compared with the endarterectomy; our follow-up studies have also verified its durability.

The most common method of visceral and renal artery reconstruction, especially in extent II and III TAAA, is a single inclusion button that encompasses the origins of the celiac, superior mesenteric, and right renal arteries (Figure 15). In extent I TAAA, a beveled distal anastomosis incorporating all renal/visceral vessels and the distal aorta is often possible (Figure 16); alternatively, either the celiac superiorly or the left renal artery inferiorly can be reconstructed with separate side-arm grafts. If the aneurysm is excessively large in the visceral aortic segment, the wide separation of the visceral/renal ostia may necessitate individual inclusion button anastomoses for each vessel. Alternatively, the superior mesenteric artery and right renal artery can be reimplanted as a single inclusion while reconstruction of the celiac trunk with a side-arm graft is deferred until later. The aortic graft is placed under tension, and an elliptical side island is excised from the main aortic graft. This ellipse usually begins on the lateral aspect of the graft and spirals posteriorly in the region of the right renal artery reconstruction. With the graft under tension, it is possible to complete the posterior portion of the anastomosis using single bites of the suture passing through both the aorta and the Dacron graft. Suture bites are taken close to the origin of the visceral vessels to avoid leaving excess aneurysmal aortic wall. As the posterior aspect of this suture line continues around the inferior border of the right renal artery, we exchange the 6F renal cold perfusion catheter for a 12F perfusion catheter to temporarily stent the origin of the right renal artery. The catheter is gently agitated up and down as the suture line moves around the renal artery orifice to ensure that it is not compromised by generous suture bites as they pass outside of the aorta. It is important to identify the course of the right renal artery with this indwelling catheter in order to avoid renal artery occlusion in circumstances where the right renal artery drapes over a large infrarenal component of the aneurysm (Figure 17). Just prior to completion of this suture line, backbleeding and patency of the celiac, superior mesenteric, and right renal arteries are verified, and the in-line mesenteric shunt is clamped and removed. A single flush of the proximal aortic cross-clamp is performed to ensure that no clot or debris has built up in the graft.

Reconstruction of the left renal artery is now accomplished with a separate side-arm graft of 6-mm PTFE. This provides a direct deliberate anastomosis in end-to-end fashion while allowing flexibility to deal with the spectrum of occlusive lesions, multiple renal arteries, and other wrinkles that may be encountered. It is important to orient this side-arm graft so that it will not kink when the left renal artery is returned to its anatomic position (see Figure 17). Some

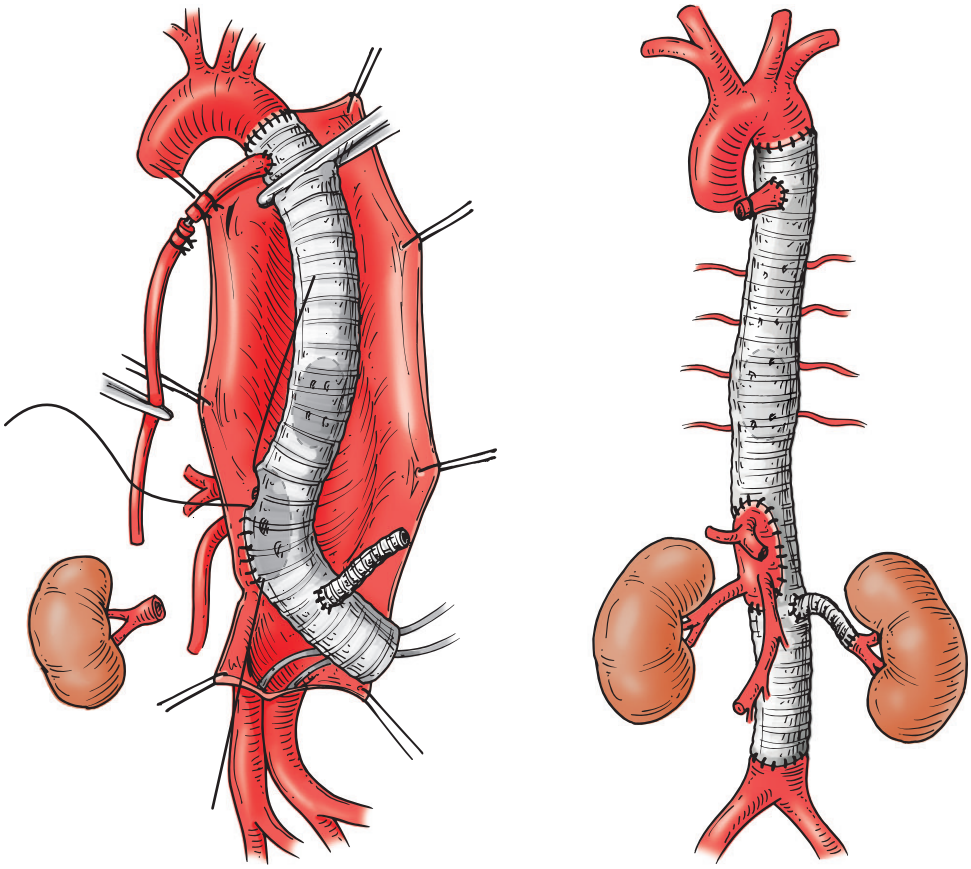

FIGURE 15 A single inclusion button is often used for efficient reconstruction of the celiac, superior mesenteric, and right renal arteries.

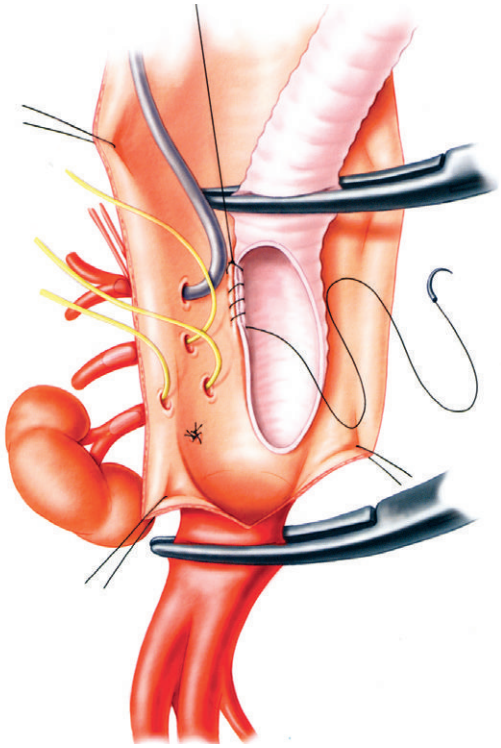

FIGURE 16 For extent I TAAA, a beveled distal anastomosis incorporating all renal and visceral vessels is often possible. As shown, the most caudal extent of the graft can often be tucked just posterior to the left renal artery origin when the aorta is not frankly aneurysmal at the renal artery level. Alternatively, the left renal caudally and/or the celiac axis superiorly can be reconstructed with separate side-arm grafts. Note in-line mesenteric shunt in celiac axis origin.

surgeons advocate the use of a single inclusion button that contains ALL renal and visceral vessels. This often requires the inclusion of too great an area of the native, aneurysmal aorta and has contributed to a so-called patch aneurysm, which has been rare in our experience.

We make every effort to perform tube type of reconstructions to the aortic bifurcation unless there is gross aneurysmal disease of the proximal common iliac arteries. After reestablishment of flow to the lower extremities and verification of adequate lower extremity perfusion by intraoperative pulse volume recordings, Doppler signals in the left renal, celiac, and superior mesenteric vessels are checked in addition to palpation of the superior mesenteric artery pulse in the root of the mesentery. A final verification of MEP is made; in rare cases, a deferred intercostal reconstruction is performed at that time. Hemostasis will usually be adequate at this point but protamine and infusions of platelets and fresh frozen plasma are typically increased at this point in the operation when a final check for hemostasis is made. Careful inspection of the inferior aspect of the aneurysm sac in both the chest and abdomen is necessary to detect backbleeding lumbar and/or intercostal vessels, which can be a source of significant postoperative hemorrhage. The redundant aneurysm sac is then sutured securely over the aortic prosthesis in the abdomen and the chest. The left kidney is returned to its anatomic position, and perinephric fat suffices to provide adequate coverage of the aortic graft in the region of the visceral aortic segment. Prior to closure, renal artery reconstructions are interrogated one final time. Closure of extensive incisions typically takes close to an hour, and two teams are utilized.

Outcomes

Treatment results as reported in the literature can be misleading; grouping patients at wide variance for complication risk leads to

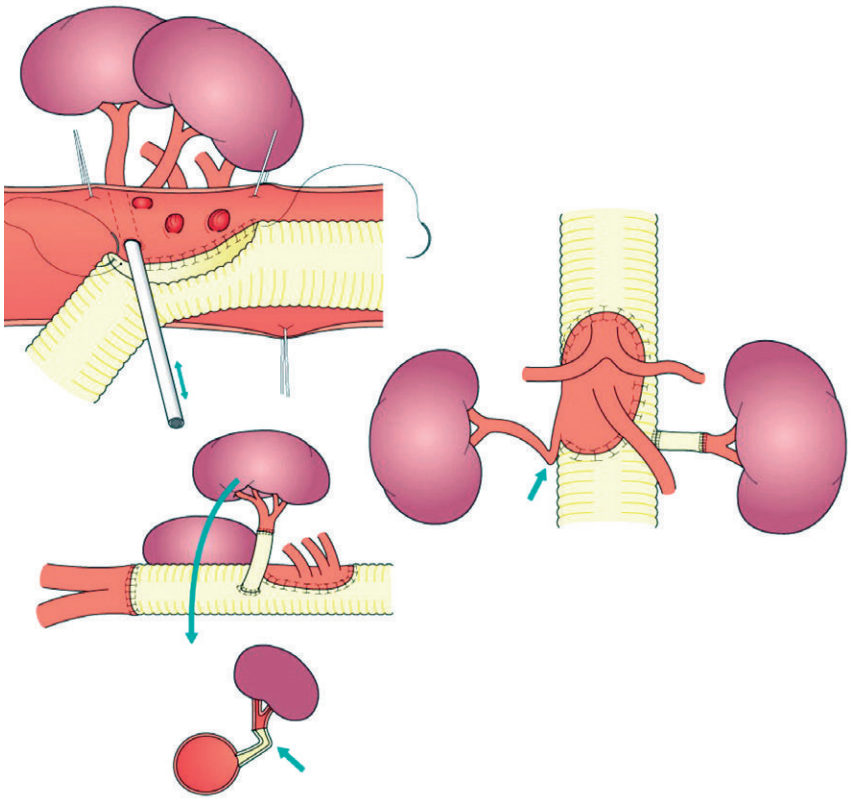

FIGURE 17 During reconstruction of the right renal artery (*top left*), a 12F perfusion catheter is used to temporarily stent the origin of the vessel. As the suture line courses around the inferior and caudal end of the right renal artery ostium, the 12F perfusion catheter is agitated to direct the operator to the course of the artery outside the aneurysm (see *Operative Technique*). This prevents the suture line from impinging or occluding the right renal artery outside the aneurysm. *Bottom left:* The orientation of the left renal artery side-arm graft is critical; it must not kink as the left kidney is returned to its anatomic position.

imprecision. For example, it is axiomatic that SCI risk is highest in extent II TAAA, whereas we and others have reported considerably reduced morbidity and mortality for type IV TAAA repair.

A review of our experience with open repair of extent IV TAAA included 179 patients, 87% of whose surgeries were completed in an elective setting. Thirty-day mortality was 2.8%, and any degree of spinal cord injury occurred in 2.2%. Five-year survival was 62% plus or minus 4%. Results of multivariate analysis showed only preoperative renal insufficiency was associated with mortality or major complications.

The initial review of our experience with the use of AFB/MEP in the repair of extent I-III TAAA demonstrated improved results, when compared with our own institutional historical controls, most of whom were treated with a clamp-and-sew technique and epidural cooling for spinal cord protection. After propensity-score matching, the 30-day mortality in the AFB/MEP group was not significantly different (2% vs 5%; $P = 0.38$), but none of those patients treated in the AFB/MEP group suffered postoperative paraplegia (vs 5% in the clamp-and-sew [CS] group). The composite death/paraplegia rate was decreased from 9% (CS) to 2% (AFB/MEP) ($P = 0.01$).

In the recent update of our experience, the impact of atriofemoral bypass with MEP, over a standard CS technique was evaluated in a retrospective, risk-adjusted series of patients undergoing extent I-III TAAA repair. One hundred patients undergoing TAAA repair with AFB/MEP were compared with 385 patients undergoing repair with the CS technique. There was no difference in the rate of intraoperative death (MEP = 1.0% vs CS = 0.5%; $P = 0.50$), length of intensive care unit stay (MEP = 9.6 ± 8.6 days vs CS = 9.5 ± 12.3 days; $P = 0.95$), or length of hospital stay (AFB/MEP = 19.9 ± 12.6 days vs CS = 21.6 ± 23.5 days; $P = 0.49$). However, the composite outcome of perioperative death and paraplegia rate was lower in the AFB/MEP cohort (7% vs 19%; $P = 0.004$). The multivariate model for predictors of this composite outcome showed that AFB/MEP was protective (OR = 0.39 [0.17, 0.9]; $P = 0.028$). Long-term (4-year) survival was improved in the AFB/MEP group as well (73 ± 6% vs 60 ± 3%; $P = 0.004$).

It has become almost fashionable to emphasize, perhaps unduly, the morbidity of and recovery from open surgical repair. Indeed, one California administrative database study reported an overall mortality of 19% one year after operation and suggested that reporting perioperative outcomes considerably understated the negative potential of surgical repair. Alternatively, we have consistently reported late outcomes in terms of both survival and functional status. These studies indicate late survival in our cohort either equates or is superior to that seen after AAA repair, indicating that the resource commitment to bring these patients through operation is indeed justified. Furthermore, permanent loss of functional status has been a rare outcome after operation.

ENDOVASCULAR SURGICAL MANAGEMENT

Stent graft repair in the thoracic aorta (thoracic endovascular aorta repair [TEVAR]) bears many comparisons with the parallel experience of such repair in the abdominal aorta, but there are important technical, anatomic, and pathologic distinctions between the two technologies. First, the significantly increased morbidity of open surgical repair in the thoracic aorta, as compared with open AAA repair, solidified the important clinical need for TEVAR. With respect to design and engineering considerations, thoracic devices are proportionately larger and thus require larger bore delivery devices when compared with those of endovascular aorta repair (EVAR). Furthermore, unless the surgeon is treating pathology in the relatively straight portion of the descending aorta, considerations of engineering, accuracy of deployment, and the like are a constant when TEVAR needs to involve the aortic arch. Indeed, overall results of TEVAR, including the potential for complications such as stroke, are highly

dependent on the proximal extent or proximal seal zone applicable in any individual case. As shown in Figure 18, a widely promulgated classification scheme stratifying the proximal seal zone is readily correlated with procedural complexity, the need for debranching, or even trans-sternal approaches, and the risk of neurologic complications, in particular, stroke. The other important distinction when compared with EVAR is that TEVAR, to date, has been applied to the spectrum of thoracic aortic pathologies beyond degenerative aneurysm and including entities such as traumatic aortic tear and acute/chronic aortic dissection.

After a series of industry-sponsored studies focusing on degenerative aneurysm, commercial applicability of a TEVAR device dates only since mid-2005. Thereafter, rapid adoption of TEVAR across the spectrum of thoracic aortic pathologies occurred. We previously reported this phenomenon in an examination of thoracic aortic repair in Medicare beneficiaries during the interval 2004 to 2007 (Table 1). Not only was there a rapid shift from open repair to TEVAR, but across the spectrum of pathologies, this transition was accompanied by significantly reduced perioperative mortality.

TEVAR (Figure 19) offers the benefit of aortic repair without the physiologic insult associated with thoracotomy and clamping of the proximal aorta. The success of TEVAR is predicated on obtaining quality aortic imaging, careful patient selection, and appropriate preprocedural planning.

Similar to endovascular AAA repair, there are several anatomic barriers to thoracic stent grafting. First and foremost, the proximal and distal seal zones should be at least 15 mm in length to ensure an adequate fixation and seal. Conventional thoracic stent graft landing zones are depicted in Figure 18; ideally the seal zone is achieved in the area from zone 2 to zone 4. Additionally, the delivery systems for thoracic endografts are larger than their abdominal counterparts. In the presence of extensively calcified or narrow iliac arteries, a prosthetic conduit sewn to the common iliac artery or aorta may be required for successful device delivery and should be planned in advance.

Outcomes

Clinical results after TEVAR for degenerative aneurysm were initially available in the form of European registry studies. Data from 249 patients undergoing endovascular repair for degenerative thoracic aneurysms in the European EUROSTAR and the United Kingdom Thoracic Endograft registries (prospectively gathered databases of aortic pathology) showed a 30-day mortality of 5.3% and paraplegia rate of 4% with an 80% one-year survival.

In North America, three industry-sponsored multicenter trials were conducted to assess the efficacy of TEVAR as compared with open surgical repair for degenerative aneurysm of the descending thoracic aorta, where anatomy was potentially amenable to repair with either open repair or TEVAR. None of these studies were randomized, and in fact, their value was somewhat diluted by the irreconcilable limitations of retrospective control groups. Nonetheless, as displayed in Table 2, the summary results from these three industry-sponsored trials allow comparison of some 500 patients treated with TEVAR, as opposed to 350 who underwent open surgical repair for isolated aneurysm of the descending thoracic aorta. The overall results strongly favor TEVAR with respect to significantly reduced perioperative mortality and SCI complications. It is worth emphasizing the fact that these trials were conducted at either

TAAA, Thoracoabdominal aortic aneurysm; *TEVAR,* thoracic endovascular aorta repair.

major academic medical centers or high-volume thoracic aortic centers. Stated differently, both the open and endovascular operations were, in general, performed by very experienced, expert surgeons. Accordingly, the favorable comparative results with TEVAR versus open operation have created the milieu where, in the eyes of most surgeons, a descending thoracic degenerative aneurysm whose anatomy is amenable to TEVAR is generally treated with this endovascular approach. Certainly, our posture is consistent with this general trend.

Recently, we compiled our own experience with 105 patients undergoing thoracic aortic stent-grafting and compared the results with those of 93 patients treated with open surgery during the same time period. Despite borderline statistical significance, the operative mortality was halved in the stent graft group when compared with the open surgery group (7.6% vs 15.1%; $P = 0.09$). While a 7.6% mortality lies in the lower end of reported rates for thoracic endografts, which have been as high as 20%, it is substantially higher than that of our updated experience with 873 infrarenal AAA endovascular repairs (1.8%) and may be related to the fact that 30% of the endograft patients were not considered candidates for open surgery. The spinal cord ischemia rate was 6.7% in our stent graft population with two patients experiencing transient paraparesis that resolved after discharge. These results are similar to those of other multicenter trials that reported spinal cord ischemia rates of 3%. In addition, available reviews suggest that 8% to 43% of landing sites in DTAAs will not allow an appropriate 15-mm length for secure proximal fixation. Indeed, in 20% of our patients, the left subclavian artery was intentionally covered (11.5% underwent preprocedural subclavian artery bypass). The 4-year survival for this group was 54% and freedom from reintervention rate was 81%. Similarly, the celiac axis may be covered, in some cases, in order to achieve an adequate distal seal zone. It is generally agreed that coverage of the celiac axis is acceptable as long as there is a large SMA and patent gastroduodenal artery that can collaterize the celiac branches.

As endovascular repair has become more widely used for ruptured AAA, thoracic stent grafting may have an analogous role in ruptured DTAAs. A recent prospective series of 59 patients undergoing endovascular thoracic stent grafting using the Gore TAG device for descending thoracic aortic catastrophes included 20 patients with ruptured thoracic aortic aneurysms. The 30-day mortality was 15%, which is nearly one half the mortality rate for open repair of ruptured aneurysms cited in the literature from centers of excellence and nearly one third the mortality rate based on data from the National Inpatient Sample. Twenty-five percent of patients had a device-related event, which included one graft infection and three endoleaks. The 1-year actuarial survival was 37%, which largely reflects the advanced age and multiple comorbidities in this group of patients.

ALTERNATIVE APPROACHES

Prior to commercial availability of TEVAR in 2005, open operation was the only technical option for most TAAAs. Thereafter, arch and/or visceral debranching with subsequent TEVAR enabled a hybrid surgical approach to many patients. Indeed, early proponents of this technique often cited unsatisfactory results with open repairs as the rationale. As intuitively expected, the reported results vary widely as a function of the patient cohorts. We applied this method to a group of some 25 patients deemed unsuitable for conventional repair and showed that hybrid repair is not without significant morbidity and mortality. In addition to a mortality rate of 21.7% (trending toward two times that for open repair at our institution), hybrid repairs presented new concerns, including a 10% rate of visceral bypass graft thrombosis. Looking specifically at renal artery bypass, grafts performed during hybrid procedures had a significantly higher rate of thrombosis (19%) as compared with those done for open repairs (1.6%). In a series of 252 patients undergoing thoracic stent graft procedures, one group reported that a debranching procedure was an independent risk factor for late mortality overall and specifically in the subgroup of asymptomatic patients. Hybrid procedures may be appropriate for certain high-risk groups, but the morbidity and mortality associated with visceral debranching is not insignificant. Corroborative data are available from the North American Registry; Oderich and colleagues reviewed results with hybrid operation in 208 patients with extent I-IV TAAA and noted a 14% mortality and a 10% rate of paraplegia.

For DTAAs extending into the visceral aorta, branched and fenestrated stent grafts may provide novel options for previously excluded anatomy. Many of the initial fenestrated trials have focused on juxtarenal AAA and type IV TAAAs. It is logical to assume that total endovascular repair will be an important advance in the treatment of TAAA, just as has occurred with DTAA. However, the technology has been slow in advancing. Fenestrated grafts are custom designed stent grafts with three types of fenestrations (small, large, and scalloped) through which visceral artery stents are placed, thus preserving the patency of the artery (Figure 20). The French multicenter trial of the Cook fenestrated stent graft involved 80 patients in whom 237 visceral arteries were perfused through fenestrations. During follow-up (which ranged from 1 to 38 months with a mean of 10 months), there were no ruptures and no open conversions. Ten percent of patients required secondary procedures to correct endoleaks or to treat threatened visceral vessels. Most of these patients however did not have true TAAA.

In the United States, although slow to evolve from an engineering and regulatory perspective, total endovascular repair of extensive TAAA is on the horizon. Yet the scant available information from the true experts advancing this technology indicates overall outcomes have still not equaled those of open repair with spinal cord protection strategies. Greenberg and colleagues reported a series of 633 patients undergoing endovascular repair of TAAA or juxtarenal abdominal aortic aneurysms. In that cohort, 188 patients underwent repair of extent I-III TAAA. Of that subset of patients, the 30-day mortality was 5.9%, and the 4-year survival was estimated to be 59%.

A direct comparison by Greenberg and colleagues of open and endovascular outcomes for TAAA was reported in 2008. That series reported a borderline improvement in spinal cord ischemia rates for those undergoing endovascular repair. It is noteworthy, however, that there was a significant difference in the extent of aneurysms between the groups, with more extent IV aneurysms found in the endovascular group. Nonetheless, the incidence of spinal cord ischemia for those with extent I-III TAAA in the endovascular group was 10%.

A parallel series outlining the experience of Chuter's group, reported early and intermediate results of endovascular TAAA repair in 81 patients. There were zero extent I aneurysms in this series, and 40 patients with extent II and III disease. The overall mortality in that study was 6.2%. Permanent paraplegia occurred in three patients

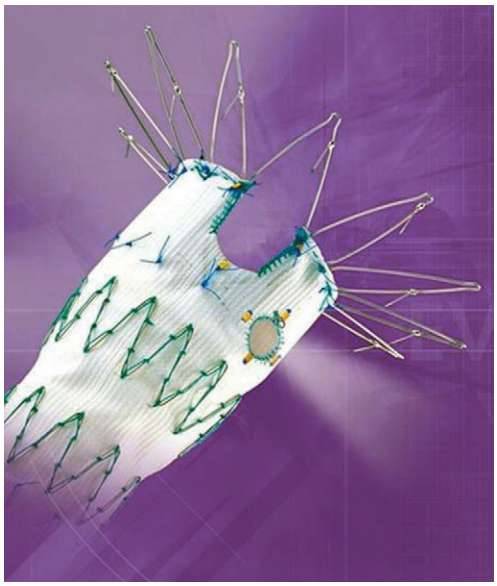

FIGURE 20 Fenestrated stent grafts employ fenestrations and scallops to preserve patency of branch vessels.

(3.7%), and transient paraplegia/paraparesis occurred in 16 patients (19.8%). Sixteen branches occluded (nine renal, two celiac) or developed stenoses (four renal, one superior mesenteric artery), requiring stenting. Multicenter trials evaluating the role of branched totally endovascular repair for TAAA will soon be underway.

The Management of Acute Aortic Dissections

Karen M. Kim, MD, and
Thomas E. MacGillivray, MD

OVERVIEW

Acute aortic dissection is the most common catastrophe of the human aorta. With a reported incidence of 3 out of 100,000 patients each year, aortic dissections are a deadly disease with an early mortality of 1% to 2% per hour. Without appropriate treatment, the 2-week mortality of aortic dissections involving the ascending aorta is approximately 90%. While the presentation may be classic, symptoms can be nonspecific and can occur in patients with no evident risk factors. Misdiagnosis leading to even a slight delay in treatment is associated with increased mortality. Therefore, proper diagnosis and expeditious therapy are essential for improved survival.

CLASSIFICATION

Acute aortic dissection can manifest in several different patterns, which have different therapeutic and prognostic implications. There are two classification schemes in use worldwide to describe aortic dissection: the DeBakey and Stanford systems (Figure 1). The DeBakey system categorizes the dissection based on the origin of the intimal tear and the extent of the dissection. Aortic dissections involving the ascending and descending aortas and the aortic arch are DeBakey type I. Dissections confined only to the ascending aorta are DeBakey type II. Aortic dissections that originate and propagate distal to the left subclavian artery are DeBakey type III (IIIa is limited to the descending thoracic aorta, whereas IIIb extends below the diaphragm).

The Stanford classification system divides dissections into two categories: those that involve the ascending aorta (proximal to the innominate artery) and those that do not. Stanford A dissections include all dissections involving the ascending aorta (DeBakey types I and II) regardless of the site of origin. Stanford B dissections describe dissections not involving the ascending aorta, including those involving the aortic arch.

"Acute" dissections are those present for 14 days or less, whereas "chronic" dissections describe those present for more than 2 weeks. Acute Stanford A dissections account for more than 60% of all dissections and are considered to be surgical emergencies requiring immediate operation. Acute Stanford B dissections are further classified as "complicated" or "uncomplicated." Complicated Stanford B dissections include approximately 20% of patients with rupture or impending rupture, malperfusion, and/or refractory pain or hypertension for whom open surgical or endovascular therapy is recommended. Uncomplicated Stanford B dissections are managed effectively with aggressive medical therapy.

Intramural hematoma (IMH) represents approximately 10% to 20% of patients who present with the clinical picture of acute aortic dissection but, on imaging, have no blood flow in the false lumen or any identifiable intimal lesions. It is sometimes inappropriately referred to as a dissection with a thrombosed false lumen. IMH may result from a microscopic intimal tear, hemorrhage of the vasa vasorum, or a penetrating aortic ulcer. Although it is a matter of discussion and debate, the authors manage IMH the same way as acute aortic dissection.

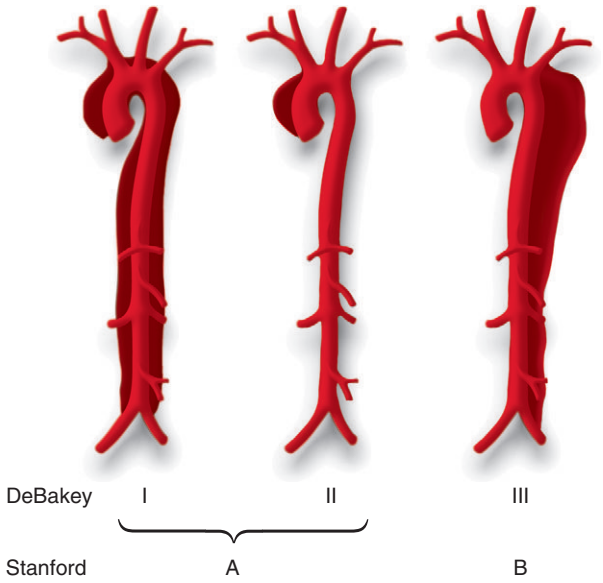

FIGURE 1 Anatomy and classification of aortic dissection: DeBakey and Stanford systems. *(Modified from Cambria RP, Brewster DC, Gertler J, et al: Vascular complications associated with spontaneous aortic dissection,* J Vasc Surg *7(2):199-209, 1988.)*

PRESENTATION AND DIAGNOSIS

An acute aortic dissection results from a sudden aortic intimal disruption, which leads to the pressurized propagation of blood flow plowing through the false lumen within the media of the aorta. Circulatory collapse and death can occur within seconds as a result of aortic rupture frequently misdiagnosed as a massive myocardial infarction. The classic presentation is acute, severe, "10/10," "tearing," or "ripping" chest pain radiating to the back between the scapulae. Occasionally, patients will present with little or no pain. Afflicted patients often appear listless and possess a sense of impending doom.

Because blood flow in the false lumen can disrupt and occlude branching vessels of the aorta, patients can present with symptoms and signs of malperfusion. A new neurologic deficit or a pulseless extremity can distract the unsuspecting clinician, who may be focusing on just the tip of the iceberg. Electrocardiographic changes or a new diastolic murmur can occur from retrograde dissection into the coronary arteries or the aortic valve which may result in myocardial ischemia or congestive heart failure. Acute paralysis, abdominal pain, renal insufficiency, and syncope are all well-recognized atypical presentations of acute dissection. Difficult-to-control hypertension can be a risk factor and a presenting sign in patients with aortic dissection. Hypotension and shock are concerning signs of tamponade, cardiac dysfunction, or ongoing hemorrhage. A high index of suspicion for aortic dissection is imperative for any patient with asymmetric pulses or differential blood pressures in the extremities.

High-resolution contrast-enhanced computed tomographic angiography (CTA) has replaced conventional aortography as the gold standard diagnostic study to confirm or exclude the diagnosis of acute aortic dissection. CTA has a diagnostic sensitivity and specificity of 90% to 100% and is readily available in most hospitals. False positive diagnoses can occur because of artifactual lines resulting from mistiming of contrast boluses or inappropriate gating with the cardiac cycle. Although scans limited to the thoracic aorta can confirm the diagnosis, it is helpful to scan the entire aorta and iliofemoral vessels to assess for subclinical malperfusion and to assist in planning the surgical strategy.

Transesophageal echocardiography (TEE) is a valuable tool used to diagnose and manage patients with acute aortic dissection. Although TEE requires special expertise, it can rapidly assess for tamponade, valvular dysfunction, and cardiac wall motion abnormalities, particularly in the hemodynamically unstable patient transported directly to the operating room. Magnetic resonance imaging, conventional aortography, and coronary angiography have a very limited role in the acute management of patients with aortic dissection.

MANAGEMENT

Once the diagnosis of acute aortic dissection is suspected, invasive hemodynamic monitoring and aggressive antiimpulse therapy should be instituted without delay. A radial or femoral arterial monitoring cannula should be placed in the extremity with the best pulse and blood pressure. Intravenous beta-blockade should be the medication of first choice to decrease the aortic dP/dT by titrating the infusion to a goal heart rate of 60 to 70 beats per minute and a systolic blood pressure of 100 to 110 mm Hg. Once adequate beta-blockade has been achieved, vasodilators can be added to further control hypertension. Initial blood pressure control with vasodilators like nitroprusside or hydralazine should be avoided. Although vasodilators will lower the blood pressure, they can increase the dP/dT and shear forces in the aorta, thereby increasing the risk of rupture. Acute Stanford A dissection patients with a diastolic murmur or TEE evidence of significant aortic valve regurgitation should not be managed with beta-blockers because of the high risk of exacerbating congestive heart failure.

Acute aortic dissection can be a very dynamic disease with a rapidly evolving clinical course. Patients diagnosed with acute type A aortic dissection should be emergently transferred to a cardiac surgical center for immediate surgical repair. Time is critical. Unnecessary testing or optimizing medical therapy should not be allowed to delay definitive treatment, which is surgery. Even patients with cerebral, renal, visceral, and/or extremity malperfusion should be managed with central aortic reconstruction as a first step, which will frequently correct the malperfusion syndrome. Although nonoperative management carries a very high risk of death, good clinical judgment always has an important role in the management of patients at very high risk.

SURGICAL MANAGEMENT OF STANFORD A DISSECTIONS

The goal of surgical therapy for patients with acute type A aortic dissection is to prevent imminent death from exsanguination or tamponade due to aortic rupture, acute aortic insufficiency, or malperfusion to the coronary, cerebral, and systemic circulations. The primary technique to accomplish these goals is to replace the ascending aorta with a tube interposition graft, thereby reestablishing flow in the true lumen of the aorta.

Invasive arterial and central venous pressure monitoring are helpful in the induction and conduct of general anesthesia. Temperature monitoring of the nasopharynx, central venous or pulmonary arterial blood, and bladder can ensure uniform perfusion and cooling. TEE, electroencephalogram, and cerebral oximetry are useful adjuncts for monitoring.

Cardiopulmonary bypass is required, so the surgeon must determine the site of arterial perfusion. Traditionally, the common femoral artery has been the most common approach for arterial cannulation given its size, easy accessibility, and surgeons' familiarity. In recent years, experienced aortic surgeons have been using the right axillary/subclavian artery as the preferred site for arterial perfusion. The arterial cannula can be connected to an 8-mm to 10-mm Dacron graft that is anastomosed in end-to-side fashion to the axillary artery. This approach allows for antegrade systemic perfusion and the option of

selective antegrade cerebral perfusion during circulatory arrest should extensive arch reconstruction be required. Some experienced surgeons advocate the use of direct central ascending aortic cannulation with the use of TEE guidance. This approach can be challenging, but central aortic cannulation can be lifesaving in the management of an unstable patient.

Through a median sternotomy, the heart and ascending aorta are readily exposed. The right atrium is cannulated easily for venous drainage to initiate cardiopulmonary bypass. Most aortic surgeons recommend deep hypothermia in preparation for an open distal aortic anastomosis. During cooling, it is imperative that the surgical, anesthesia, and perfusion teams monitor the patient to ensure uniform perfusion and cooling. Occasionally, cannulation strategies must be altered to manage malperfusion during cardiopulmonary bypass. Given the increased frequency of aortic insufficiency and coronary malperfusion, the surgeon should be prepared to vent the left ventricle on bypass and meticulously protect the myocardium with direct antegrade coronary ostial and retrograde coronary sinus cardioplegia strategies.

Although there is considerable debate about the optimal temperature for profound hypothermia and circulatory arrest, the author achieves 18° C in the nasopharynx before turning off the circulation. With the patient in reverse Trendelenburg position, the entire ascending aorta from the sinotubular junction up to the innominate artery is resected. The aortic tissues are extremely fragile, and they should be delicately handled. Without an aortic cross clamp, the aortic arch can be inspected for complex intimal disruptions and to confirm that the brachiocephalic branches are intact and arising from the true lumen. All of the layers of the proximal aortic arch are then reconstructed, obliterating the false lumen to allow flow through the true lumen once central perfusion has been reestablished. Some surgeons reconstitute the aortic wall between two felt strips and anastomose a Dacron graft to the aortic-felt sandwich (Figure 2, *A*). The author prefers to sew the Dacron graft to the aortic wall buttressed with a strip of Dacron around the adventitia. The use of glues during these operations. Although glues allow for easier tissue handling, they can be destructive to the aorta and promote late pseudoaneurysm formation.

With the distal anastomosis completed, the aortic arch is de-aired, the proximal end of the graft is clamped, and cardiopulmonary bypass is resumed through the Dacron graft to promote true lumen flow (see Figures 2,*B* and 2,*C*). Generally, aortic arch replacement is not routinely necessary for managing most patients with acute type A aortic dissection. Arch replacement increases the complexity and length of the procedure, which can add to the already high-risk operation. Situations when the aortic arch should be considered for

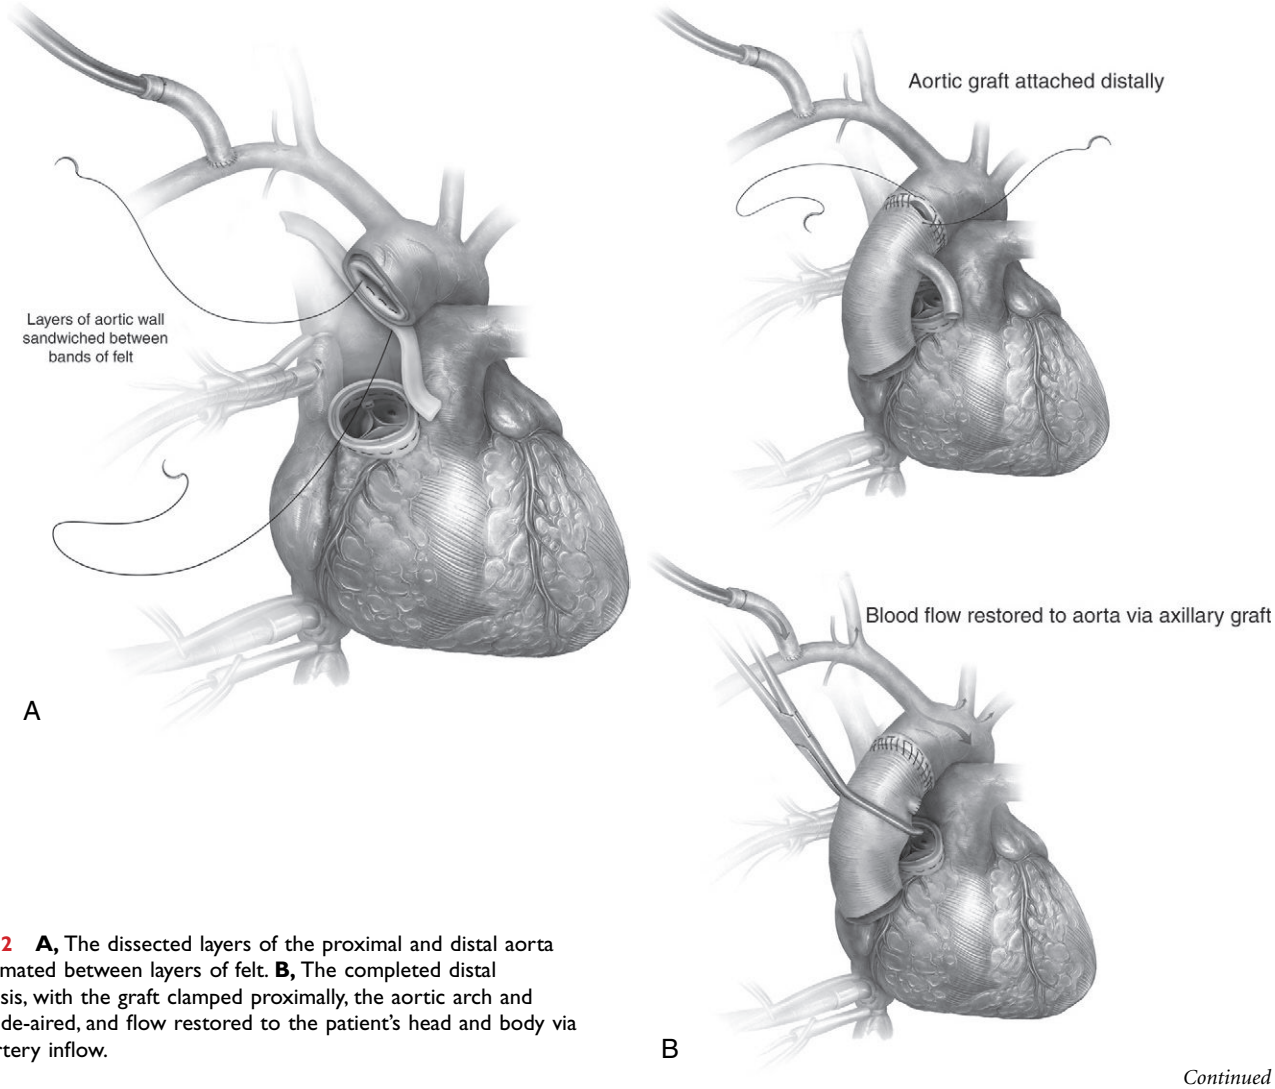

FIGURE 2 **A,** The dissected layers of the proximal and distal aorta reapproximated between layers of felt. **B,** The completed distal anastomosis, with the graft clamped proximally, the aortic arch and branches de-aired, and flow restored to the patient's head and body via axillary artery inflow.

Continued

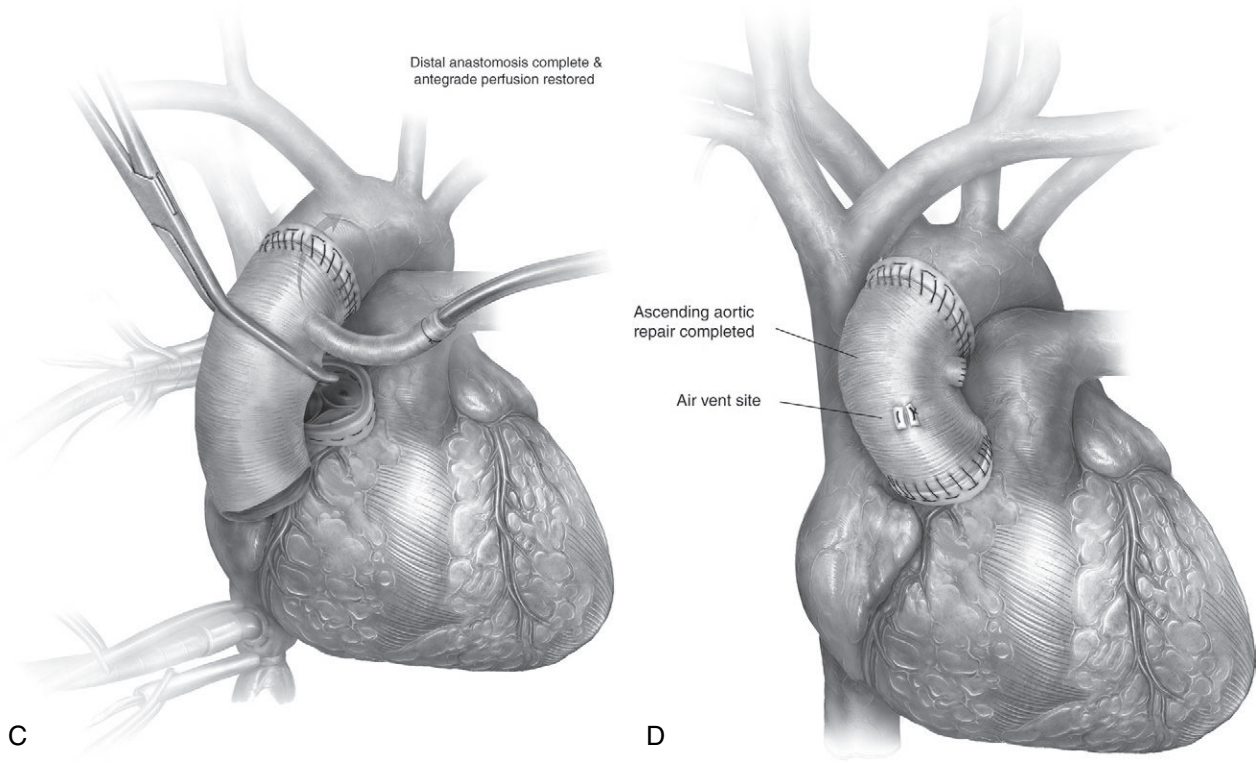

FIGURE 2, cont'd **C,** Distal reperfusion reinitiated through a side-arm of the ascending graft. **D,** The completed procedure, with the dissected ascending aorta removed, the valve resuspended, all air evacuated from the left circulation, and the patient decannulated. *(From Bolman RM 3rd: Acute type A aortic dissection,* Oper Tech Thorac Cardiovasc Surg *14(2):124-135, 2009.)*

replacement in patients with acute dissection include when there are complex intimal disruptions in the arch, arch aneurysms larger than 5 cm, or connective tissue syndromes (e.g., Marfan, Loeys-Dietz, Ehlers-Danlos). Arch replacements should be performed with the use of selective antegrade cerebral perfusion, which has been demonstrated to improve outcomes.

During rewarming, the aortic root and proximal ascending aorta are assessed and reconstructed (see Figure 2,*D*). Often, the aortic root is minimally involved with the dissection, and the sinotubular junction can be reconstructed in a similar sandwich-type fashion as the distal anastomosis. Attention is required when operating on patients who present with aortic regurgitation and in those who have complex aortic root dissections approaching the coronary ostia. Aortic regurgitation is the most common cardiac complication associated with acute type A dissection. There are three possible dissection-related mechanisms that can contribute to aortic regurgitation. Acute dilation of the sinotubular junction and root caused by the expanding false lumen can result in incomplete coaptation of the valve cusps. The dissection can also extend into the aortic root, disrupting the commissural posts and resulting in prolapse of the valve cusps. Additionally, an aortic flap can itself prolapse through the valve in diastole, thereby preventing appropriate valve function. In most patients, the sinotubular junction can be reconstructed, the aortic valve commissures resuspended, and the aortic root left alone. Situations when composite aortic root replacement with coronary button reimplantation should be considered include when patients have aneurysms of the aortic root exceeding 5 cm, complex aortic valve pathology, dissection approaching the coronary ostia, or connective tissue syndromes (e.g., Marfan, Loeys-Dietz, Ehlers-Danlos). Valve-sparing aortic root replacement should be reserved for highly experienced aortic surgeons in this setting.

SURGICAL RESULTS WITH ACUTE TYPE A DISSECTIONS

According to the International Registry of Acute Aortic Dissection (IRAD) database, the overall surgical mortality of acute type A aortic dissection is 25%. In unstable patients (preoperative presence of tamponade, shock, congestive heart failure, stroke, coma, myocardial ischemia/infarction, acute renal failure, or mesenteric ischemia), the surgical mortality is 31%. Postoperatively, patients with aortic dissection are at risk for coagulopathic bleeding requiring transfusions and reexploration. Transient neurologic dysfunction, stroke, renal insufficiency, acute lung injury, new malperfusion syndromes, multiorgan system failure, and refractory hypertension are some of the possible early postoperative complications requiring intensive care and prolonged hospital care of these complicated patients. There is variability of outcomes reported from different centers, but the fact remains that acute type A aortic dissection is a highly lethal condition which, even when appropriately managed, has a high risk of morbidity and mortality.

MANAGEMENT OF ACUTE TYPE B DISSECTIONS

Medical management of patients who have uncomplicated type B dissections with antiimpulse therapy remains the preferred treatment, resulting in reported in-hospital mortality rates of less than 10%. Historically, the results of open surgical therapy for patients with acute type B dissection have been associated with a higher

mortality rate than medical therapy, perhaps due to patient selection or complications requiring surgery. For patients with complicated type B dissections, thoracic endovascular aortic repair (TEVAR) has largely replaced open surgery and has improved results. Whether TEVAR proves to be superior to medical management in high-risk patients with uncomplicated type B dissection remains to be proven.

Carotid Endarterectomy

Robert J. Beaulieu, MD, and
Christopher J. Abularrage, MD, FACS

OVERVIEW

Stroke was the third most common cause of death in the United States in 2010, with an estimated annual cost of $73.7 billion. Approximately 800,000 strokes occur every year, with up to 35% of strokes causing death or severe disability. Extracranial carotid disease represents the most common preventable cause of ischemic stroke. Thus, carotid endarterectomy (CEA), since it was first performed by DeBakey in 1954, occupies a prominent position in stroke prevention.

CLINICAL PRESENTATION

Clinical Status

Clinical status and degree of stenosis are the two most important factors in determination of the appropriate treatment for patients with known carotid disease. Clinical status, determined by the presence or lack of symptoms, confers differing degrees of future stroke risk. Indeed, most patients with carotid disease are completely asymptomatic. This group of patients is frequently identified with an asymptomatic carotid bruit or with screening duplex ultrasound scan. The finding of a carotid bruit, however, is insensitive as only 30% to 50% of patients have high-grade carotid stenosis. Moreover, only 20% to 50% of patients with carotid stenosis have a bruit. Thus, anatomic imaging is imperative to confirm the diagnosis of carotid stenosis in patients with a carotid bruit.

Symptomatic clinical status is defined by temporary or permanent neurologic deficit as a result of an ischemic, embolic event. Although only a small minority of patients has symptoms, the events can often have devastating consequences. Temporary ischemic events include amaurosis fugax, transient ischemic attack (TIA), and reversible ischemic neurologic deficit (RIND). Amaurosis fugax involves monocular blindness from temporary occlusion of the ophthalmic artery. Patients frequently report a shade coming down over the eye. TIA is a temporary interruption in normal neurologic function that resolves within 24 hours (80% resolve within 2 hours). TIA is characterized by temporary numbness, paresthesia, paralysis, or difficulty with speech. RINDs are similar to TIA except they last between 24 and 48 hours. Finally, symptoms of a stroke last beyond 24 hours and are most often permanent.

In determination of a patient's symptomatic status, other causes of stroke, such as cardiac thrombus, endocarditis, and intracranial cerebrovascular disease, are important to rule out. Also imperative is confirmation that a patient's symptoms are referable to the anatomic finding of carotid stenosis because the threshold for performing a CEA would be different. Symptoms of amaurosis must be ipsilateral to a carotid stenosis, and symptoms from TIA, RIND, or stroke are typically contralateral.

Imaging Studies

Carotid duplex ultrasound scan is currently the imaging modality of choice in evaluation of carotid artery disease. It allows for the evaluation of both anatomy (B-mode analysis) and flow-velocity patterns (duplex mode or spectral analysis) for determination of the degree of stenosis (Figure 1). When compared with catheter angiography, duplex ultrasound scan is more than 90% accurate. Duplex ultrasound scan is operator dependent, and frequent comparisons with measurements on the basis of catheter angiography are necessary for quality assurance.

Other noninvasive means of providing anatomic data beyond duplex scan include computed tomographic angiography (CTA) and magnetic resonance angiography (MRA). CTA can be performed in an expeditious manner and provides data on the aortic arch, common carotid artery, tortuosity, and unusual lesion anatomy. MRA, similarly, defines lesion anatomy and has the added benefit of helping with determination of cerebral infarction in the early hours after a stroke. As many as 10% of asymptomatic patients and 30% of symptomatic patients have evidence of cerebral infarct on magnetic resonance imaging (MRI) or computed tomographic scan. MRA can be limited by the fact that it may overestimate degree of stenosis, especially in the absence of intravenous contrast.

Catheter angiography is the gold standard for determination of degree of stenosis and is defined as: % stenosis = [1 − minimal residual lumen/normal distal cervical internal carotid artery diameter] × 100 (Figure 2). Angiography, however, is associated with a 1% to 2% risk of stroke and is now most often used in cases of concerns about vascular anatomy or when noninvasive tests are discordant.

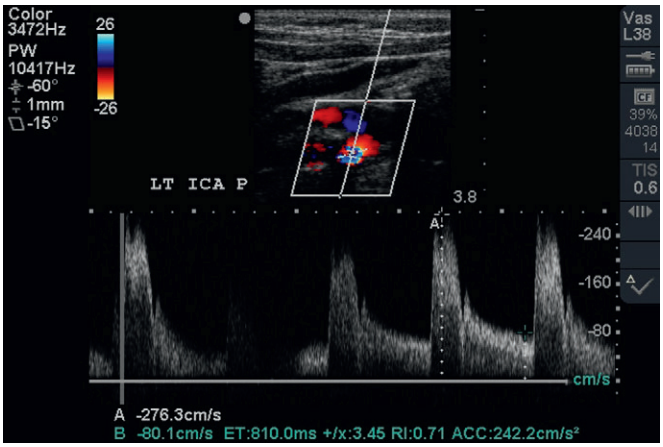

FIGURE 1 Preoperative duplex ultrasound scan shows increased velocities at the area of a high-grade carotid stenosis.

FIGURE 2 Preoperative angiogram shows a high-grade carotid stenosis with normal distal internal carotid artery.

INDICATIONS

Carotid endarterectomy is one of the best studied peripheral vascular surgical operations, with indications based on multiple randomized trials (Table 1). The Asymptomatic Carotid Atherosclerosis Study (ACAS) trial randomized asymptomatic patients with more than 60% stenosis to CEA and medical management versus medical management alone. The 5-year stroke rate among patients managed with surgery was 5.1% compared with 11% for those undergoing medical management alone, which accounted for an absolute ipsilateral stroke risk reduction of 5.9% and a relative risk reduction of more than 50%. The Asymptomatic Carotid Surgery Trial (ACST) confirmed these findings with an absolute any stroke risk reduction of 5.4% and a relative risk reduction of 46%. One should note that best medical management in these studies was antiplatelet therapy alone as the studies were performed before the statin era. Comparisons of antiplatelet therapy and statins with surgery have not been performed.

The estimated 5-year incidence rate of stroke among patients who have had a TIA is 35% to 45%. Several large center trials have explored the benefit of surgically treating this patient population. The North American Symptomatic Carotid Endarterectomy Trial (NASCET) compared surgery and medical management with best medical management alone in symptomatic patients with carotid stenosis. Patients treated with best medical management were shown to a have 2-year cumulative risk of ipsilateral stroke of 26%, whereas patients treated with surgery had a 9% risk, a 17% absolute risk reduction. In those with moderate stenosis (50% to 69%), a decrease was seen in the 5-year ipsilateral risk of stroke from 22.2% to 15.7%. The European Carotid Surgery Trial (ECST) further confirmed these results with an absolute ipsilateral stroke risk reduction of 13.8%.

Current recommendations from the Society for Vascular Surgery (SVS) recommend CEA and best medical management for the treatment of asymptomatic disease with carotid stenosis greater than 60% and symptomatic disease with greater than 50% stenosis. A joint statement from the SVS and the American Heart Association released updated recommendations for 2011 to further clarify these standards. Currently, high-level evidence recommends CEA for the symptomatic patients (TIA or nondisabling ischemic stroke) with more than 50% stenosis within 6 months of symptoms provided the anticipated rate of perioperative stroke or mortality is less than 6%. According to the American Association of Neurological Surgeons and the American Stroke Association, treatment with CEA within 2 weeks of presentation for acute stroke is reasonable and appropriate. For asymptomatic patients, CEA for stenosis greater than 60% is recommended as long as the perioperative risk of stroke and death is less than 3%.

TABLE 1: Randomized trials comparing carotid endarterectomy with medical management of carotid stenosis

Trial	Stenosis indication	Medical stroke risk	Surgical stroke risk	Risk reduction	Time period
Asymptomatic					
ACAS	≥60%	11.0%	5.1%	5.9%	5 y

Carotid Endarterectomy Versus Carotid Stenting

As the technique of carotid artery stenting (CAS) becomes more widespread, comparison of the outcomes with the gold standard of endarterectomy is important. CAS was initially used for patients with high-risk medical or anatomic criteria; however, it is now being applied to those with both symptomatic and asymptomatic disease.

Although multiple trials have examined the outcomes of CAS, perhaps the most accepted study is the Carotid Revascularization Endarterectomy Versus Stenting Trial (CREST) trial. This trial encompassed a group of 2502 symptomatic and asymptomatic patients. The periprocedural stroke rate was higher in the CAS group (4.1% vs 2.3%; $P = 0.01$); however, the periprocedural myocardial infarction rate was higher in the CEA group (2.3% vs 1.1%; $P = 0.03$). After this period, the ipsilateral stroke rate was similar between the CAS and CEA groups (2.0% and 2.4%, respectively; $P = 0.85$). In comparison of symptomatic and asymptomatic patients, the difference in the periprocedural stroke rate was accounted for by the symptomatic group. With examination of the 4-year study period outcomes, however, a trend was found towards an increased risk of stroke in the asymptomatic patients ($P = 0.07$) but not in the symptomatic patients ($P = 0.25$). Although decisions must be made on an individual basis and newer stent technologies could bring differing results, these data are a reminder that CEA remains the gold standard for treatment of carotid occlusive disease.

CAROTID ENDARTERECTOMY: OPERATIVE TECHNIQUE

Preoperative Medical Regimen

Optimization of the medical management of patients with carotid disease is essential to reduce risk of perioperative stroke. Before surgery, all patients should be placed on antiplatelet therapy with aspirin or clopidogrel. The dosing of aspirin therapy has been extensively examined, and clear evidence exists that 81 mg or 325 mg daily is an appropriate dose, with no additional benefit (and possible increased risk) with an increase to 650 or 1300 mg daily. Perioperative clopidogrel use results in decreased number of observed embolic events with transcranial Doppler scan in patients undergoing CEA, a surrogate measure that correlates with the risk of stroke. Clopidogrel is not associated with an increased risk of perioperative bleeding, and dual perioperative antiplatelet therapy may be associated with a decreased risk of stroke compared with single antiplatelet therapy.

Statin therapy has also been shown to benefit patients with carotid disease both before and after surgery. The author's institution has shown a lower rate of cerebrovascular symptoms among patients with known carotid disease presenting for CEA. Further, among 1600 patients undergoing CEA in a large series, statin use decreased the 30-day risk of stroke and TIA, and mortality. The protective effects of statin therapy appear largely related to its pleiotropic arterial effects rather than the lipid-lowering effects; therefore, all patients should be started and subsequently continued on statin therapy regardless of serum lipid profile. On hospital discharge, antiplatelet and statin therapies are continued long term in the patient for CEA.

Dextran has been used for its antiplatelet effects during carotid endarterectomy. A dextran-40 drip can be started just before clamping of the internal carotid artery at a rate of 5 to 10 mL per hour and continued in the immediate postoperative period. Although dextran therapy was common years ago, more recent evidence suggests that it may be associated with an increased risk of congestive heart failure and other perioperative complications without decreasing the risk of stroke.

Anesthesia

CEA may be performed with a variety of anesthetic methods, including general, regional, and local anesthesia. Selection of anesthetic method requires consideration of several factors. General anesthesia provides a secure airway in a patient asleep, which allows the surgeon to operate without the patient having undue anxiety. Despite suggestion from early reports that patients undergoing CEA with general anesthesia need longer hospital lengths of stay, current evidence does not show a significant difference compared with patients undergoing CEA with regional anesthesia. Many reports have shown improved cardiac stability in patients undergoing CEA with regional anesthesia, but evidence does not support a subsequent reduction in the incidence of myocardial infarction compared with general anesthesia. Regional anesthesia may be inappropriate in the anxious patient who is unlikely to tolerate the necessary surgical positioning and technique. Among regional anesthesia techniques (deep versus superficial or intermediate blocks), equal efficacy appears to exist in analgesia; however, regional anesthesia with deep block is associated with a significantly higher rate of conversion to general anesthesia, with approximately 2% of patients needing conversion. One proposed benefit among regional or local methods versus general anesthesia may be in regards to selective shunting (see subsequent discussion). The author's current practice is to perform CEA with general anesthesia unless the patient has excessive cardiac risk and is not a candidate for carotid stenting.

Patient Positioning

Appropriate patient positioning is fundamental to achieve adequate exposure and reduce risks of complications, including loss of orientation, hyperextension injury, and unnecessary extension of skin incision. The patient is placed in the supine position at the edge of the bed on the operative side, and a roll is placed behind the scapula to achieve some hyperextension of the neck (Figure 3). A padded ring is placed under the head to prevent neck injury from extreme

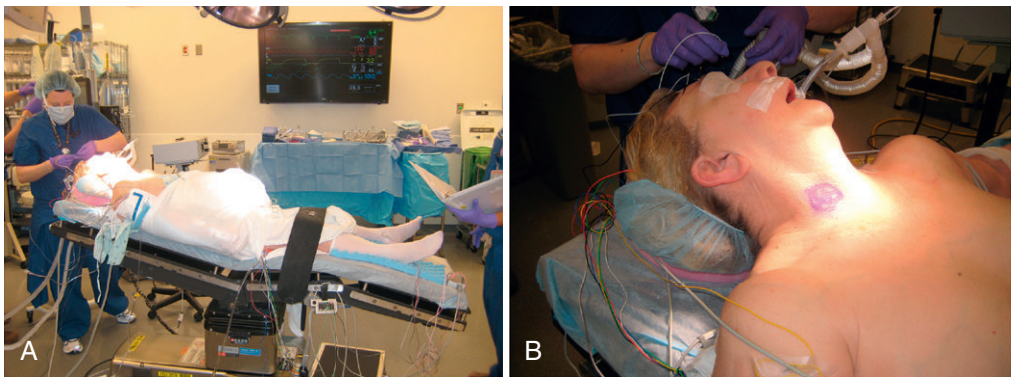

FIGURE 3 **A,** The patient is positioned supine on the operating room table in the "beach-chair" position. **B,** The patient's neck is then extended and turned to the contralateral side to assist with exposure. Note the electroencephalogram electrodes and wires placed for selective shunting and draped away from the operative field.

hyperextension. If local or regional anesthesia is used, a Mayo stand is placed over the patient's head so that the surgical drapes may be suspended away from the patient's face in an effort to prevent sensations of claustrophobia. With general anesthesia, the endotracheal tube is secured to the corner of the mouth opposite the side of the operative field. Nasotracheal intubation may be necessary for a high lesion or a high bifurcation. The operating table is then adjusted to the "beach chair" position, with a moderate amount of reverse Trendelenburg's position to decompress the venous system. The prepped area should be from the base of the earlobe and the mastoid process down to the sternal notch.

Skin Incision

The standard incision for CEA is a longitudinal incision parallel to the medial border of the sternocleidomastoid muscle. If the preoperative evaluation indicates the need for more cephalad exposure above the angle of the jaw, the upper portion of the incision is angled posterior to the earlobe in an effort to avoid the parotid gland. Improved cosmesis may be obtained from a transverse incision placed within a skin crease 1 to 2 cm inferior to the angle of the jaw. However, difficulty with exposure may be encountered if this incision is made in an improper location. Proper location can often be determined with identification of the location of the carotid bifurcation on preoperative imaging and the transverse incision made over this point.

Operative Technique

Fundamental principles of good surgical technique are paramount to a successful CEA. Obscuration of vital structures of the neck with unintentional bleeding can result in injury and disastrous consequences. The dissection begins with division of the platysma and mobilization of the medial border of the sternocleidomastoid muscle with electrocautery. Care should be taken to avoid severing the external jugular vein, which runs immediately deep to the platysma, in the event that it is needed for patching. Dissection through a transverse skin incision is more likely to encounter the external jugular than it is through a longitudinal incision. The greater auricular nerve exits at the lateral border of the sternocleidomastoid muscle and heads towards the ear. Transection of this nerve in the superoposterior aspect of the wound results in a cutaneous sensory deficit of the earlobe.

Once the sternocleidomastoid muscle is retracted laterally, the carotid sheath is then entered. The internal jugular vein is identified and dissected along its entire medial length. The facial vein commonly serves as a landmark for the carotid bifurcation and is identified medially crossing the base of the wound. Division of the facial vein allows lateral retraction of the internal jugular vein. At this point, the vagus nerve should be identified in its typical course running between the carotid artery and internal jugular vein. An important consideration is that the vagus nerve may be located anterior to the common carotid artery (CCA) in approximately 5% of patients. The patient is then given 80 U/kg of heparin. An activated clotting time (ACT) is maintained at 200 to 250 seconds.

Circumferential control is obtained around the CCA with an umbilical tape and Rummel tourniquet (Figure 4). The ansa cervicalis can then be identified running medial to the distal CCA. Preservation of the ansa is not necessary, but it may be useful to track it superiorly to its junction with the hypoglossal nerve in an effort to identify the hypoglossal, which crosses medially from a superior to inferior location.

Sharp dissection is continued along the anterior aspect of the CCA to its bifurcation. Manipulation of the carotid artery should be minimized in this region to reduce the risk of intraoperative embolization. The carotid bulb may be injected with 1% lidocaine to anesthetize the carotid body and reduce hemodynamic instability. The superior thyroid artery is typically the first branch of the external carotid artery (ECA). It is identified coming off the medial border of the carotid bifurcation or proximal ECA and is controlled with a vessel loop in Potts fashion. The ECA is dissected and encircled with a vessel loop.

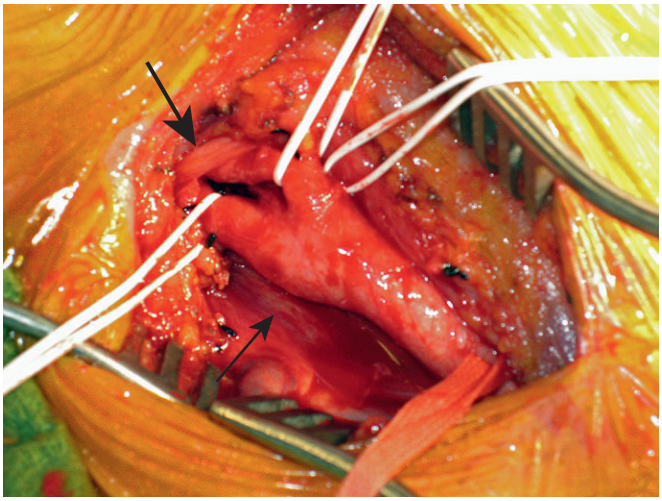

FIGURE 4 Intraoperative exposure of the carotid bifurcation. The common carotid artery is encircled with an umbilical tape, and the internal carotid, external carotid, and superior thyroid arteries are encircled with vessel loops. Care is taken to identify and avoid the vagus nerve *(small arrow)* and the hypoglossal nerve *(large arrow)*.

As sharp dissection is continued along the internal carotid artery (ICA), it is imperative to ensure the ICA is controlled beyond the distal extent of disease process. This may require ligation of small crossing veins, ligation of the occipital artery, or working superior to the hypoglossal nerve. Once superior to the plaque, the ICA is encircled with a vessel loop.

The superior thyroid is controlled with the vessel loop, and the ICA is clamped first to prevent distal embolization during clamping of subsequent vessels. As with vessel loop placement, the clamp must be placed beyond the distal aspect of carotid plaque to reduce the risk of embolization or incomplete endarterectomy. The CCA and ECA are subsequently clamped. A longitudinal arteriotomy is made with an 11 or 15 blade and extended with Potts scissors from normal CCA to normal ICA.

At that point, a determination must be made whether to shunt. The type of shunt used is based on surgeon preference, but it should be opened and available if necessary. The author prefers to use the Argyle shunts (Covidien, Mansfield, Mass) because they can be sized to the ICA (Figure 5). The shunt, when needed, is first placed in the distal ICA and allowed to back bleed. The proximal end is then placed into the CCA. Certain surgeons choose to shunt all patients; however, the author prefers selective shunting to reduce the small risk of stroke or ICA dissection associated with shunt insertion. If local or regional anesthesia is used on a patient, a decrease in hemispheric or global neurologic function signifies poor cerebral perfusion that necessitates shunting. With general anesthesia, electroencephalogram (EEG) monitoring can be used to identify cerebral ischemia. A 50% decrease in fast background activity, an increase in delta wave activity, and a complete loss of EEG signals constitute the criteria for shunting. Patients with a recent stroke, TIA, or amaurosis are routinely shunted to avoid cerebral hypoperfusion of at risk regions.

Less common methods for cerebral monitoring include carotid stump pressure measurement and cerebral oxygen saturation. Carotid stump pressure measurement is performed after clamps are placed on both the ECA and the CCA, with the ICA remaining patent. A needle is connected to a pressure line and inserted into the distal CCA

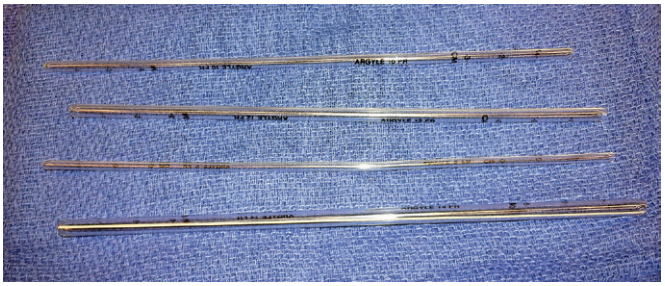

FIGURE 5 Argyle shunts (Covidien, Mansfield, Mass) come in different sizes that can be matched to the internal carotid artery.

below the carotid bifurcation. A stump pressure of 50 mm Hg is used as a threshold for shunting. Stump pressure measurements are limited by the risk for embolization with clamping of the CCA or insertion of the needle, and watershed cerebral hypoperfusion despite adequate pressures. Cerebral oxygen saturation is measured with near-infrared spectroscopy probes placed before surgery on the patient's right and left forehead. An ipsilateral baseline cerebral oxygen saturation less than 55% or a decrease of greater than 15% with clamping is predictive of ischemia requiring shunting. Although this technique is associated with a 94% specificity, sensitivity is only 68%, resulting in unnecessary shunt placement in certain patients.

The endarterectomy is begun with a Freer or Penfield elevator in the plane between the media and adventitia, starting within the mid plaque (Figure 6). Once an endpoint in the distal CCA is established, the plaque is transected. The endarterectomy is then continued up into the ICA. At the endpoint of the plaque, it can either be flared across the ICA by pulling the plaque off transversely or transected with Iris scissors. Either way, a smooth transition from endarterectomized surface to normal intima is mandatory to prevent embolization or dissection with reperfusion. Gentle injection of saline solution onto the surface may reveal an intimal flap that must be remedied with further endarterectomy or 7-0 polypropylene tacking sutures. Tacking sutures should be avoided unless absolutely necessary because these are potentially thrombogenic and may increase the risk of perioperative stroke. The endarterectomy is continued back towards the ECA. The ECA clamp is removed, and the remainder of the plaque is endarterectomized in eversion fashion. Once the endarterectomy is complete, a Schnidt or pediatric intestinal clamp is passed up into the external carotid artery to remove any remaining debris. The endarterectomized surface is then carefully inspected, and all residual fragments of intima and media are removed with DeBakey forceps.

The current body of literature supports closure of the arteriotomy with a patch because it is associated with a decreased rate of restenosis compared with primary closure. A variety of patch materials are available, including autologous vein, polytetrafluoroethylene (PTFE), woven polyester (Dacron; Atrium Medical Corporation, Hudson, N.H.), and bovine pericardium (Figure 7). Recent comparisons of closure methods report no difference in perioperative bleeding, infection, or pseudoaneurysm formation between patch materials, and surgeons may therefore use the material with which he or she is most proficient. Autogenous vein or bovine pericardium should be used in infected fields.

At that point, antegrade and retrograde flushing maneuvers should be performed. If a shunt was used, it is removed before final closure of the artery and back bleeding from the ICA can occur to clear debris created with shunt manipulation. The arteriotomy is then closed, and the clamp on the ICA is briefly released to fill the vessel with blood. It is then replaced while the clamps on the CCA and ECA are released. This directs any remaining debris or air up the ECA before reperfusion of the ICA. Finally, the ICA clamp is removed.

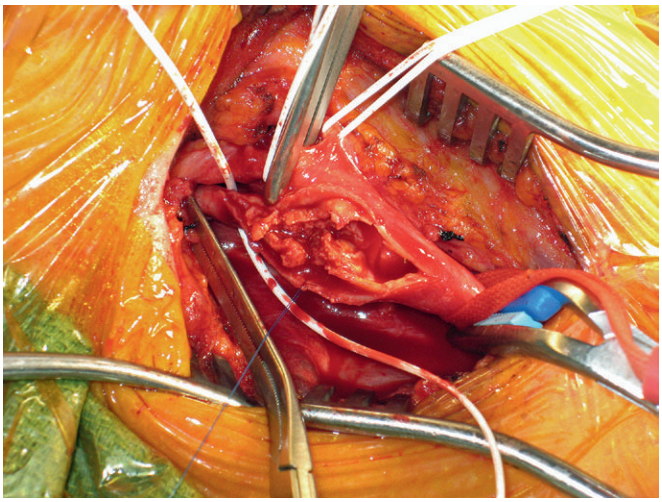

FIGURE 6 Intraoperative photograph shows the plaque within the carotid artery.

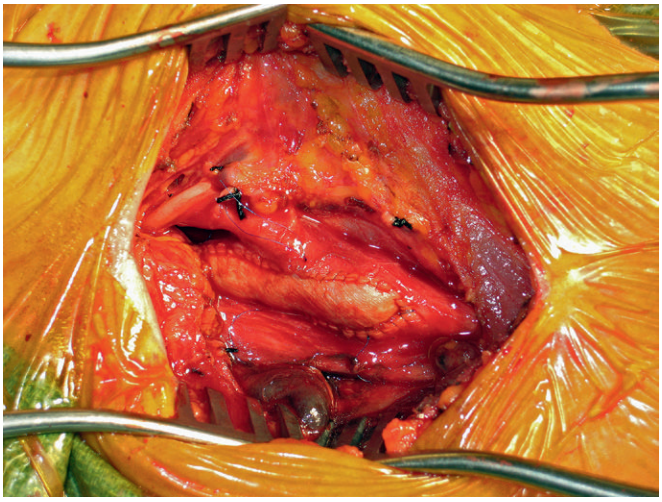

FIGURE 7 Completion intraoperative photograph shows the bovine pericardial patch sewn with 6-0 polypropylene sutures in running fashion.

Eversion Endarterectomy

Eversion endarterectomy is an alternative technique for carotid revascularization. Exposure of the carotid artery is performed in a similar manner to the previous description. It is technically difficult to shunt, and the authors therefore advocate performing a test clamp of the ICA before committing to this technique. If there is no indication of cerebral ischemia and no need for shunting, one may proceed with the eversion technique. If the patient does need shunting, the author falls back on the conventional endarterectomy with patch technique.

For performance of eversion, the ICA is obliquely transected at its origin and everted. The plaque is pulled away from the rolled back adventitia until the distal limit is exposed and is then transected. The ECA/CCA is then endarterectomized. The ICA is then reanastomosed to the carotid bifurcation with running 6-0 polypropylene suture. Advantages of eversion endarterectomy include a shorter clamp time, no lengthening of the ICA, and no need for patching. Disadvantages include the difficulty in shunting. Eversion endarterectomy has also been purported to have lower restenosis rates; however, a recent systematic review of the literature showed no

difference in stroke or clinically significant restenosis rates. Surgeons should use the technique most familiar to them to decrease the risk of perioperative stroke.

Completion Studies

Among the several potential etiologies of stroke in patients undergoing CEA, thromboembolism and carotid artery thrombosis from inadvertent technical error remain preventable. The most common intraoperative completion studies, including handheld continuous Doppler scan, duplex ultrasound scan, and intraoperative angiography, have all been used to mitigate this risk.

Handheld continuous Doppler scan evaluation can be rapidly used to assess for areas of high turbulence and velocity changes in the repair. However, it is highly operator dependent and less sensitive than duplex ultrasound scan, especially to small intimal flaps and subtle stenoses. Duplex ultrasound scan is a sensitive tool that provides both anatomic imaging and real-time physiologic information regarding blood flow through the endarterectomy repair. Both duplex ultrasound scan and intraoperative angiography are equally sensitive in detecting "major" technical defects. However, duplex ultrasound scan has been shown to be more sensitive in detecting "minor" flaws (87% vs 59%).

Although the author regularly performs completion duplex ultrasound scan, an interesting note is that certain studies have not found completion imaging to decrease the risk of perioperative stroke but rather to only decrease the rate of restenosis. Moreover, no consensus exists as to criteria for reexploration. Most studies agree that "minor" technical abnormalities should be left alone because of a significant association between intraoperative revision and perioperative stroke. "Major" abnormalities may need to be addressed. These may include a peak systolic velocity in the ICA greater than 125 cm/s, an ICA/CCA velocity ratio greater than 2.0, spectral broadening throughout systole, a B-mode flap in the ICA 2 mm, or any other obvious major anatomic problem, such as a severe kink or intravascular thrombus.

Unexpected Intraoperative Findings of the Internal Carotid Artery

High Carotid Bifurcation

Occasionally one encounters a high carotid bifurcation or a superiorly ending plaque that necessitates further cephalad exposure of the internal carotid artery. When it is anticipated before surgery, nasotracheal intubation is the simplest maneuver to gain better exposure. This leaves the mouth closed and obtains a few extra centimeters. Preoperative anterior subluxation of the mandible by an otolaryngologist also provides superior exposure. For more exposure once the operation has started, the hypoglossal nerve can be dissected out, which allows the surgeon to work on both sides of it. One must be careful not to cause traction injury when doing so. Ligation and division of the occipital artery may also afford the surgeon a bit more working room. Division of the digastric muscle is the next step to gain exposure; however, care must be taken to avoid the hypoglossal nerve, which frequently lies directly posterior to the muscle belly. If the aforementioned maneuvers are insufficient, assistance should be obtained from an otolaryngologist in performing resection of the styloid process.

Hypoplastic Internal Carotid Artery

Severe stenosis of the internal carotid artery may lead to the findings of a small ICA distal to the lesion. This can result from one of two things: either the artery is normal but underfilled because of poor perfusion pressure, or the artery itself is hypoplastic (Figure 8). A normal artery should look normal on the outside. If one suspects a hypoplastic artery, however, an on-table angiogram can be performed. If the hypoplasia extends to the skull base, then anticoagulation therapy is indicated. If the artery has already been opened, then one should proceed with ligation with postoperative anticoagulation therapy.

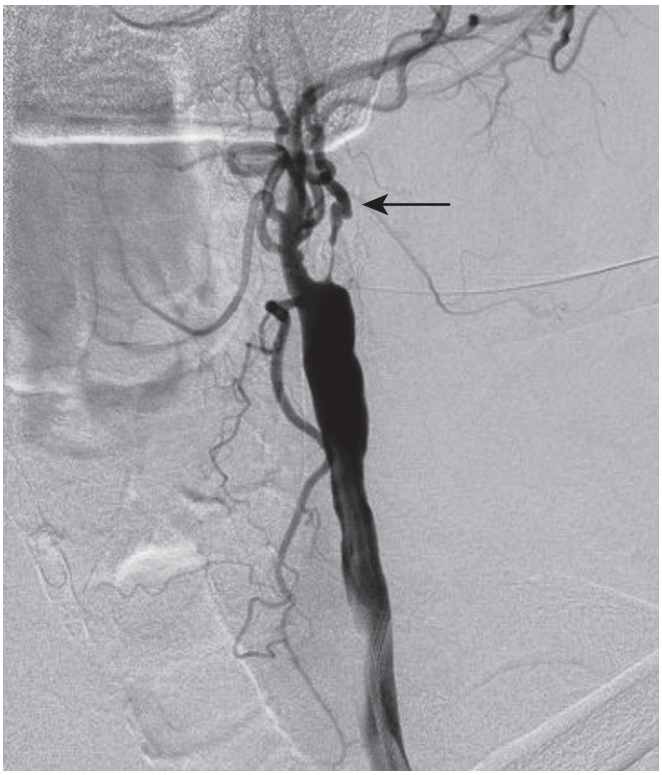

FIGURE 8 Angiogram shows a string sign with a hypoplastic distal internal carotid artery *(arrow)*.

Thrombosed Internal Carotid Artery

Occlusion of the internal carotid artery is never treated surgically because this is associated with an increased risk of stroke. However, lesions may progress during the preoperative period. The author tries to ensure that the patient has a duplex ultrasound scan within 6 weeks of surgery to avoid this scenario. An acutely thrombosed artery found at the time of surgery should lead to abandonment of the case. Manipulation of the ICA in this case increases the risk of stroke.

COMPLICATIONS

Stroke

The risk of perioperative stroke is directly related to the indication for the operation. A recent large, multicenter trial showed perioperative stroke rates of 3.2% among symptomatic patients and 1.4% in asymptomatic patients. Commonly, these strokes are ipsilateral to the side of operation; however, significant risk of contralateral stroke remains, and symptoms in this distribution should be investigated thoroughly in the postoperative period. The observation of contralateral stroke after endarterectomy has supported the belief that many of these neurologic events result from emboli or microemboli that enter cerebral circulation during the manipulation of the carotid artery. Through observation with transcranial Doppler monitoring during endarterectomy, the periods of highest risk for embolic events

are immediately before institution of cerebral protection through applying vascular clamps and immediately on removal of the clamps. Therefore, the principals of delicate tissue manipulation and minimal plaque disruption before protection are of extreme importance in reducing the risk of stroke during endarterectomy.

Changes in the patient's neurologic status recognized in the immediate postoperative period should be considered the result of thrombosis until proven otherwise. In the author's center, the protocol for stroke recognized in the recovery room is to urgently obtain a carotid duplex scan. The surgeon can then make the decision regarding to proceed directly to the operating room or, in the case of negative duplex scan results, to obtain an MRI to look for acute ischemic changes that necessitate the involvement of the neurology team.

Nerve Injury

Cranial nerve injuries are the most frequent complications after CEA, with rates in large prospective trials between 4% and 9%. Because of their anatomic relationship to the carotid arteries, the hypoglossal, recurrent laryngeal, superior laryngeal, and marginal mandibular nerves are subject to traction and minor trauma during the operation. Injuries to these nerves are usually transitory, typically resolving in a few days or weeks.

Myocardial Infarction

The presence of carotid disease serves as a marker for widespread arterial disease in most patients. In fact, the most common cause of death after CEA is cardiac disease. In the CREST trial, the rate of postoperative myocardial infarction was shown to be 2.3% among a combined group of symptomatic and asymptomatic patients. Maximization of the preoperative risks of patients undergoing CEA is essential with correct modification of cardiac risk factors, including the introduction of aspirin and statin therapy to the patient's current regimen, when appropriate. In patients with multiple cardiac risk factors, including diabetes, hypertension, recent history of coronary intervention, and creatinine greater than 2.0 mg/dL, cardiology workup before carotid surgery may be indicated.

Hyperperfusion Syndrome

A small percentage of patients have an entity known as hyperperfusion syndrome after CEA. This clinical syndrome involves loss of autoregulation of the cerebral vessels as a result of chronic dilation under the ischemic conditions produced by long-standing stenosis. After restoration of normal blood flow, the increased pressure in the cerebral vasculature causes cerebral edema and hemorrhage. Clinical sequelae typically occur within 2 weeks of CEA and consist of headache ipsilateral to the side of repair, focal seizures, and radiographic evidence of intracerebral hemorrhage. Prevention of hyperperfusion syndrome consists of strict blood pressure control in the immediate postoperative period, especially in patients who were treated for high-grade stenosis. If clinical signs develop, patients should be immediately admitted to an intensive care unit for antihypertensive and antiseizure therapy.

RECURRENT CAROTID STENOSIS

After endarterectomy, patients are followed in the clinic with carotid duplex scan within 6 weeks. In the author's practice, if initial imaging shows an intact repair, the next follow-up appointment is scheduled for 6 months. Recurrent stenosis occurs in approximately 5% to 22% of patients. Analysis suggests that the rate of recurrence may be dependent on the time from CEA, with a 10% restenosis rate in the first year, 3% rate in the second, and 2% rate in the third year after surgery. Neointimal hyperplasia is the most common cause of restenosis, although early restenosis may result from an inadequate endarterectomy. Serial carotid duplex scan examinations in patients with neointimal hyperplasia show that up to one third spontaneously regress, and therefore, restenosis within the first 6 months should not be operated on and should be followed up with a repeat duplex scan at 1 year confirming persistence of the restenosis. Lesions that develop after 36 months most likely represent recurrent atherosclerotic disease.

Populations with increased risk of restenosis include women, patients who continue to smoke, and those with cardiovascular risk factors such as hypertension, hypercholesterolemia, or diabetes mellitus. Technical factors during the operation may also influence the rate of restenosis. In particular, injury from intraluminal shunt placement, arterial clamping, or placement of tacking sutures in the vessel may predispose to early intimal hyperplasia. Restenosis is more common with primary closure of the arteriotomy; however, no difference in restenosis was found in a recent comparison of eversion endarterectomy with conventional endarterectomy with patch closure.

In the setting of recurrent stenosis, repeat carotid endarterectomy has the potential to be performed successfully with excellent results. Several large studies have shown low stroke and death rates (combined measure of 3.7%) after repeat CEA. However, additional challenges with technique and dissection increase the risks of injury to surrounding structures. Intimal hyperplasia is a firm, rubbery plaque rich in fibroblasts and smooth muscle cells surrounded by dense accumulation of collagen and acid mucopolysaccharide. It is less prone to ulceration or thromboses than primary lesions or late restenotic, atherosclerotic lesions. No prospective randomized trials exist to support repeat CEA, but most available evidence encourages treatment of symptomatic and very high-grade asymptomatic recurrent stenoses.

Carotid angioplasty and stenting (CAS) has been proposed as an alternative to mitigate these risks, but recent trials have not confirmed a therapeutic benefit of CAS compared with CEA. Ultimately, careful planning and technique are of paramount importance in obtaining excellent results in repeat CEA.

COMBINED CAROTID ENDARTERECTOMY–CORONARY ARTERY BYPASS

Still another class of patients has asymptomatic carotid disease that is found in the course of preoperative workup for coronary artery bypass grafting (CABG). Although no consensus exists regarding the best timing for both surgeries, meta-analyses suggest that the risk of stroke, myocardial infarction, or death varies depending on which procedure is performed first. Staged CEA-CABG or CABG-CEA is associated with a lower cumulative risk of stroke/myocardial infarction/death than synchronous CEA-CABG, but these subgroups had a lower incidence of acute preoperative cardiac or neurologic symptoms. At the author's institution, synchronous CEA-CABG is typically performed because the operative stroke risk is less than 5%. Because patients are heparinized for the CABG, a drain is left in the surgical bed and the skin is not closed until the CABG is completed.

The Management of Recurrent Carotid Artery Stenosis

Timothy K. Williams, MD, and Bruce A. Perler, MD, MBA

INCIDENCE OF RESTENOSIS

Estimates are that approximately 140,000 carotid endarterectomy (CEA) procedures are performed annually in the United States alone. Despite a low risk of periprocedural complications and well-documented durability after CEA, a small minority of patients have recurrent stenosis develop in the treated artery over time. For example, in the Asymptomatic Carotid Atherosclerosis Study, the recurrent stenosis rate after CEA was approximately 7% at 60 months of follow-up. In a meta-analysis that included 55 studies, the rate of recurrent carotid stenosis after CEA ranged from 6% to 14% and documented an annual incidence rate of 1.5% to 4.5%. In another analysis, the rate of restenosis was 10% within the first year, 3% within the second year, and 2% in the third year after CEA, which indicates that the rate of restenosis is not linear.

Carotid angioplasty and stenting (CAS) is increasingly performed as an option for patients deemed to be unacceptable candidates for CEA. Although the incidence of restenosis after CAS is not as well defined in the literature, the rate of restenosis appears to be higher than after CEA. For example, a recent study documented an in-stent restenosis rate of 15% at 4 years (defined as >60% luminal narrowing). In the study with the longest follow-up period reported to date, the rate of 70% or more restenosis was 19% after CAS, including 16% who underwent reintervention, and 0 after CEA at a mean follow-up period of 5 years. However, symptomatic recurrence is rare, occurring in only 1% to 5% of patients after either CEA or CAS.

TIMING OF RESTENOSIS AND PATHOGENESIS

The pathophysiology of recurrent carotid stenosis, and the necessity for reintervention, is related to the timing of presentation. It is important to differentiate early recurrent stenosis from residual stenosis or stenosis from technical imprecision in the performance of the CEA. Technical issues include performance of an incomplete endarterectomy, residual dissection flaps, clamp-related intimal injury, and stenosis related to the suture line. Although considerable debate and conflicting data are found with respect to its efficacy, the authors believe performance of a completion study before the neck incision is closed markedly reduces the likelihood of leaving the patient with residual defects from technical error; the authors' preference is the performance of a completion duplex scan (Figure 1). Technical issues after CAS are largely related to residual stenosis after stent placement. Identification and correction of these immediate technical imperfections are crucial to reduce acute thrombotic complications in addition to later restenosis.

Early recurrent stenosis generally develops within the first 2 years after CEA and results from the development of myointimal hyperplasia. Although the pathophysiology of this process is not completely understood, it is believed to represent a variable response of the vessel wall to injury. The process involves the proliferation of vascular smooth muscle, collagen, and a variety of other extracellular matrix proteins. The luminal surface of this lesion is typically lined

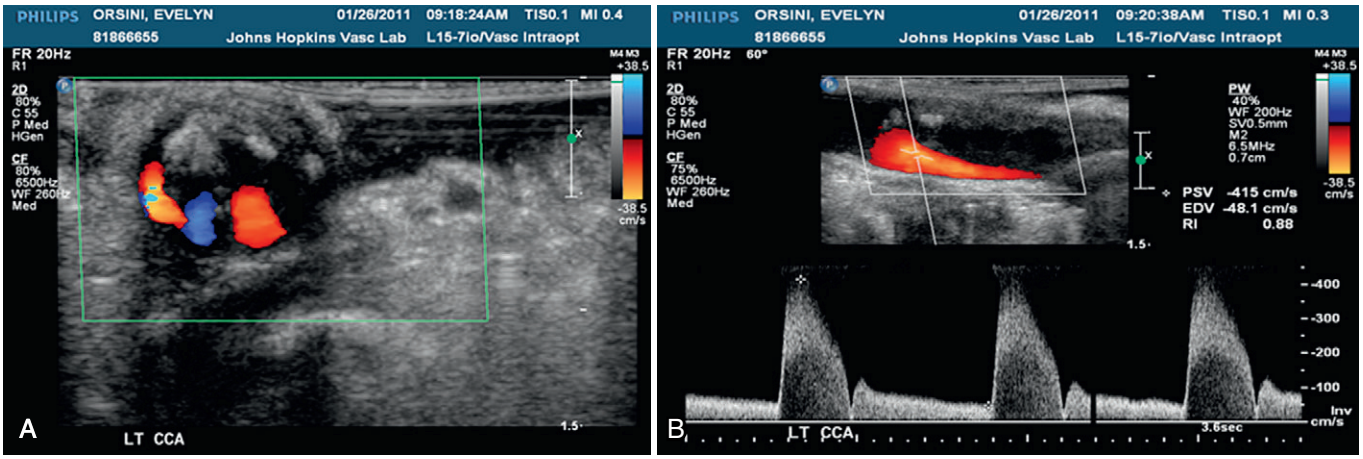

FIGURE 1 **A,** Completion carotid duplex scan. Note the intimal dissection in the common carotid artery from clamp injury on this transverse image. **B,** Note the elevated velocities at the site of intimal dissection from the clamp injury during carotid endarterectomy.

with endothelium. As such, it tends to be nonthrombogenic with a low thromboembolic potential. Myointimal hyperplasia accounts for most cases of recurrent carotid stenosis and usually peaks around 1 year after surgery. This lesion often has a smooth tapered appearance on duplex ultrasound scan or angiography. In a small percentage of patients after both CEA and CAS, myointimal hyperplasia can result in a hemodynamically significant lesion. The molecular basis for this process may be linked to the inflammatory process of the initial atherosclerotic lesion. Some studies have shown that lipid-rich and heavily macrophage-infiltrated plaques result in a more robust myointimal proliferation in the postoperative setting, likely related to an abundance of various inflammatory molecules including specific matrix metalloproteases.

Late recurrent stenoses, defined as developing more than 2 years after CEA, and usually much later, typically result from progressive or new atherosclerotic disease, although these lesions may have a component of underlying intimal hyperplasia. Although myointimal hyperplastic lesions are characteristically smooth, recurrent atherosclerotic plaques have a varied appearance similar to that of primary plaques. They typically are irregular and heterogeneous in both gross and radiographic appearance.

RISK REDUCTION

Multiple factors, modifiable and nonmodifiable, have been associated with the development of recurrent carotid stenoses. Most studies have examined risk factors specific for patients undergoing CEA; less long-term follow-up data are found on CAS.

The most important nonmodifiable risk factor is female gender, very likely related to the relatively smaller diameter of the carotid vessels in women. In addition, chronic renal insufficiency has been associated with an increased risk of early recurrent stenosis. The most robust risk factor associated with late restenosis is hyperlipidemia. Statin therapy has been associated with a significantly reduced rate of both early and late restenosis after CEA. In addition to the benefit of lowering lipid levels, the so-called pleiotropic effects of statins may also be operative in ameliorating the pathophysiologic process of restenosis. A reduction in the rate of recurrent stenosis associated with statin use has not been identified in patients undergoing CAS, however.

On the other hand, typical risk factors for atherosclerosis, such as ongoing smoking, hyperhomocysteinemia, hypertension, and diabetes, have not been shown to have strong links to the development of myointimal hyperplasia. Furthermore, although platelet inhibition with agents such as aspirin and clopidogrel has clearly been associated with a reduced risk of cardiovascular and cerebrovascular events in patients with carotid stenoses, these medications do not have a clear impact on the natural history of recurrent carotid stenosis. Conversely, some recent evidence suggests that cilostazol, a phosphodiesterase inhibitor commonly used to treat intermittent claudication, may modify the progression of myointimal hyperplasia and has shown some benefit in patients undergoing CAS. More study is warranted to validate this finding.

Without question, the most important modifiable factor in reducing the incidence of restenosis after CEA is technical. In addition to avoiding technical imperfection at the time of the endarterectomy as noted previously, closure of the arteriotomy with a patch has consistently been shown to be associated with a significantly lower incidence of restenosis compared with primary closure. In a Cochrane review, the use of a Dacron or vein patch reduced the rate of restenosis by 76% compared with primary closure. In the only large randomized trial to compare standard endarterectomy with eversion endarterectomy, the Eversion carotid endarterectomy versus standard (EVEREST) trial, the 4-year cumulative risk of restenosis was 3.5%, 1.7%, and 12.6%, for eversion, conventional endarterectomy with patch, and conventional endarterectomy with primary closure, respectively. On the basis of the reported experience to date, no consensus exists on the superiority of a particular patch material (i.e., Dacron, polytetrafluoroethylene [PTFE], bovine pericardium, greater saphenous vein, or cervical vein).

DIAGNOSIS OF RESTENOSIS

Duplex ultrasound scan, the gold standard diagnostic modality for the detection and monitoring of carotid artery disease, is likewise the noninvasive method of choice for the diagnosis of recurrent carotid stenosis after both CEA and CAS. Although no consensus exists with respect to the most appropriate timing of baseline and interval evaluations after surgery, most clinicians obtain an initial postoperative study within the first 6 to 12 months. Retrospective studies have shown that evaluations earlier than 6 months rarely diagnose a clinically significant abnormality. The authors' preference is to obtain a completion duplex scan in the operating room and then a postoperative duplex scan at 6 and 12 months and then yearly thereafter. The scanning interval may be dictated by other factors such as the status of the contralateral carotid artery (e.g., a high-grade contralateral stenosis). When a greater than 50% stenosis is present, the authors' practice is to perform duplex scan examinations at 6-month intervals.

Duplex criteria for the quantification of the degree of stenosis in the native carotid artery do not correlate directly with the velocity criteria for establishing the degree of carotid restenosis after CEA or CAS. After CEA with patch angioplasty, a funneling or bottleneck effect is believed to be created, whereby blood flowing through the relatively large diameter carotid bulb is funneled down into the narrow lumen of the internal carotid artery (ICA), creating turbulent high-velocity flow. This is believed to result in an artifactually higher peak systolic velocity (PSV) than would be expected in a native ICA of a similar diameter. With respect to CAS, the relatively noncompliant, nondistensible stent appears to create an architecture that more closely resembles the hemodynamic pattern seen within a rigid tube. Therefore, this serves to artificially elevate the PSV above what would be expected for a given degree of stenosis in a native ICA.

The effects of these hemodynamic changes have been rigorously examined, and correlation of duplex scan findings with computed tomographic angiography (CTA) and traditional angiography has been used to validate these findings. A recent study examined duplex ultrasound scan in patients after CEA with patch closure and showed that a PSV of 213 cm/s or more and an end-diastolic velocity (EDV) of 60 cm/s or more were optimal for detection of a greater than 50% restenosis, with a sensitivity of 99% and a specificity of 100%, respectively. In addition, an ICA to common carotid artery (CCA) PSV ratio of 2.25 or higher was found to be most accurate for detection of a 50% or greater restenosis. For detection of a stenosis of greater than 70%, a PSV of greater than 274 cm/s and an EDV of 80 cm/s had a sensitivity of 99% and a specificity of 91%, respectively. The optimal ICA:CCA PSV ratio for detection of a 70% or greater stenosis was 3.34.

Revised duplex scan criteria after CAS have also been reported and include a PSV of greater than 220 cm/s for detection of a greater than 50% stenosis, with a sensitivity of 100% and a specificity of 96%, respectively. A PSV of greater than 340 cm/s or an ICA:CCA PSV ratio of greater than 4.15 was ideal for determination of an 80% or greater restenosis after CAS, with a sensitivity of 100% and a specificity of 98%, respectively.

Other diagnostic modalities may be performed when doubt exists regarding the degree of restenosis with duplex scan. CTA provides excellent visualization of the neck and cerebral vasculature and has largely obviated the need to perform conventional angiography. However, CTA may yield equivocal results when a very severe preocclusive stenosis exists so that conventional angiography may be indicated to definitively assess the vessel. Magnetic resonance angiography (MRA) is also a useful option but requires longer acquisition time and may overestimate the degree of stenosis. It is also not a desirable

option after CAS because the metal stent produces significant artifact. MRA may be beneficial in assessment of plaque morphology, a factor that is increasingly recognized as a predictor of embolic risk.

INDICATIONS FOR REINTERVENTION

Only a minority of patients in whom a recurrent carotid stenosis develops after endarterectomy needs reintervention. For example, in an institutional series of 950 CEAs, reintervention was necessary in only 3.8%, with a mean follow-up period of 4.5 years. The decision to reintervene in a patient with recurrent carotid stenosis depends on several factors, including the patient's symptomatic status, the degree of stenosis, progression in the degree of stenosis, associated comorbidity, and the anticipated risk of the procedure. No level I evidence exists, and therefore, no definitive guidelines exist to establish absolute indications for reintervention. Thus, this clinical judgment must be individualized.

The most compelling indication for reintervention is the symptomatic patient with a greater than 50% restenosis on the ipsilateral side, regardless of the type of previous procedure or the time of presentation of the restenosis. Among asymptomatic patients, the decision to reintervene is most dependent on the timing of the development of restenosis, which implies the underlying pathologic lesion and also the severity of the stenosis.

Within the first 24 to 36 months after CEA, restenosis is most likely the result of myointimal hyperplasia. These lesions are typically very smooth and rarely ulcerated and have low thromboembolic potential. In addition, the development of myointimal hyperplastic lesions is a dynamic process, and many of these lesions regress over time as documented with serial duplex scan examinations. In fact, some studies have indicated that as many of one third of these lesions significantly regress over time. Therefore, the threshold for reintervention within the first 2 to 3 years in the asymptomatic patient is very high. The authors follow patients with serial duplex scan examinations, unless there is a greater than 80% to 90% stenosis, and are even more conservative in the patient with considerable associated comorbidity. Other considerations include the rate of progression of the stenosis during follow-up and the status of the remainder of the cerebral circulation.

On the other hand, recurrent stenoses that develop more than 3 years after the CEA are likely the result of progressive atherosclerosis. Similar to early recurrent stenoses from myointimal hyperplasia, most symptomatic patients warrant reintervention. On the other hand, the threshold for reintervention for the asymptomatic patient with a late recurrent stenosis should be lower than for early asymptomatic recurrent stenoses. Although the natural history of late recurrent stenosis after endarterectomy is not as well documented as for primary carotid atherosclerotic disease, one can assume that the thromboembolic potential is similar.

INTERVENTION FOR RECURRENT CAROTID STENOSIS

Once a decision to reintervene has been reached, the next decision is whether to perform a reoperative CEA or a CAS procedure. This decision should be based on a number of factors, including the anatomic location of the carotid bifurcation and the extent of the recurrent lesion, the timing of the restenosis (early versus late), and associated comorbidity. Although duplex ultrasound scan is the diagnostic modality of choice to identify recurrent carotid stenoses and follow patients long term, the authors believe that further imaging is usually required before undertaking a reoperative procedure. In most cases, the necessary anatomic information may be obtained with a CTA, although angiography remains the gold standard to provide the most definitive information. These contrast studies define the bifurcation location and the extent of the recurrent lesion and, in conjunction with the duplex scan, characterize the underlying pathology (myointimal hyperplasia versus atherosclerosis).

To date, most patients treated for recurrent carotid stenoses have undergone reoperative endarterectomy. CAS has been reserved for patients with high bifurcations or very distal recurrent lesions, previous radiation therapy, or radical neck surgery, and the authors have had a lower threshold for electing CAS for early, myointimal hyperplastic lesions where the risks of CAS appear lower than in the treatment of atherosclerotic lesions. Furthermore, for patients who have undergone bilateral CEA procedures, knowledge of the status of the contralateral recurrent laryngeal nerve is important before considering reoperative CEA. CAS is the preferred option in the setting of contralateral recurrent laryngeal nerve paresis. Finally, this decision should also weigh the patient's overall severity of comorbidity, electing CAS for patients with prohibitive operative risk, although this is rarely encountered in the authors' practice.

REOPERATIVE CAROTID ENDARTERECTOMY

Reoperative CEA is associated with increased risk when compared with primary CEA. These challenges include the difficulty of dissection and identification and protection of crucial structures in a scarred field and technical challenges with respect to the method of arterial repair. However, with proper preoperative evaluation and careful attention to operative technique, excellent results have been achieved in this clinical setting.

Before undertaking a reoperative CEA, one must know as much as possible about the original procedure (e.g., whether the patient underwent a primary closure, patch closure, or eversion endarterectomy). One also should identify whether any cranial nerve injury or other complications occurred. Before surgery, a regimen of aspirin 81 mg per day and a statin should be started, and a beta blocker may also be indicated depending on the patient's cardiovascular risk profile.

Technical Details

The operative approach to reoperative CEA is very similar to that of the initial operative intervention with certain caveats. In the case of an unusually cephalad exposure during the initial operation or concern for very distal disease at the time of reoperation, nasotracheal intubation should strongly be considered. With the jaw closed in the absence of an endotracheal tube in the mouth, several millimeters of additional distal arterial exposure are afforded. The authors prefer a longitudinal incision through the original incision, but with extension proximally and distally. Dense scar tissue is likely to be encountered, so one should try to expose the common carotid artery proximal and the internal carotid artery distal to the previous operative field through unscarred tissues. Division of the posterior belly of the digastric muscle may be necessary to gain further distal exposure, with care exercised to identify the crossing glossopharyngeal nerve. Resection of the styloid process or mandibular subluxation represents further options to gain additional distal exposure. The sternocleidomastoid muscle should be sharply dissected off its medial attachment from the adjacent vascular structures. The internal jugular vein should be carefully dissected free from the previously endarterectomized carotid artery to which it is typically quite adherent. The operator should be constantly vigilant to identify the vagus nerve that not infrequently is encased more anteriorly or superficially than usual in the perivascular scar tissue and the hypoglossal nerve at the apex of the incision. It is not necessary to dissect free the entire length of the carotid artery; this increases the risk of injury to surrounding structures, particularly for the external carotid artery,

which can typically be controlled with a clamp after anterior exposure or intraluminally after the arteriotomy is made. One should avoid subadvential dissection of the arterial structures. Once proximal and distal control is achieved, one can then proceed with the dissection of the carotid bifurcation and external carotid artery.

After administration of systemic heparin anticoagulation and clamping, a longitudinal arteriotomy is performed, through the patch if previously patched, or the native artery if not, or if there was a previous eversion endarterectomy. Once the artery is opened, the incision is carried proximally and distally with Potts scissors until healthy artery is reached beyond the disease process in the common and internal carotid arteries. The placement of an intraluminal shunt is dependent on surgical preference, following the same guidelines as used for a primary CEA.

If the recurrent stenosis results from atherosclerosis, a clean dissection plane is usually achievable and endarterectomy is performed in similar fashion to the initial operation; it then is repaired as a patch angioplasty. Others have performed eversion endarterectomy in this setting with comparable results. When dealing with myointimal hyperplasia, the fibrous tissue is generally very adherent to the underlying vessel wall so that a clean dissection plane is not easily established and therefore a conventional endarterectomy may not be possible. In this situation, a generous patch angioplasty is usually sufficient to restore a widely patent lumen (Figure 2).

On the other hand, when a long-segment stenosis is encountered, especially when it is dense and fibrotic, another useful option is to simply resect the segment and replace it with an interposition common-internal carotid graft with a prosthetic graft or greater saphenous vein (Figure 3). The shunt can be temporarily removed and replaced through the graft while the anastomoses are performed. The external carotid artery may then be reimplanted into the graft, or simply ligated. Finally, in some cases in which the intensity of scar tissue around the carotid artery makes the dissection excessively risky, one can preferentially perform a bypass from the common carotid to the internal carotid artery in relatively unscarred tissues. The authors have preferentially used a 6-mm ringed PTFE graft for carotid interposition bypass procedures with excellent long-term results (see Figure 3).

In the patient with a significant restenosis after CAS, CEA can often be performed. In many cases, the carotid stent is not well incorporated and can easily be removed with a conventional endarterectomy with patch angioplasty. In some cases, however, a dense neointimal hyperplastic response is encountered with a smooth vessel lumen. In this case, the anterior wall of the artery and stent can be opened or partially excised, and a patch closure can be performed. For atherosclerotic lesions with dense incorporation of the stent, extraction of the stent from the vessel is sometimes not possible, requiring excision and performance of an interposition bypass as described previously. In the rare case in which a common-internal carotid bypass is not feasible because of extensive common carotid disease after either CEA or CAS, an ipsilateral subclavian-internal carotid artery bypass is an option.

Results

Reoperative CEA is more risky than a primary operation. Whereas the American Heart Association guidelines include a stroke and death rate of less than 3% for asymptomatic and less than 6% for symptomatic patients undergoing primary CEA, the acceptable stroke and death rate for reoperative CEA is less than 10%. Numerous series have documented acceptable results in properly selected patients in the hands of experienced vascular surgeons. For example, a recently published review of 28 series that included nearly 2000

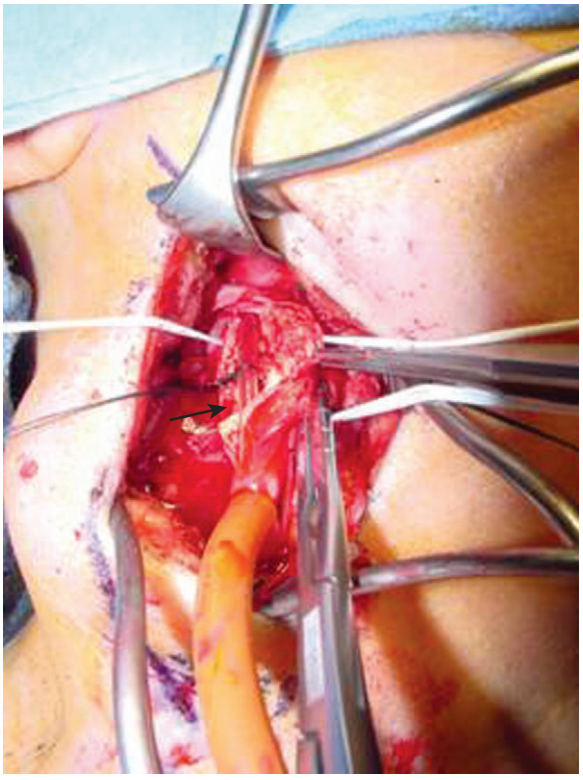

FIGURE 2 Completed reconstructions with Dacron patch angioplasty (Maquet Getinge Group, Atrium, Hudson, NH). *(From Cronenwett J, Johnston W, editors: Rutherford's vascular surgery, ed 7, Philadelphia, 2010, Saunders.)*

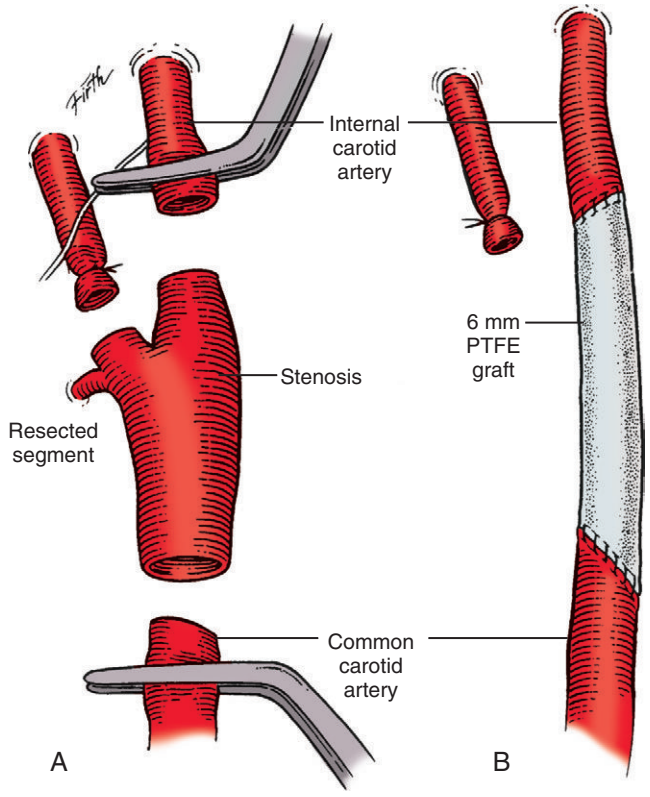

FIGURE 3 **A,** Resection of diseased segment of carotid artery with ligation of external carotid artery. **B,** Continuity restored with placement of interposition polytetrafluoroethylene (PTFE) common-internal carotid artery bypass graft.

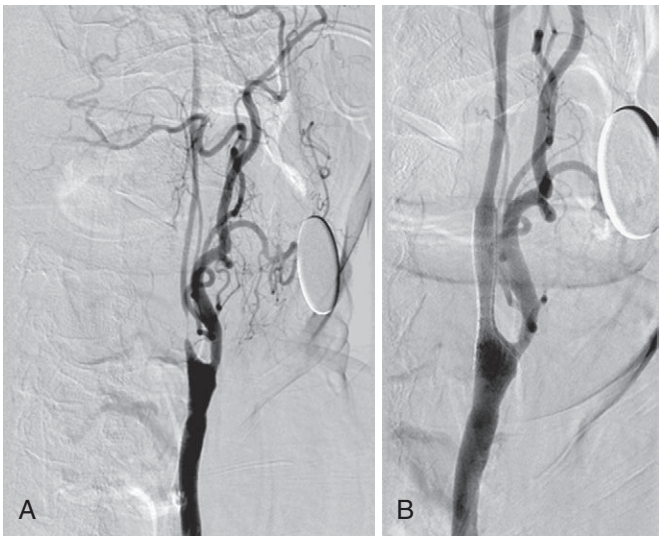

FIGURE 4 **A,** Diagnostic arteriogram shows high-grade recurrent internal carotid stenosis. **B,** Completion arteriogram after successful angioplasty and stent placement.

cases documented a combined perioperative stroke and death rate that ranged from 0 to 10.5%, with a rate of 0 to 5.6% in 26 of the 28 series. In a series of 59 patients who underwent eversion CEA for recurrent stenoses, the 30-day stroke rate was 4.5%.

The greatest risk of reoperative CEA is cranial nerve injury. Although the incidence rate of cranial or cervical nerve injury has been reported to be as high as 21% after CEA for restenosis in one prospective cohort study, most recent studies have documented a cranial nerve injury rate of 0 to 7%. In the review of 28 series that included nearly 2000 patients noted previously, the rate of cranial nerve injury ranged from 0 to 19% in the 25 reports in which this complication was reported. The rate of cranial nerve injury was 7% or less in 17 of the 25 reports. In a series of 59 patients undergoing eversion CEA, the cranial nerve injury rate was 4.5%.

Furthermore, reoperative CEA has been shown to yield extremely durable long-term results. In a review of 13 series, the 5-year stroke-free rate ranged from 82% to 96%. The restenosis-free survival rate ranged from 83% to 95% at a 5-year follow-up and from 68% to 86% at a 10-year follow-up.

CAROTID ANGIOPLASTY AND STENTING

The techniques and devices for CAS have continued to evolve over the past decade. To date, this endovascular therapy has been used primarily in patients at high risk, and recurrent carotid stenosis has been a relatively common indication. CAS represents an attractive option, especially when the recurrent stenosis has resulted from myointimal hyperplasia (Figure 4). This includes fibrous lesions that develop after CEA and in-stent restenosis after CAS. In general, these types of lesions are thought to be less prone to distal embolization during CAS than restenotic plaques formed later by the progression of atherosclerosis.

Relative contraindications to CAS for recurrent disease are similar to those for treatment of primary atherosclerotic disease. These include anatomic factors related to the aortic arch, such as a type III arch and bovine arch anatomy, severe vessel tortuosity, circumferentially calcified plaque, suspected plaque rupture with thrombus formation, and inability to achieve safe vascular access. Other relative contraindications include a recent major stroke, a contraindication to systemic anticoagulation therapy or appropriate antiplatelet therapy, a severe contrast allergy, and stage IV chronic renal failure.

Technical Details

The patient should begin a regimen of clopidogrel 75 mg daily 7 days before the procedure or receive a loading dose of 300 mg the morning of the procedure in addition to aspirin 81 mg daily. These medications are continued in the postoperative period; however, the duration of dual-antiplatelet therapy for CAS is not well established. The authors routinely continue dual antiplatelet therapy for a minimum of 3 months.

The techniques used to perform CAS for recurrent disease after CEA are essentially the same as those used for treatment of primary disease and are outlined in greater detail elsewhere in the text. For the patient with a recurrent stenosis after CAS, repeat carotid angioplasty or stenting is a viable option. Evidence suggests that balloon angioplasty alone has an unacceptably high repeat recurrence rate of approximately 25%, so additional stent placement is usually necessary. However, use of a cutting balloon may provide a significant benefit over traditional angioplasty in this clinical scenario.

Results

Although reported clinical experience is limited, the available evidence suggests that CAS is a safe and effective treatment option for patients with recurrent carotid stenoses. In a multicenter study that included 358 CAS procedures for recurrent stenosis, the 30-day stroke and death rate was 3.7% and the 3-year freedom-from-stroke rate was 96%. In a recent institutional series that included 83 CAS procedures performed for recurrent stenoses in 75 patients, the periprocedural stroke rate was 3.6%. With a mean follow-up period of 22 months, recurrent stenoses occurred in 4 cases (5%).

SUMMARY

Recurrent stenosis is a relatively uncommon complication after carotid interventions and appears to occur more commonly after CAS as compared with CEA. The decision to reintervene in the patient with a recurrent carotid stenosis must be individualized on the basis of the patient's symptomatic status, the severity of the stenosis, the timing of presentation of the restenosis and underlying responsible pathology, the status of the cerebral circulation in general, and the patient's overall comorbidity. Likewise, although reoperative CEA has been the standard of care, CAS has emerged as an important endovascular option with acceptable clinical outcomes.

Balloon Angioplasty and Stents in Carotid Artery Occlusive Disease

Charles S. O'Mara, MD, MBA

BACKGROUND

The approximately 800,000 strokes each year in the United States make stroke the nation's third leading cause of death. On average, a stroke occurs every 20 seconds in this country. Nearly three quarters of patients with stroke are over the age of 65 years, and this condition is a leading cause of permanent disability. The estimated direct and indirect costs of stroke of $70 billion per year are indeed staggering. Atherosclerosis of the internal carotid artery (ICA) is the cause of stroke in 20% to 40% of cases. These facts indicate that prevention of stroke from carotid occlusive disease is a major national health issue.

Carotid endarterectomy (CEA) for treatment of carotid artery atherosclerosis was first performed about 60 years ago. The efficacy of this operation later came under scrutiny but in the early 1990s was confirmed by two large multicenter randomized trials, the North American Symptomatic Carotid Endarterectomy Trial (NASCET) and the Asymptomatic Carotid Atherosclerosis Study (ACAS), both of which compared CEA with medical therapy alone and showed significant benefit from the surgery.

After the development of endovascular interventions for other arterial occlusive lesions, carotid artery balloon angioplasty and stenting (CAS) was proposed as an alternative to CEA for treatment of carotid atherosclerosis. Although both CAS and CEA can be performed with local anesthesia with similar operative and hospitalization times, CAS offers the advantage of percutaneous groin arterial access rather than a neck incision for direct carotid artery exposure, which carries risk of incisional pain, cranial nerve injury, wound infection, and neck hematoma.

This potential advantage of CAS led to its initial limited clinical use and then to the performance of several randomized trials that compared CAS with CEA (Table 1). These trials produced varied results and often showed poor performance for CAS. However, the studies were criticized because of inconsistent operator skill and experience with CAS, nonuniformity of embolic protection device (EPD) use, and incomplete use of periprocedural antiplatelet therapy.

In 2010, results were reported for the Carotid Revascularization Endarterectomy versus Stenting Trial (CREST), which is the largest prospective randomized trial to date comparing CAS with CEA. This National Institutes of Health (NIH)-funded study enrolled 2502 symptomatic and asymptomatic patients from 117 U.S. and Canadian centers. The rate of achieving the primary composite endpoint of any stroke, myocardial infarction (MI), or death during the periprocedural period or ipsilateral stroke in follow-up was 7.2% for CAS versus 6.8% for surgery, a difference that was not significant (Table 2). However, periprocedural stroke rate was significantly higher with stenting at 4.1% versus 2.3% with surgery, and MI was significantly higher with CEA at 2.3% versus 1.1% with CAS. Quality of life after recovery for those patients who had a stroke was worse than for those patients who had an MI. Rate of ipsilateral stroke during a mean follow-up period of 2.5 years was not significantly different between groups with 2.0% for CAS and 2.4% with CEA. Counterintuitively, younger patients tended to have better results with stenting, and older patients did better with surgery. The study showed a higher risk for periprocedural stroke with stenting in patients of advanced age (more than 70 years) and with recent (within 2 weeks) neurologic ischemic symptoms.

CREST results are encouraging in showing that both procedures are effective in long-term stroke prevention. However, certain components of CREST have been intensely debated and interpreted differently according to one's bias for or against CAS or CEA. Stenting enthusiasts argue that statistical similarity in the primary composite endpoint establishes equipoise for the procedures. In contrast, others question the inclusion of MI as a component of the primary endpoint for procedures that have stroke prevention as their principal objective. They argue for the use of only stroke and death as a more appropriate composite endpoint, which significantly favors endarterectomy in CREST.

Suffice it to say, CREST has produced valuable level I data comparing CAS with CEA but has not fulfilled the expectation by some of proving undeniably that CAS is better than or even equal to CEA. Hopefully, additional data analysis from CREST and results of future clinical trials will facilitate the decision process of applying each procedure to its most appropriate clinical situation. In addition, recent information about treatment of carotid occlusive disease with a combination of antiplatelet agents and statins, along with healthy lifestyle habits such as regular exercise, dietary discretion, and tobacco abstinence, suggests that medical management alone may assume an increasingly important role in the future for this patient population.

TECHNICAL CONSIDERATIONS IN PERFORMANCE OF CAROTID ARTERY STENTING

Preprocedural assessment includes a complete history focused on cardiovascular elements and on symptoms of neurologic or ocular ischemic events. Thorough physical examination is essential, with an emphasis on palpation of pulses, auscultation for bruits, and complete neurologic assessment. Preprocedural imaging often includes carotid ultrasound scan, computed tomographic angiography, and magnetic resonance imaging and angiography (MRI/MRA). These imaging modalities give important information about the presence and hemodynamic significance of carotid occlusive disease, the condition of the brain parenchyma, the presence of additional intracranial or extracranial vascular anomalies (e.g., saccular aneurysms, vascular malformations), and the anatomy of the aortic arch.

Before CAS, patients should begin dual antiplatelet therapy. The author's regimen typically consists of clopidogrel 75 mg daily and aspirin 81 mg daily beginning 3 to 5 days before the procedure. In emergency circumstances, when antiplatelet therapy has not been started before the procedure, the author uses a loading regimen of clopidogrel 600 mg and aspirin 325 mg given at the time of the procedure. In addition, for patients who have been taking antiplatelet therapy on a chronic basis, the author typically gives a smaller loading dose of clopidogrel 150 to 300 mg immediately after the procedure. If oral administration is not possible, clopidogrel can be given via nasogastric tube; aspirin can be given similarly or per rectum (300 or 600 mg suppository).

Femoral arterial access is accomplished with care to avoid distracting and potentially dangerous access site complications, especially in patients with severe peripheral artery disease. The author routinely uses fluoroscopic assistance and has a low threshold for ultrasound scan guidance and initial micropuncture to facilitate safe femoral artery access. A limited femoral arteriogram in ipsilateral

oblique orientation is routinely done through the sheath immediately after its placement to document a satisfactory entry site into the common femoral artery.

After arterial access is achieved, systemic anticoagulation therapy is initiated either with intravenous heparin bolus administration (100 units per kg body weight) or with bivalirudin (Angiomax; Medicines Company, Persippany, NJ) via continuous infusion (0.75 mg/kg intravenous [IV] bolus, followed by 1.75 mg/kg/h IV infusion) to maintain during the procedure activated clotting times in the range of 250 to 300 seconds. Introduction of a J wire always includes fluoroscopically following the tip during its passage from the femoral sheath to the aortic arch to avoid an errant course with resultant arterial injury. A 6F pigtail catheter passed over the J wire and into the aortic arch is used to perform arch aortography in 35-degree to 40-degree left anterior oblique orientation of the fluoroscopy unit. The author usually hand injects 10 mL of contrast with a closed manifold system to provide sufficient anatomic mapping for subsequent selective catheter placement, while limiting the amount of contrast media used. However, if preprocedure imaging leaves questions about arch anatomy or pathology, power injection of 15 to 20 mL of contrast gives additional angiographic detail to resolve such issues.

On the basis of aortic arch anatomy, an appropriately shaped angiography catheter is chosen for selective cannulation of the aortic arch branches. Typical aortic arch anatomy allows for use of a selective catheter with a simple curve (Berenstein, vertebral; Merit Medical, South Jordan, Utah), and increasingly complex and tortuous aortic arch anatomy requires the use of selective catheters that have either an intermediate curve (H1; Cook Medical, Bloomington, Ind, JR4; Cordis, Hialeah, Fla) or a complex curve (Simmons; Cook Medical, Bloomington, Ind, Vitek; Cook Medical, Bloomington, Ind). All catheter exchanges are done over a guidewire. Extreme care is given to avoid the introduction of microthrombi and tiny air bubbles with frequent guidewire wiping with heparinized saline sponges and with meticulous heparinized saline solution flushing of catheters and sheaths.

In general, complete four-vessel cerebral arteriography with digital subtraction technique is performed before proceeding with stenting to document baseline vascular anatomy and recruited collateral pathways. However, the approach to each patient's arteriographic requirements is individualized based on preprocedure imaging information and on individual clinical circumstances, such as need to expeditiously complete the procedure (patient discomfort or anxiety) or need to minimize total contrast media administered (renal insufficiency). These considerations are tempered by the understanding that incidental lesions discovered with angiography (intracranial carotid stenosis or aneurysm) may alter the therapeutic plan.

After completion of selective arteriography for the target carotid artery, the external carotid artery (ECA) is selectively cannulated with an angle-tipped angiography catheter over a soft, angled hydrophilic guidewire that is then exchanged for an exchange-length, floppy-tipped 0.035-inch stiff wire (Supracore; Abbott Vascular, Abbot Park, Ill). Extreme caution is taken to avoid passing the wire too far and causing vessel perforation with resultant neck hematoma. A posterior ECA branch is selected so that if perforation were to occur, it could be manually compressed easily in the back of the neck (Figure 1). In contrast, anterior ECA branch perforation is difficult to manually

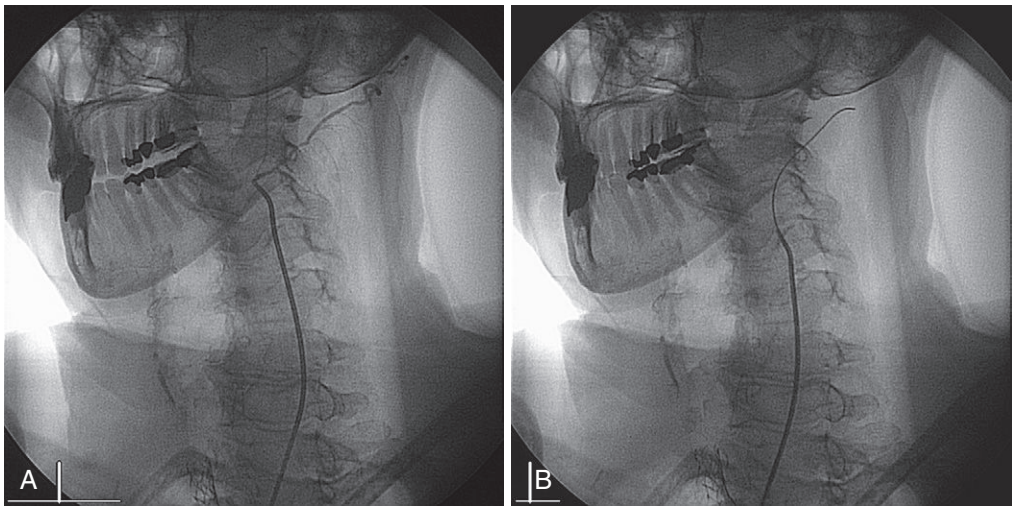

FIGURE 1 **A,** Selective injection to document catheter location in a posterior branch of the external carotid artery before placement of the exchange-length wire used for positioning of the long sheath into the distal common carotid artery. **B,** Wire placement into the external carotid artery branch through the selective catheter. Inadvertent vessel perforation by the wire could be readily managed with manual compression against the posterior neck muscles.

compress and has been reported to produce an expanding hematoma with resultant airway compression and respiratory compromise. If concern arises about wire crossing of a worrisome carotid bifurcation lesion or if the ECA is occluded, curling the floppy tip of the wire before its introduction usually allows adequate purchase of the stiff portion of the wire for subsequent passage of the sheath into the common carotid artery (CCA) without the wire extending beyond the distal CCA.

Once the long stiff wire is in place, the angiography catheter is removed and the femoral sheath is exchanged for a 6F hydrophilic-coated, 90-cm sheath (Shuttle; Cook Medical, Bloomington, Ind) with its tip in the distal CCA. The sheath dilator and the stiff wire are removed. Currently, a distal filter typically is used for embolic protection. The distal filter, attached to a 0.014-inch wire, is passed through the sheath, carefully maneuvered through the carotid stenosis, and placed in the distal cervical ICA, where it is deployed with removal of its covering sheath. Very tight carotid stenoses that cannot be safely negotiated with the tip of the embolic protection device may require use of a low-profile microcatheter (Prowler; Johnson & Johnson, New Brunswick, NJ) and steerable microwire (Transcend; Boston Scientific Corp., Miami, Fla). Occasionally, predilation of a tight stenosis with a low-profile coronary angioplasty balloon may be necessary to allow subsequent crossing of the lesion with the distal filter. Also, problems imposed by vessel angulation and tortuosity can be resolved with use of a "buddy wire" to slightly straighten the anatomy and facilitate crossing of a lesion by the distal filter, angioplasty catheter, or stent. Furthermore, in situations in which passage of the distal filter is difficult, maneuvers such as having the patient take deep breaths, having the patient turn the head far to one side or the other, or careful manual pressure on the side of the patient's neck by an assistant can be helpful. Obviously, to avoid embolization of plaque material, manual pressure should not be applied directly to the carotid bifurcation.

The carotid lesion is predilated if stenosis is severe enough to impair stent positioning or to constrain it after deployment. Predilation is done with an angioplasty balloon that is 3 or 4 mm in diameter and 15 or 20 mm in length, depending on the anatomy of the lesion. For reduction of risk of associated bradycardia and hypotension, intravenous atropine 1.0 mg is routinely administered several minutes before this balloon predilation, which is done with a rapid inflation-then-deflation sequence. Patients with severe aortic stenosis may be intolerant of even mild bradycardia and hypotension with balloon inflation. Therefore, consideration should be given in such patients to anesthesia monitoring and a temporary pacemaker in place for the procedure.

The self-expanding stent is positioned precisely to cover the carotid lesion and is deployed with withdrawal of its constraining cover. Carotid bifurcation lesions typically are best treated with a tapered stent that has a larger diameter proximally to match the CCA and a smaller diameter distally to match the ICA. The stent often crosses the ECA origin, but flow into that artery continues through the interstices of the stent (Figure 2). Occasionally, more than one stent is necessary to treat a long carotid stenosis, but preference is given to use of only one stent if possible.

Postdeployment balloon angioplasty is typically done with a balloon that is 5, 5.5, or 6 mm in diameter and 20 mm in length. Diameter selection is made according to size of the ICA. Care is taken to inflate the balloon only within the confines of the stented segment of the artery. Postdeployment balloon angioplasty is used to achieve an angiographically acceptable but not necessarily perfect result. If a residual stenosis of less than 30% is present after stent placement alone, poststenting balloon angioplasty is forgone based on knowledge that nitinol stents tend to expand slowly after deployment and that embolic events may occur during balloon angioplasty even after stent deployment (Figure 3).

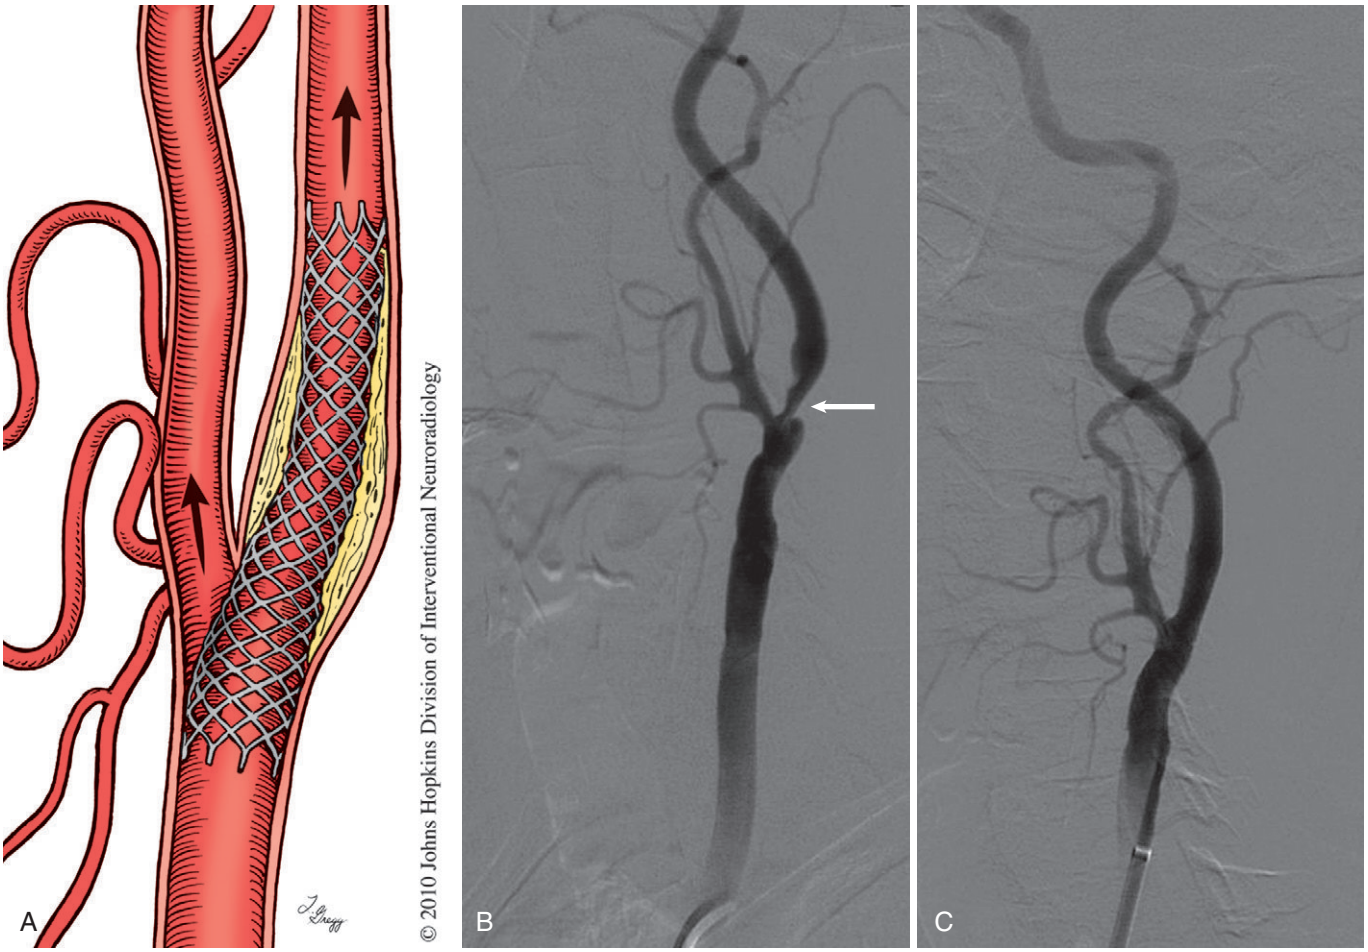
The balloon angioplasty catheters and the carotid stent are passed into position over the wire attached to the distal filter. The same wire is used for passage of a retrieval sheath that captures the filter along with any microemboli that have been trapped during the procedure. After retrieval and removal of the filter and its wire, completion arteriograms are obtained of the treated carotid artery and of the cerebral territory that it supplies with injection of contrast through the long sheath. The long sheath is then removed over its dilator and a guidewire to avoid vessel trauma during exit. Systemic anticoagulation therapy is discontinued. After sheath removal, the femoral artery puncture site is sealed with either manual compression or use of a closure device.

Current practice is to observe patients for several hours after CAS in a cardiovascular recovery suite where personnel are trained and experienced in perioperative cardiovascular and neurologic assessment. The patient is then transferred to a step-down cardiovascular unit for observation over night and discharged the following morning.

DESIGN OF CAROTID STENT SYSTEMS

Carotid Stents

Endovascular stents are constructed in two basic configurations: balloon-expandable and self-expanding. Balloon-expandable stents are appropriate for lesions located at the origin of the CCA and the innominate artery (Figure 4), where precise placement of the proximal end of the stent relative to the artery orifice is critical and where the possibility of compression is not an important consideration. In



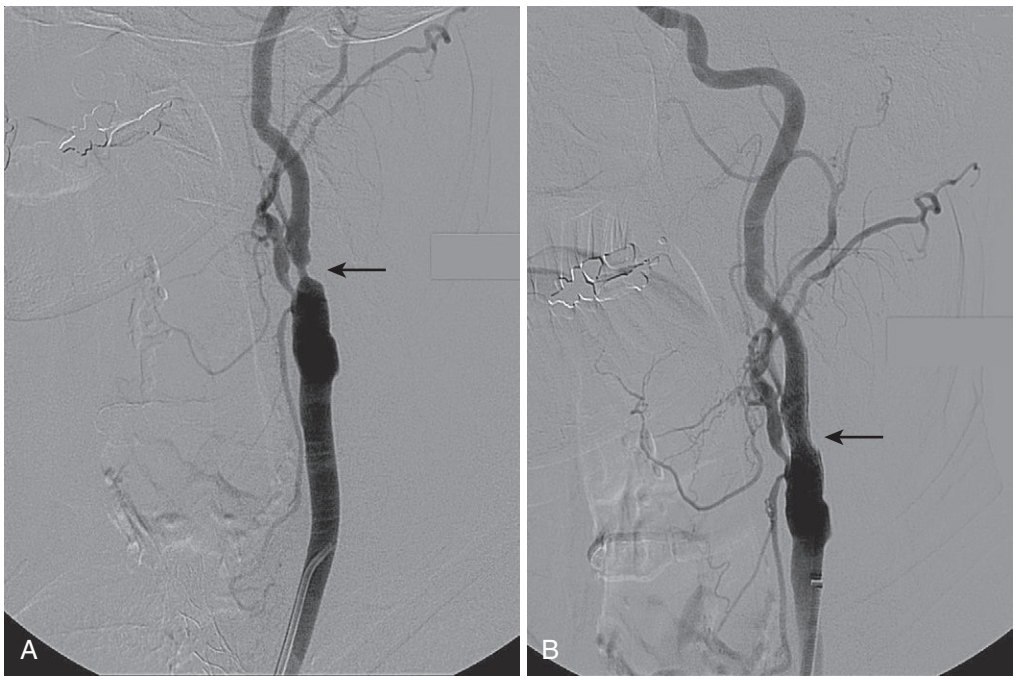


FIGURE 2 **A,** Schematic representation of a stent deployed across the carotid bifurcation to treat a proximal internal carotid artery lesion. Blood flow continues into the external carotid artery through the interstices of the stent. **B,** Digital subtraction arteriogram (DSA; left common carotid injection, lateral neck projection) showing a severe stenosis in the proximal internal carotid artery *(arrow)*. **C,** Completion DSA after placement of a stent across the carotid bifurcation. Note white linear markings of electronic calibrations for length and diameter measurements for planning of subsequent innominate stent placement. **B,** Digital subtraction arteriogram (DSA; right common carotid injection, lateral neck projection) showing high-grade recurrent stenosis after carotid endarterectomy in the distal common carotid artery *(larger arrow)* and the proximal internal carotid artery *(smaller arrow)*. Note the 360-degree loop *(circled)* in the internal carotid artery distal to the stenosis; the external carotid artery is superimposed in this projection. **C,** DSA after the lesions were successfully treated with two overlapping carotid stents. Distal internal carotid artery tortuosity precluded use of a distal filter. Note the wire still in this segment of the artery *(circled)*. **D,** Completion DSA after treatment of the innominate stenosis with a balloon-expandable stent based on electronically calibrated measurements done previously (see **A**). Innominate stenting was done immediately after the carotid stenting was accomplished. The bracket depicts the extent of the stent.

contrast, cervical carotid lesions are better treated with self-expanding stents that are tolerant of neck mobility and that spontaneously reexpand if externally compressed.

Self-expanding stents are made in two basic designs: open-cell and closed-cell. The advantage of an open-cell design is a greater flexibility that permits better vessel wall apposition and easier navigability through tortuous vascular anatomy. However, open-cell stents have the disadvantage of lower radial force that may limit stent expansion as a result of recoil, especially in heavily calcified lesions. Open-cell design may be more prone to in-stent restenosis. Closed-cell stents offer the advantage of greater radial force, but they are less flexible and more prone to result in kinking when used in tortuous arteries. The Space-Protected Angioplasty versus Carotid Endarterectomy (SPACE) trial suggested a higher rate of embolic complications with open-cell carotid stents. However, recent data show no differences in specific carotid stent cell designs with respect to risk of stroke or mortality.

Embolic Protection Devices

From the inception of CAS, the greatest concern has been the potential for atheroembolic stroke associated with the procedure. EPDs were incorporated into the CAS procedure to minimize this risk. Despite the absence of robust clinical or trial data establishing efficacy, use of an EPD during CAS has become generally accepted. EPDs provide temporary cerebral protection by one of the following methods (Figure 5): (1) balloon occlusion of the distal cervical ICA; (2) placement of a filter in the distal cervical ICA; and (3) balloon occlusion of the CCA combined with balloon occlusion of the ECA

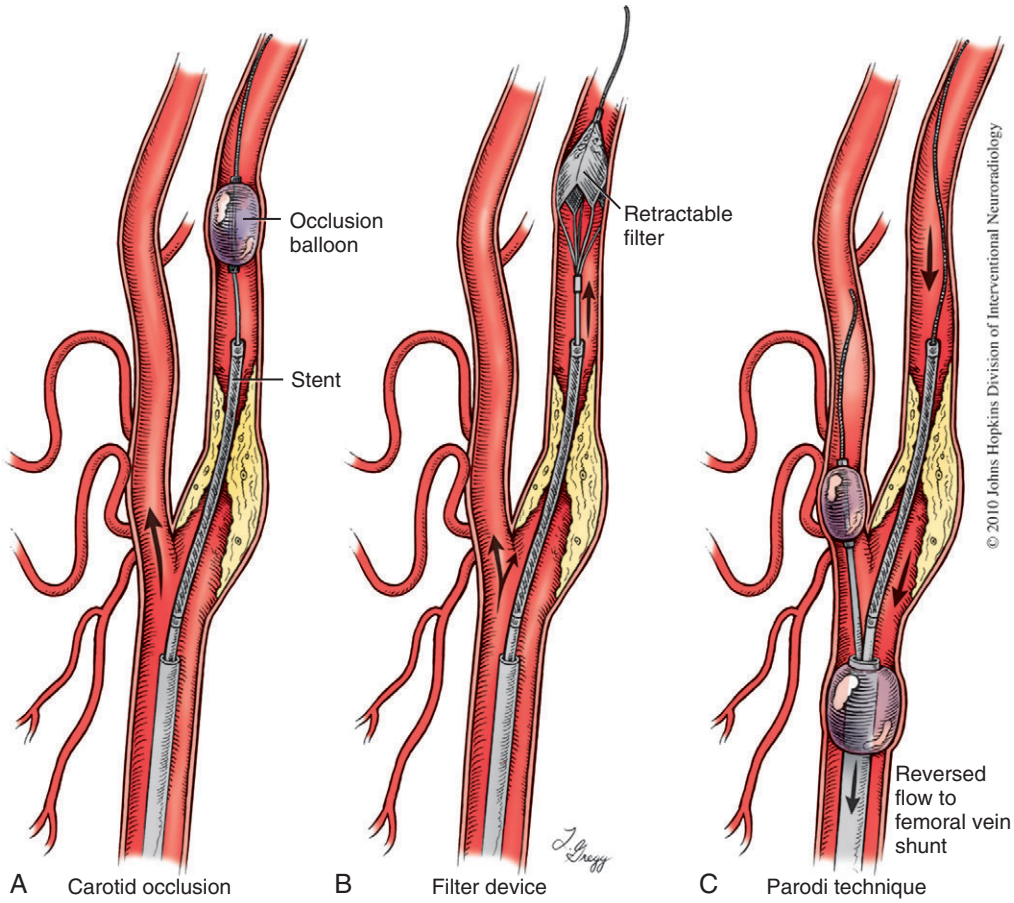

FIGURE 5 Schematic representation of the different methods of embolic protection devices. *Arrows* indicate the direction of blood flow. **A,** Distal occlusion. Stenting is performed with internal carotid artery flow temporarily interrupted by inflating a balloon within the distal internal carotid artery. After stent deployment and after dilation, stagnant blood proximal to the balloon, which may contain plaque debris, is aspirated through the delivery catheter. After aspiration, the dead space below the balloon is flushed with saline solution to chase any remaining material into the external carotid artery. The balloon is then deflated and removed. **B,** Distal filtration. A filter is delivered through the stenosis and deployed in the distal internal carotid artery by withdrawing its constraining sheath. After stenting, a recovery catheter is used to retrieve the filter and its contents. **C,** Proximal protection. During stenting, two occluding balloons are inflated, one in the common carotid artery and the other in the external carotid artery. Flow reversal is created either with active aspiration from the delivery catheter in the common carotid artery distal to the common carotid artery balloon or with directing flow from this catheter to a catheter in the femoral vein. With use of a system that returns blood to the femoral vein, a filter is used within the connection to trap debris from the carotid plaque. *(Illustration courtesy of Lydia Gregg, 2010 Johns Hopkins Interventional Neuroradiology.)*

and either aspiration or flow reversal in the ICA (proximal protection). Various EPDs are currently commercially available (Table 3).

Distal protection with either balloon or filter has the disadvantage that the carotid lesion must be crossed before initiation of cerebral protection. Nevertheless, because of simplicity and ease of use, and the avoidance of carotid flow interruption, distal protection with a filter has evolved as the most common method currently used for cerebral protection. However, transcranial Doppler scan studies have shown that particles smaller than the pore size of the filters (60 to 140 μm) can evade capture because of flow through the filter. Such microemboli may be associated with new white lesions on the diffusion-weighted MRI of the brain, but the clinical consequences of this "controlled embolization" are unclear. In addition, incomplete apposition of the filter rim to the vessel wall may allow emboli of various sizes to pass around the filter. Finally, filters occasionally can be difficult to retrieve and they may become occluded from obstructing debris captured during CAS.

With the distal balloon occlusion method, after the stent is deployed, a catheter is advanced across the treatment site and is used to aspirate debris before deflating and recovering the balloon. With the distal filter method, after stent placement, the filter attached to the working wire is recovered, bringing with it any plaque debris trapped in its mesh. In contrast, proximal protection methods involve the inflation of a balloon in the ECA and another on the guiding catheter in the CCA. With the Gore Flow Reversal System (W.L. Gore & Assoc., Newark, Del), a closed circuit is then established between the guiding catheter and the venous system by way of the femoral vein to create retrograde flow in the ICA being treated. A filter in the tubing that connects the guiding catheter to the femoral vein traps any embolic debris dislodged from the site of carotid stenting. With

the Mo.Ma Ultra device, (Medtronic, Minneapolis, Minn), after stenting, blood in the ICA is aspirated until clear of debris.

The concept of proximal protection is appealing because crossing the lesion with the protection device is not required. Recent reports suggest that proximal protection, in experienced hands, is associated with low risk of microembolic events during CAS, acceptable 30-day stroke and death rates, low incidence of femoral access complications, and low (less than 1%) rate of patient intolerance to temporary proximal occlusion. In addition, proximal embolic protection provides an option when marked arterial tortuosity or a limited landing zone precludes use of distal protection. Nevertheless, clinicians have been slow to adopt proximal protection devices because they require larger sheath access (9F or 9.5F), are more complicated to use than distal filter devices, and may be poorly tolerated by patients with poor intracranial collateral circulation. Also, this method of embolic protection has the disadvantage of limiting the ability of the operator to visualize angiographically the precise location of the lesion during stent deployment.

Special attention is appropriate for the small but important incidence of cerebral atheroembolization remote from the target lesion being stented, a situation for which an EPD is not helpful. These events probably result from catheter manipulation in a diseased aortic arch or branch vessel, sometimes involving the cerebral hemisphere contralateral to the site of treatment. This potential occurrence warrants extreme care and meticulous attention to catheter manipulations in these patients, who often have diffuse atherosclerotic disease. In patients who have a markedly diseased aortic arch or hostile arch anatomy for branch vessel access, transcervical access to the proximal CCA through a small incision low in the neck may provide safer access for CAS than a transfemoral approach.

PERIPROCEDURAL MANAGEMENT

Antiplatelet Therapy

As mentioned previously, antiplatelet therapy is essential for success of CAS. Dual antiplatelet therapy with clopidogrel (75 mg daily) and aspirin (81 or 325 mg daily) is the current standard. The considerable individual variation in the degree of platelet inhibition provided by antiplatelet therapy is now well known. Information is accumulating about the impact of clopidogrel or aspirin resistance on long-term stent patency and restenosis rates. Testing for such resistance may become a more common practice in the future to foster individualization of antiplatelet therapy. Ticlopidine (250 mg twice daily) can be used in patients who cannot tolerate clopidogrel. If a patient cannot take antiplatelet therapy, carotid stenting should be reconsidered, as the postprocedural stroke risk is unacceptably high. Dual antiplatelet therapy should be continued for at least 3 months after the stent procedure, and daily aspirin should be continued indefinitely thereafter.

Glycoprotein IIb-IIIa inhibitors are associated with increased risk of intracranial hemorrhage after carotid stenting, and their role should be confined to the treatment of acute thrombus formation during or immediately after the procedure. For management of acute in-stent thrombosis, abciximab is administered by giving one half of the 0.25-mg/kg bolus dose intraarterially near the clot and administering the second half of the bolus dose intravenously over 5 minutes, followed by an intravenous infusion of 0.125 μg/kg/min for 12 to 24 hours.

Hemodynamic Instability

Periprocedural bradycardia caused by carotid sinus stimulation has been associated with inflation of the angioplasty balloon in the proximal ICA. It is rarely seen in patients who have previously undergone CEA, probably because of the denervating effect of surgical dissection near the carotid bulb. Periprocedural bradycardia has been infrequent in the author's practice, possibly related to routine use of atropine intravenously just before angioplasty balloon inflation. However, bradycardia, profound hypotension, and asystolic cardiac arrest can occur. Refractory periprocedural bradycardia is managed with cardiac pacing in addition to atropine administration.

Arterial hypotension may accompany periprocedural bradycardia and is usually managed with volume expansion. Moderate bradycardia and mild hypotension, similar to that seen occasionally after CEA related to carotid baroreceptor stimulation, are best treated with fluid supplementation, close observation for any neurologic dysfunction, and occasional use of low-dose vasopressor support.

Control of postprocedural hypertension is important to minimize risk of cerebral hyperperfusion syndrome (CHS). Severe headache associated with hypertension after CAS should heighten suspicion of CHS, which can also present with seizures and focal neurologic deficits. Proper management of CHS entails early diagnosis, rapid control of hypertension, anticonvulsant therapy, osmotic diuresis, and neurologic consultation.

Distal cervical ICA vasospasm is sometimes induced with catheter or wire manipulation or with distal filter or balloon placement. Avoidance of movement of the distal filter once deployed helps to minimize vasospasm at the site. Resolution of the vasospasm often occurs spontaneously but can be hastened with transcatheter administration of nitroglycerin (200-μg bolus) into the involved artery.

Periprocedural Neurologic Assessment

Distal embolization is one of the main complications of CAS, but the consequences of cerebral embolic events vary widely. Microemboli may produce white lesions on diffusion-weighted MRI scan without apparent neurologic sequelae. Larger emboli may produce a small stroke with MRI yet remain clinically silent or they may cause devastating neurologic deficit, depending on the function of the cerebral tissue that has been damaged. Therefore, operators who perform CAS must be familiar with the anatomy of the brain and its vasculature so that intracranial cerebral branch vessel occlusion can be readily

identified. It is equally important that operators be thoroughly familiar with normal neurologic function and the clinical manifestations of stroke. In addition, dedicated expert neurologic support is essential for a successful carotid stenting program.

Follow-up

Patients are usually discharged from the hospital on the day after undergoing CAS. Follow-up office visit occurs 4 to 6 weeks after surgery, again 6 months later, and annually thereafter. Follow-up includes a complete neurologic assessment and carotid ultrasound scan examination. Each visit also includes a global cardiovascular evaluation with emphasis on possible coronary, renal, and peripheral arterial occlusive problems. Hypertension and hypercholesterolemia are managed aggressively. Because of antiinflammatory and plaque stabilization effects, statin therapy is advised for almost all patients, even in the absence of laboratory evidence of cholesterol abnormalities. Healthy lifestyle habits are encouraged, with emphasis on regular aerobic exercise, dietary discretion, and complete abstinence from tobacco use.

SUMMARY AND PERSPECTIVE

Results of clinical trials have shown that both CAS and CEA are effective procedures for stroke prevention; each has an important place in carotid disease management. Defining the clinical situations treated best with one procedure or the other, or with medical management alone, continues to be an evolving process.

Currently, concerns about higher stroke risk with CAS, coupled with reimbursement restrictions and cost-effectiveness issues for CAS, make CEA the standard, and much more commonly performed, method of treating carotid occlusive disease when intervention is warranted. In the author's practice, CAS is reserved for patients with recurrent stenosis after CEA, a history of neck irradiation or radical neck dissection, lesions located high in the neck (above the level of the C2 cervical vertebra), and contralateral vocal cord paralysis. Most of the author's patients undergoing CEA are at "high risk" with traditional trial criteria, and only rarely is the author compelled to use CAS because of extreme cardiopulmonary risk factors that make surgical treatment prohibitive.

CAS should be used with reservation in situations where the risk of periprocedural stroke is higher than usual. These circumstances involve both clinical and anatomic factors. Clinical factors include age older than 80 years and recent (within 2 weeks) neurologic ischemic symptoms. Anatomic factors include vessel angulation greater than 60 degrees, heavily concentrically calcified lesions, heterogeneous plaque composition as assessed with grayscale ultrasound scan, and a severely diseased aortic arch, especially when combined with branch vessel configuration that is hostile for sheath access.

In the future, technologic advances will probably make CAS safer and more attractive as a replacement for CEA in many cases. Also, more frequent use of proximal embolic protection, replacement of bare metal stents with covered stents, and selective use of transcervical access may lower the stroke risk of CAS. In the meantime, skilled vascular surgeons who are trained and experienced in performing both CAS and CEA bring a unique perspective and ability to judge the multiple variables that must be weighed carefully in deciding which of these two good procedures is the better choice for an individual patient.

The Management of Aneurysms of the Extracranial Carotid and Vertebral Arteries

Jerry Goldstone, MD, FACS, FRCSEd (hon), and Virginia L. Wong, MD, FACS

INTRODUCTION

Atherosclerotic occlusive and ulcerated lesions of the cervical carotid arteries are extremely common, but aneurysms of these vessels are rare, particularly when compared to the frequency of aneurysms involving the intracranial carotid arteries and their branches. Contemporary reports indicate that only 0.2% to 2% of all carotid procedures are performed for aneurysms. In the most recent review, there were 19 operations for aneurysms during an interval in which over 3000 procedures were performed for occlusive disease. Vertebral artery aneurysms are even rarer. Thus, there are no randomized or even large studies available, leaving relatively small, single-institution case series as all that are available to guide management and predict outcomes.

CAROTID ARTERY ANEURYSMS

Etiology

In early reports there was a predominance of infectious causes of extracranial carotid aneurysms, many associated with pharyngeal and other head and neck septic lesions. These occurred mostly in younger patients who had tonsillar and pharyngeal infections, such

as peritonsillar abscess. With the availability of antibiotics, infected carotid aneurysms have largely disappeared except for those caused by infected prosthetic patches after carotid endarterectomy. The majority of carotid aneurysms now are either atherosclerotic or degenerative in nature. These are true aneurysms, commonly saccular rather than fusiform in shape and involve the carotid bifurcation and first portion of the internal carotid artery. About 15% of carotid aneurysms are pseudoaneurysms caused by patch infection following carotid endarterectomy or trauma (blunt, penetrating, and iatrogenic). Patch angioplasty–related aneurysms occur at the carotid bifurcation. There have been a few reports of infected carotid stents causing carotid aneurysms. Blunt traumatic injuries tend to involve the distal extracranial internal carotid artery, whereas most penetrating injuries, which can cause A-V fistulas as well as pseudoaneurysms, tend to involve the common carotid. The increased use of computed tomographic (CT) scans and magnetic resonance (MR) scans in trauma centers has identified carotid aneurysms that were previously not detected, so the proportion caused by trauma may be underestimated. Less frequent causes include dissection, fibromuscular dysplasia, Becet's disease, and other collagen vascular diseases. A recent report from South Africa described the emergence of human immunodeficiency virus (HIV)-related vasculopathy as an increasing cause of carotid aneurysms. In addition, extensive head and neck surgery and radiation have been cited as etiologic factors in carotid aneurysms.

Presentation and Diagnosis

Due to the changing etiology, most carotid aneurysms now occur in adults. For atherosclerotic aneurysms, the average age is over 60 years, with a 2:1 male preponderance. Patients are frequently asymptomatic at presentation, with a pulsatile neck mass being the most frequently encountered sign, present in more than 90% in some series. Symptoms, when present, vary depending on the size, location, and etiology of the aneurysm. They often consist of ischemic neurologic events such as transient monocular or hemispheric ischemic attacks or frank stroke caused by thromboembolic phenomena. Compressive symptoms from the aneurysm itself can cause neck pain and facial pain, headache, cranial nerve palsy, Horner's syndrome, hoarseness, and dysphagia. Patients with an infectious etiology may have leukocytosis and other signs of local sepsis such as peritonsillar abscess or overlying cervical cellulitis. Rupture, which was common in the preantibiotic era, is now rare, but may occur into the pharynx or externally through a draining sinus (as might occur with an infected pseudoaneurysm following carotid endarterectomy). Victims of penetrating trauma are mostly young adults with obvious cutaneous wounds but who rarely have isolated carotid injuries and who may not be actively bleeding when initially evaluated. This makes probing cervical wounds potentially dangerous and is why it should be avoided until adequate imaging has been performed.

The differential diagnosis of a pulsatile neck mass includes carotid artery redundancy (kink, coil, loop), carotid body tumor, paraganglioma, malignant neoplasm, lymphadenopathy, brachial cleft cyst, and peritonsillar abscess. A pulsatile mass at the base of the neck is one condition frequently misdiagnosed as a common carotid aneurysm. It is almost always a dilated tortuous subclavian artery, and almost always on the right side in middle-aged hypertensive women.

Duplex ultrasound should be the initial diagnostic modality (Figure 1). It is useful for vessels from the clavicle to just above the mandible and can determine aneurysm size, extent, flow characteristics, presence of mural thrombus, and dissection. Due to the presence of the mandible, lesions located high in the neck or near the skull base cannot be interrogated by ultrasound and may be missed altogether with this modality. The same is true for proximal common carotid aneurysms due to the clavicle. CT and MR are invaluable for visualizing these lesions and surrounding structures. In most centers, CT or MR angiography (CTA, MRA) can be quickly performed, allowing three-dimensional image reconstruction that provides a high-quality, detailed definition of arterial anatomy that is essential for proper treatment planning. These studies can be obtained more quickly than and can avoid the risks of catheter-based angiography, but angiography is still required when endovascular therapy is being considered. One major advantage of catheter angiography is that it allows for the measurement of carotid back pressure and balloon occlusion testing, which is helpful if carotid ligation is a possible treatment alternative.

Indications for Intervention

Intervention for carotid artery aneurysms is appropriate for the relief of symptoms caused by local compression as well as for the treatment of hemorrhage that, although rare, is associated with high rates of morbidity and mortality. The natural history of asymptomatic extracranial carotid aneurysms is not known, but the primary indication for treatment is the prevention of new or recurrent neurologic events caused by embolism of aneurysm contents into the cerebral circulation. In Winslow's classic 1926 article, nonoperative management resulted in a 70% mortality rate due to thrombosis, embolism, and rupture. Contemporary reports have not refuted these data, although some suggest that anticoagulation and antiplatelet therapy may be sufficient for selected asymptomatic patients with small, distal aneurysms caused by blunt trauma or dissection. These reports present follow-up imaging that demonstrated stabilization or resolution of the arterial pathology without clinical consequences in at least some of the patients. This approach requires close monitoring of the patients with prompt intervention for lesions that enlarge or become symptomatic. This type of observational approach is quite controversial, with most authors favoring treatment of all of these aneurysms, regardless of size, because of their potential to cause neurologic symptoms.

Treatment

A careful baseline neurologic evaluation should be performed before undertaking repair by any method. For patients with atherosclerotic aneurysms, cardiac risk assessment is appropriate. For open surgical repair, the need for intraoperative cerebral perfusion monitoring and protection should be taken into account because carotid clamp times are generally longer than required for carotid endarterectomy. Electroencephalography, transcranial Doppler, carotid back (stump) pressure measurement, and routine shunting have all been used successfully for this purpose. If an interposition vein graft is going to be used, a small, short shunt should be selected so that it can be placed through the vein. Although carotid endarterectomy using local-regional anesthesia can be successfully performed, general anesthesia is recommended for the treatment of carotid aneurysms because of the time required for a more difficult and extensive dissection and the need for more extensive cervical exposure and complex arterial reconstruction.

The objectives of treatment for most patients are to exclude the aneurysm from the circulation and restore cerebral blood flow to prevent neurologic events. The treatment selected will depend on the location and etiology of the aneurysm. As discussed earlier, the location varies with etiology. Atherosclerotic aneurysms most commonly occur at or near the bifurcation of the common carotid artery, as do pseudoaneurysms following endarterectomy (Figures 2 and 3). Injuries due to blunt trauma and arterial dysplasia occur much higher in the internal carotid artery toward the base of the skull (Figure 4). Proximal exposure of the common carotid artery and its bifurcation can be achieved through a standard longitudinal incision along the anterior border of the sternocleidomastoid muscle. This incision can be extended behind the ear if necessary to gain more distal exposure. Care must be taken to avoid manipulation of the aneurysm itself to

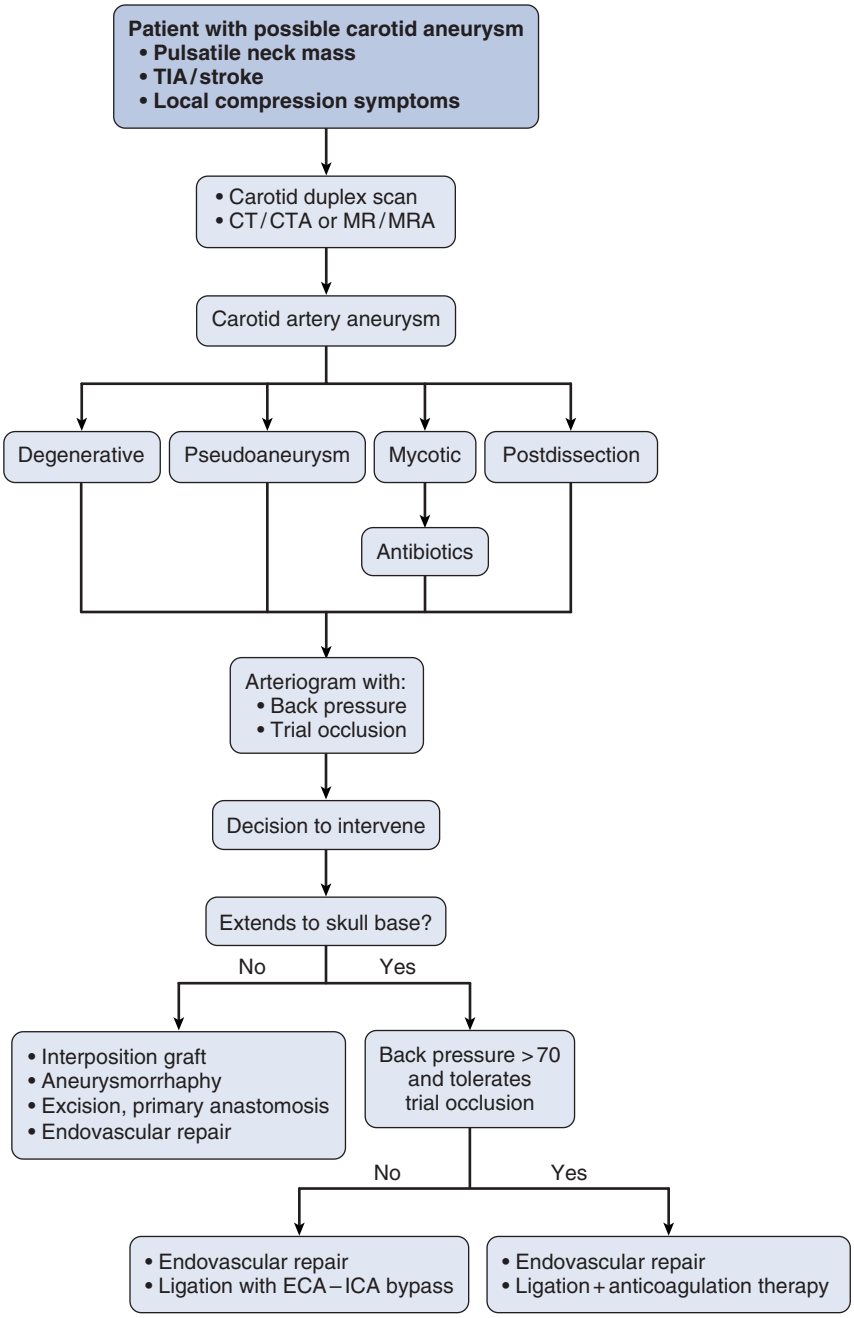

FIGURE 1 Algorithm for diagnosis and treatment of carotid aneurysms. *CT/CTA,* Computed tomographic/CT angiography; *ECA,* external carotid artery; *ICA,* internal carotid artery; *MR/MRA,* magnetic resonance/MR angiography; *TIA,* transient ischemic attack.

prevent dislodgement of thrombotic material before application of a distal occluding clamp (or vessel loop).

Several cranial nerves may be encountered in the operative field, including IX, X, XI, XII, and the marginal mandibular branch of VII, and these must be carefully protected from injury. Aneyrysm growth may have distorted the nerves' usual anatomic courses, and they may be densely adherent to the aneurysm or other structures. Use of bipolar cautery is an important adjunct when working close to these nerves. Exposure of the more distal portion of the internal carotid artery requires uncommon maneuvers, such as division of the digastric muscle, removal of the sternocleidomastoid muscle from its insertion on the mastoid, elevation of the parotid gland, and excision of the styloid process. If anticipated in advance, distal carotid exposure is facilitated by the use of nasotracheal rather than orotracheal intubation and subluxation of the mandible. Control of backbleeding from the distal internal carotid artery can be achieved with an intraluminal balloon catheter (or shunt) rather than a cross clamp. However, if still more distal exposure is necessary to permit arterial reconstruction, portions of the mastoid and petrous portion of the temporal bones can be removed. Participation of an otolaryngologist or neurosurgeon experienced in skull-base surgery is recommended for these maneuvers. The difficulties and morbidity with this type of distal exposure favor an endovascular approach whenever possible.

Open reconstructive options include ligation, resection with patch closure, or resection with restoration of arterial continuity using conduits. Ligation is the oldest form of therapy and technically the least demanding. It may be the only option for high lesions for which distal access to and control of the internal carotid artery cannot be achieved in spite of the maneuvers described or for rapid control when there is exsanguination from rupture or trauma. Unfortunately, ligation is associated with a high risk of stroke and mortality (30% to 60%).

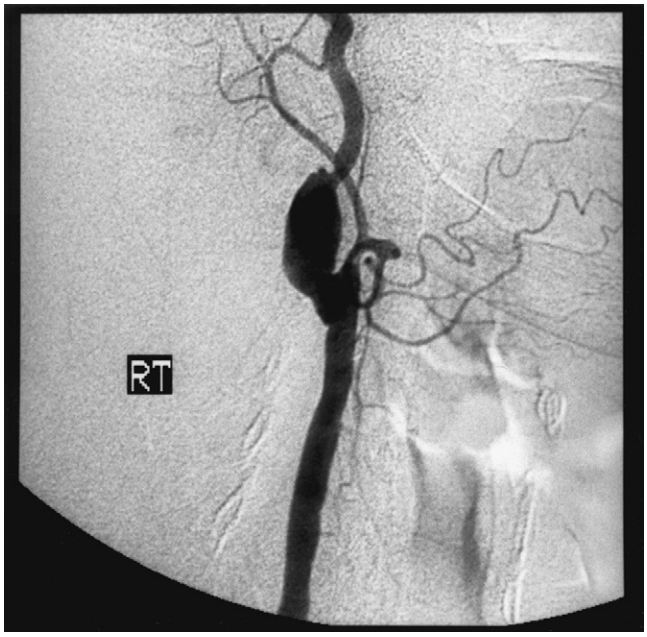

FIGURE 2 Digital subtraction angiogram showing atherosclerotic aneurysm of internal carotid artery.

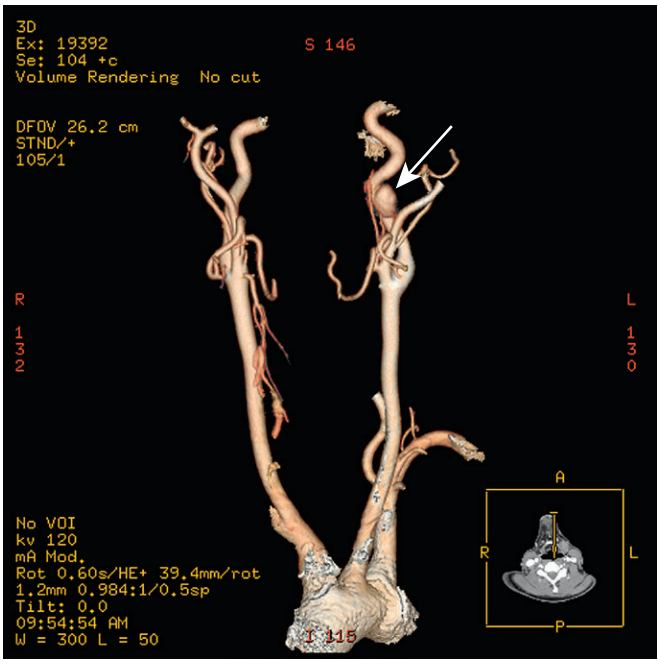

FIGURE 4 CT angiogram showing traumatic pseudoaneurysm *(arrow)* of mid-distal internal carotid artery caused by fractured mandible.

FIGURE 3 Digital subtraction angiogram showing pseudoaneurysm of left carotid bifurcation at site of previous carotid endarterectomy.

Identification of patients who will tolerate carotid ligation can be accomplished preoperatively by performing a balloon occlusion test at the time of cerebral angiography. After heparinization, a balloon is inflated in the internal carotid artery to stop antegrade cerebral flow for approximately 30 minutes while monitoring the patient's neurologic status for changes. Carotid back pressures of 70 mm Hg or greater are usually associated with freedom from neurologic symptoms and indicate collateral cerebral perfusion that is adequate to permit carotid ligation when necessary. Intraoperatively measured carotid back pressure at the same level can be used for the same purpose, but under conditions of general anesthesia, there is no way to monitor cerebral function. When this is done, maintenance of the patient's baseline blood pressure is essential. Postprocedure anticoagulation should be maintained for 6 to 12 weeks to prevent propagation and downstream embolization of thrombus off the static column of the ligated internal carotid artery. Patients who cannot tolerate carotid ligation due to low back pressure and symptoms with trial occlusion should be considered for extracranial-intracranial (EC-IC) bypass, an effective but infrequently performed procedure, before aneurysm ligation.

Aneurysm resection and patch repair of the ICA is appropriate for small-necked, saccular aneurysms or noninfected pseudoaneurysms. Use of autologous vein (usually the greater saphenous vein from the groin), bovine pericardium, and prosthetic material for patches have all been described. We have used bovine pericardium as a patch almost exclusively in recent years, even in infected fields. Prosthetic material should not be used as either a patch or conduit if the possibility of infection exists as the etiology of the aneurysm.

Complete resection of the aneurysm with restoration of arterial continuity is the preferred technique for fusiform or wide-mouthed aneurysms. If there is redundancy of the internal carotid, it is sometimes possible to mobilize enough vessel to be able to perform an end-to-end anastomosis or perform an anastomosis to the external carotid artery if it is intact. Interposition grafting can be performed using greater saphenous vein or prosthetic (Figure 5). If the field is infected and no autologous vein is available, an arterial autograft can be obtained from the superficial femoral artery, and that artery can be replaced with a prosthetic conduit in a noninfected field. In a few

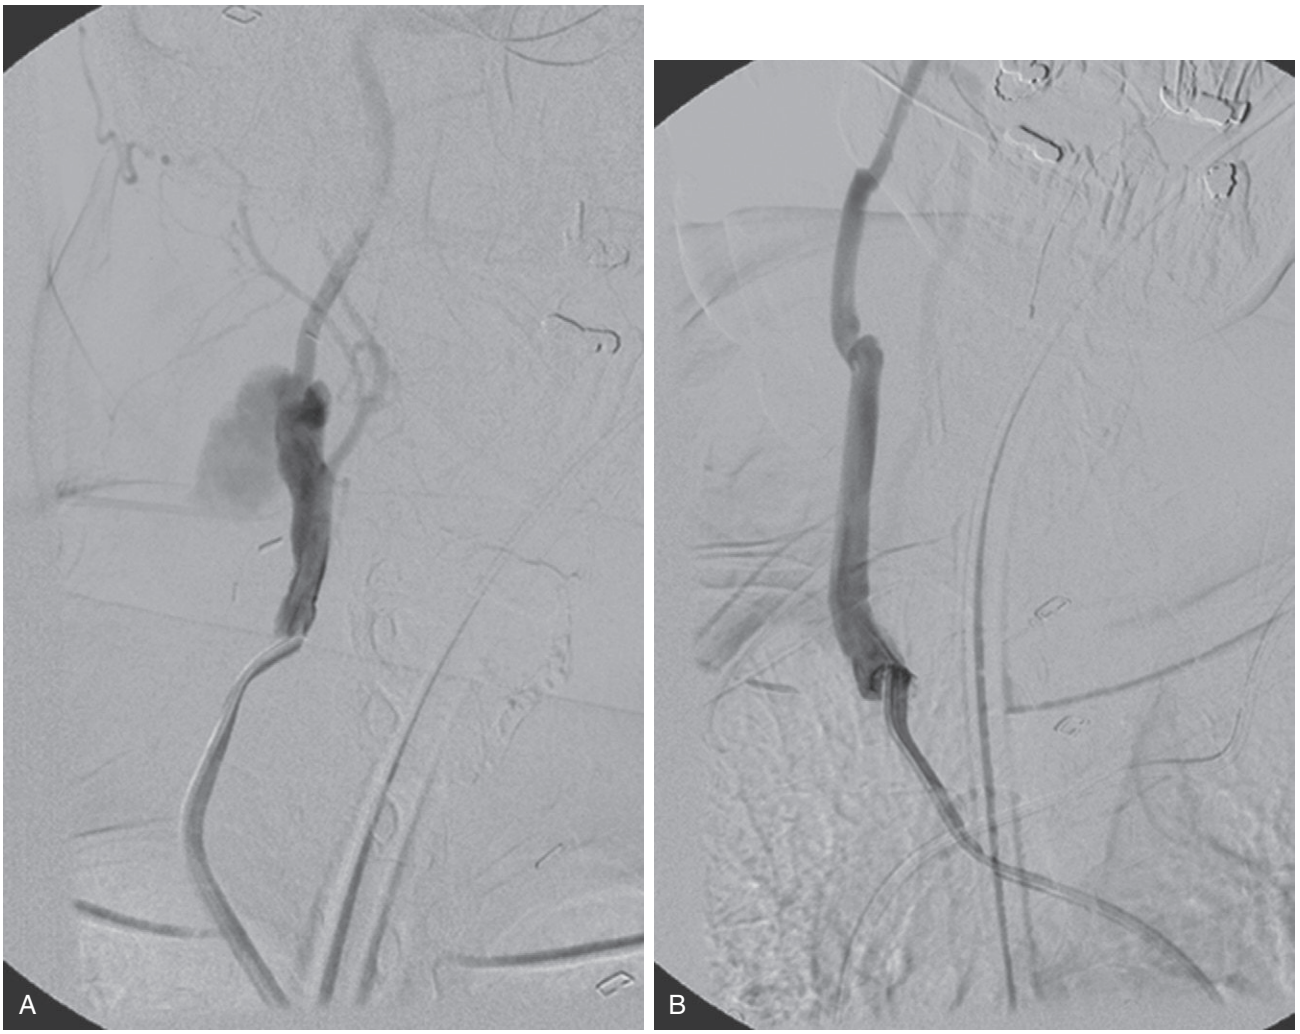

FIGURE 5 Digital subtraction angiogram of carotid aneurysm before (**A**) and after (**B**) repair with interposition vein graft. *(Courtesy of Wei Zhou, MD, Baylor College of Medicine.)*

cases, we have even used a segment of endarterectomized, occluded superficial femoral artery. Use of a shunt is facilitated by threading the shunt through the graft while the distal anastomosis is being completed and then removing it just before completion of the proximal anastomosis. For cases that are infectious in nature, culture-specific or broad spectrum antibiotics should be administered before the operation begins and continued for several weeks postoperatively. Intraoperative cultures are important for proper antibiotic selection. This process is especially important if methicillin-resistant *Staphylococcus aureus* is known or suspected of being the causative organism. All nonviable and infected tissues should be thoroughly débrided, and the arterial reconstruction should be covered with healthy vascularized tissue, ideally the sternocleidomastoid muscle. For some cases, particularly those with previous treatment for head and neck cancer, a myocutaneous flap may have to be created to ensure adequate vessel coverage.

Endovascular treatment of carotid artery aneurysms has become more common along with the advances in endovascular devices and the growing experience with the endoluminal treatment of carotid occlusive disease. Endovascular treatment avoids the need for the often difficult dissections, especially for high cervical exposure. The risks of bleeding and cranial nerve injury are markedly reduced. Multiple case reports populate the literature, and although 70% of cases in a 2006 report were treated endovascularly, no large series have been reported. Even more recent publications from 2010 and 2012 had only 0 of 19 and 3 of 30 aneurysms, respectively, treated with stents. Endovascular treatment requires an experienced staff, a modern imaging suite, and appropriate equipment and devices, including carotid-specific stents and embolic protection devices. Suitable patients must have aortic arch anatomy that can accommodate stable, selective catheterization of the common carotid artery with a large-caliber, long sheath over a supportive wire. Endovascular treatment should be preferentially considered for surgically inaccessible lesions, when there is a hostile operative field (prior radiation or cervical surgery), or for patients deemed unfit for a lengthy general anesthetic.

Although treatment techniques have mostly used a transfemoral approach, both transaxillary and transcarotid approaches have been described. Following systemic heparinization and selective catheterization of the common carotid artery with the long sheath, an embolic protection device is deployed in the internal carotid artery distal to the aneurysm. Bare metal stents, double stents, vein-covered stents, and prosthetic-covered stents have all been successfully used. Covered stents are most frequently used, but they require larger sheaths and delivery systems. The covered stent (stent-graft) can then be deployed across the aneurysm to exclude it from the circulation, thereby preventing expansion and rupture as well as emboli entering the flow channel. Accurate sizing of the proximal and distal landing zones is necessary to ensure adequate seal. The stent may occlude side-branch flow—that is, the external carotid artery—but this is

usually well tolerated. Bare metal stents can be used to tack down a dissection entry point (flap) or even to cover a small aneurysm neck sufficient to impede flow and cause aneurysm sac thrombosis. Thrombogenic materials, such as microcoils, detachable balloons, synthetic particles, or glue, can be injected directly into the aneurysm sac through the interstices of a noncovered stent to induce thrombosis. However, extreme care must be taken to prevent the escape of such materials into the parent artery, which could cause thrombosis or distal embolization. Postprocedure antiplatelet therapy should be administered as with carotid stenting for occlusive disease.

Results

There are no randomized or controlled trial data available for analysis of the treatment of extracranial carotid artery aneurysms. Proximal lesions and those associated with a very tortuous internal carotid are probably best managed with open surgical repair, whereas large aneurysms and those involving the distal one third of the internal carotid are safer managed with endovascular techniques. The results of observation alone, with or without anticoagulation, parallel the natural history of the disease with 50% to 70% morbidity and mortality rates. Ligation also results in a high rate of stroke and death ranging from 30% to 60%, but careful patient selection can reduce this risk substantially, as shown in one recent report of a 12% stroke and death rate. Results of open surgical treatment with arterial reconstruction are much better and appear to vary with the size, location, and etiology of the lesion. In the report from the Texas Heart Institute, which included data from 13 single-center series that were reviewed in that paper, combined stroke and mortality was just 10%. The average rate of cranial nerve injury, which is more frequent in repairs involving the distal internal carotid artery, is much higher at approximately 30%. Fortunately, many of these cranial nerve deficits are temporary. Long-term results also seem to be generally favorable, with most deaths occurring from other cardiovascular diseases or diagnoses not related to the carotid aneurysm repair. In patients who have had postprocedure imaging studies, most arterial reconstructions have been reported as patent, and those that were not usually were not associated with symptoms.

Initial technical success rates with endovascular treatment are high, with acceptably low periprocedural stroke and death rates, but all reported series are small. Cranial nerve injuries, access site complications, and hospital length of stay are all reported to be much lower when compared to open repair. Short-term and midterm results of up to 4.5 years after treatment are encouraging with persistent exclusion of the aneurysm and patency of the parent vessel. It is somewhat surprising that there are not more long-term data published about this subject.

VERTEBRAL ARTERY ANEURYSMS

Extracranial carotid aneurysms are rare, but vertebral aneurysms are extremely rare. Most are caused by blunt and penetrating trauma, resulting in pseudoaneurysm formation or true aneurysmal dilatation following intimal dissection. Spontaneous dissection has been the most frequent etiology in several recent reports. Forceful head turning from trauma or iatrogenic manipulation (chiropractic), vascular catheterization, arterial dysplasia, prior radiation, and collagen vascular disease have all been described as causes of vertebral artery aneurysm.

The most frequent manifestations are headache and neck pain or symptoms of vertebrobasilar territory ischemia. If the intracranial portion of the vertebral artery is involved, rupture can cause subarachnoid hemorrhage. Palpation of a pulsatile neck mass is less frequent than with carotid aneurysms. Duplex ultrasound is not very useful for evaluation of vertebral arterial pathology other than the determination of the presence of flow and flow direction. The best diagnostic imaging modality in the past has been contrast angiography, but CTA and MRA are now favored because they are quicker to obtain and provide important anatomic information about the vessels and adjacent structures that may influence the interventional approach. More than 80% of vertebral dissections resolve spontaneously, and for this reason, most patients can be managed nonoperatively with anticoagulation and close follow-up with repeat imaging. However, in patients with hemorrhage (i.e., rupture), continued neurologic symptoms, aneurysmal enlargement or absence, or impaired flow in the contralateral vertebral artery, intervention may provide the best outcome.

Surgical exposure of the vertebral artery can be challenging due to its anatomic position, arising from the subclavian artery (V1 segment) deep in the neck and then running within the transverse processes of the cervical vertebrae emerging at the level of C-2 (V2 segment), where it courses around the transverse process (V3 segment) and enters the foramen magnum (V4 segment). Exposure of the proximal vertebral artery from its origin off the subclavian to where it enters the vertebral foramen of C-6 is achieved through a transverse supraclavicular incision. Repair options here include ligation, resection with repair, transposition onto the common carotid artery, or bypass from the subclavian. All of these are challenging due to the small working space and the short segment of artery available. If the contralateral vertebral artery is normal, it is safer in most cases to simply ligate the affected artery. However, this does not always solve the problem of bleeding because of backflow from the contralateral vertebral artery, so distal ligation or balloon occlusion is also required.

Surgical repair of the vertebral artery in its intraosseous location can be especially challenging due to bony structures and the luxuriant venous plexus that accompanies the artery at this location. The more distal portions of the vertebral artery at C-2 and above also provide challenges to exposure because most vascular surgeons have little experience working in this area. A posterior cervical approach may be necessary, and repair is accomplished by bypass from the carotid or subclavian arteries to the distal vertebral or transposition of the vertebral to the carotid circulation. Because of these technical challenges, there has been widespread adoption of endovascular treatment. Endovascular access and repair using covered stents, detachable coils, or balloons have been reported for lesions at all levels of the vertebral artery and may be especially useful for surgically inaccessible areas. Both ligation and endovascular occlusion of the vertebral artery are well tolerated in the presence of a normal contralateral vertebral artery. With both methods, trapping the aneurysmal segment of artery both proximally and distally may be necessary to control bleeding or aneurysm expansion. An aneurysm involving a dominant or single vertebral artery is best treated by a method designed to maintain its patency and prevent distal embolization. Both intraluminal stents and bypass with aneurysm exclusion have been used successfully with good results.

Brachiocephalic Reconstruction

Gregory J. Pearl, MD

INTRODUCTION

The most common anatomic configuration of the brachiocephalic vessels off the transverse aortic arch is three separate and discreet branches: the innominate artery, the left common carotid artery, and the left subclavian artery. The innominate artery gives rise to the right subclavian and right common carotid artery. The most common variant of arch anatomy is the bovine arch in which the left common carotid artery shares a common origin with the innominate artery off the arch or that arises directly off the innominate artery. Other variants include the left vertebral artery arising directly off the arch between the left common carotid and the left subclavian arteries and the aberrant right subclavian artery that arises just distal and posterior to the left subclavian artery, coursing across the midline between the esophagus and anterior spinal ligament to the right upper extremity (Figure 1).

The brachiocephalic vessels supply the upper extremities as well as the brain, so any disease entity that affects these vessels, either as a result of flow limiting stenosis or as a source of embolization, may produce serious symptoms that are difficult to correct surgically (Figure 2). The underlying lesions affecting the great vessels may be a result of, and associated with, disease arising in the aortic arch or may be secondary to lesions intrinsic to the brachiocephalic vessels themselves. The pathologic entities include atherosclerotic disease, inflammatory arteritides, blunt or penetrating trauma, or a pathologic process involving the ascending or transverse aortic arch such as aortic dissection or aneurysm. Additionally, occlusive or aneurysmal lesions of the subclavian arteries may be associated with arterial thoracic outlet syndrome. Debranching procedures of the brachiocephalic vessels have also become an important adjunct in the endovascular treatment of aortic dissections or aortic aneurysmal disease involving the transverse arch or proximal descending thoracic aorta.

CLINICAL PRESENTATION

The clinical manifestations of lesions involving the brachiocephalic arteries are in large part dependent on the underlying pathogenesis and extent of vessel involvement, such as single-vessel versus multivessel disease, as well as the anatomic location of the culprit lesions. In Berguer's report on brachiocephalic revascularization, he identified an approximately 40% incidence of multivessel involvement of the brachiocephalic arteries.

Atherosclerotic disease involving the arch vessels is not uncommon and in most instances is asymptomatic. Symptoms caused by occlusive lesions involving the brachiocephalic vessels may be those typical of carotid artery distribution transient ischemic attack (TIA) or stroke, vertebrobasilar events, or upper-extremity ischemia such as arm fatigue or digital ischemia. Multivessel occlusive lesions, as seen in patients with advanced atherosclerotic disease or Takayasu arteritis, may produce nonlateralizing neurologic symptoms such as dizziness and visual disturbances secondary to cerebral hypoperfusion. Patients presenting with classic lateralizing hemispheric neurologic events that cannot be attributed to cervical or intracranial carotid disease should undergo aggressive interrogation of the brachiocephalic vessels as a potential source of these symptoms.

Severe occlusive disease in the proximal subclavian arteries may produce reversal of flow in the ipsilateral vertebral artery, leading to the condition known as subclavian steal syndrome. Reversal of flow in the vertebral artery noted on duplex ultrasound examination of the neck is not an uncommon finding and is frequently asymptomatic. However, in the classic clinical picture of subclavian steal, the patient will experience typical symptoms of vertebrobasilar insufficiency associated with arm exercise. Complaints of arm fatigue secondary to proximal subclavian atherosclerotic occlusive disease are uncommon due to the extensive capacity of collateral flow to the upper extremity combined with the decreased physical demands inherent in the atherosclerotic age group and therefore rarely require intervention. However, findings of unilateral digital ischemia as a result of microembolization should lead to a high index of suspicion for the culprit lesion to be located in the proximal subclavian or brachiocephalic vessels. Interrogation for the source lesion in this setting should not be delayed and should be pursued aggressively because ongoing embolization could potentially lead to extensive distal tissue loss and consequent severe functional impairment.

DIAGNOSTIC EVALUATION

A thorough history and physical examination are paramount in the initial evaluation of these patients. Careful palpation of the carotid and upper-extremity pulses in conjunction with auscultation of the neck, including the parasternal and paraclavicular areas, for the presence of bruits is necessary. Bilateral upper-extremity blood pressure measurements may easily and quickly be performed and yield useful information if a significant discrepancy is discovered. Any significant alteration in the comparison of the quality of pulses, the presence or absence of bruits, or significant upper-extremity blood pressure discrepancies of greater than 20 mm Hg is highly suggestive of hemodynamically significantly subclavian or brachiocephalic disease. Of note, a significant blood pressure discrepancy in the upper extremity in an asymptomatic elderly patient is not uncommon and does not necessarily warrant additional investigation in the absence of symptoms or worrisome physical findings of digital ischemia.

Duplex ultrasound is extremely useful and sensitive in the interrogation of the cervical portion of the carotid arteries; however, it is of more limited use in the assessment of the brachiocephalic vessels

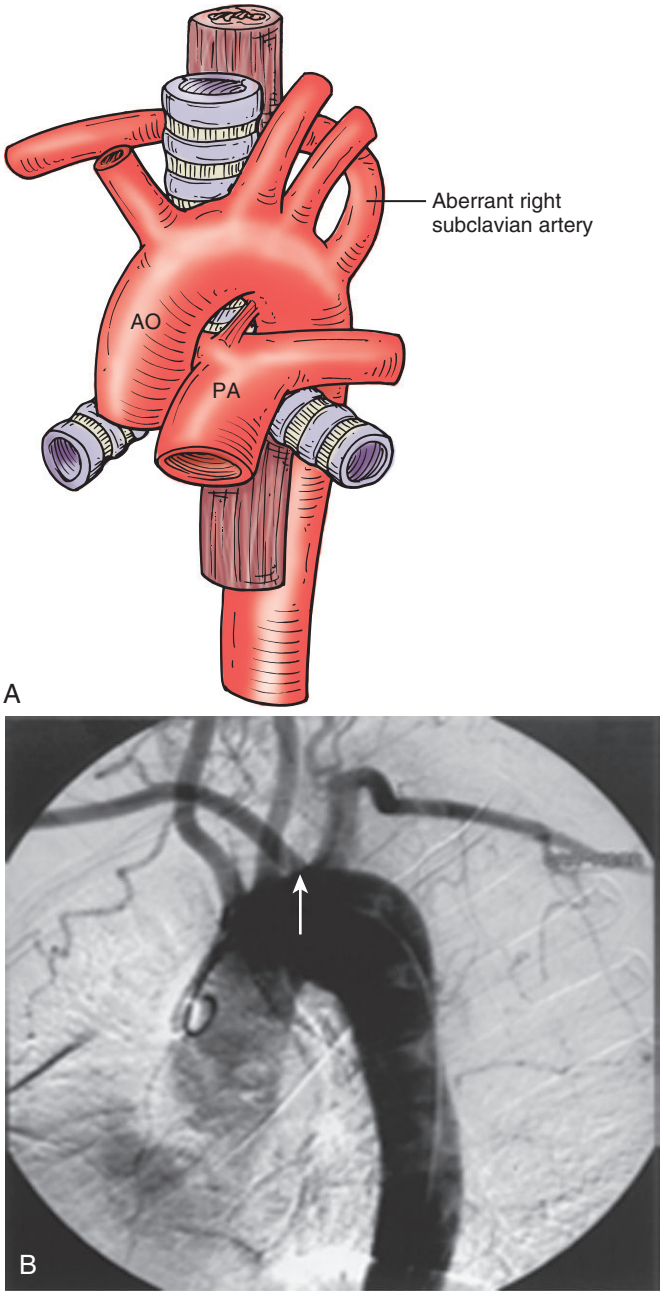

FIGURE 1 Drawing and digital subtraction arteriogram demonstrating the anatomic configuration of aberrant right subclavian artery *(arrow)*.

due to their intrathoracic location. A diminished carotid pulse noted on palpation in conjunction with altered low velocity and dampened waveforms in the carotid artery at the base of the neck may be indirectly indicative of a hemodynamically significant proximal occlusive lesion that may mandate further investigation depending on the clinical setting. As described previously, duplex ultrasound can easily detect reversal of flow in the cervical part of the vertebral artery suggestive of proximal subclavian occlusive disease. Magnetic resonance angiograms (MRA) and computed tomographic angiography (CTA) are additional noninvasive imaging modalities that are useful in the assessment of the aortic arch and brachiocephalic vessels. Both modalities require intravenous contrast administration for adequate imaging of these vascular structures. In our experience, MRA tends to be fraught with motion artifact related to the underlying cardiac

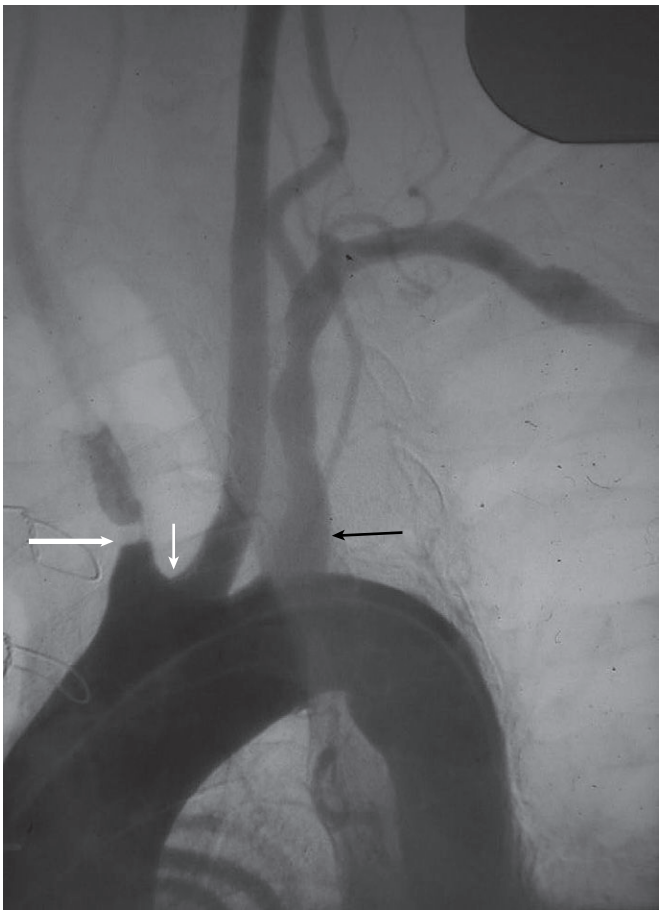

FIGURE 2 Digital subtraction angiogram showing multivessel atherosclerosis involving brachiocephalic (*bold horizontal arrow*), left common carotid (*short arrow*), and left subclavian (*thin black arrow*) arteries.

cycle and respiratory variation and also tends to overestimate the degree of stenosis of the occlusive lesions. CTA seems to be better tolerated by the patients due to the much shorter time required to complete the study and obviates the problems associated with claustrophobia seen in many patients undergoing MRA. Multiplanar digital subtraction angiography remains the gold standard imaging modality, and despite its more invasive nature, it remains particularly appropriate in those patients for whom potential endovascular treatment of the brachiocephalic disease is being considered.

TREATMENT

Indication for Treatment

The most frequent indication for the treatment of brachiocephalic disease includes patients with the location and severity of disease appropriate to their symptoms and clinical presentation. The symptoms may include lateralizing neurologic hemispheric symptoms, vertebrobasilar insufficiency, or upper-extremity ischemic symptoms. One would expect to identify significant lesions in the common carotid, subclavian, or innominate artery compatible with the lateralizing neurologic clinical presentation of the patient. In patients with nonlateralizing symptoms related to global hypoperfusion, multivessel brachiocephalic involvement, bilateral carotid disease, or tandem lesions should be suspected and confirmed on thorough workup. Classic subclavian steal syndrome with onset of vertebrobasilar

symptoms with arm exercise would indicate a need for treatment as well. There is a paucity of natural history data to direct decision making in patients with asymptomatic brachiocephalic disease. The rich data from retrospective analyses and, subsequently, prospective analysis of the risks inherent in severe asymptomatic carotid bifurcation disease do not exist for asymptomatic brachiocephalic disease. General agreement exists that asymptomatic subclavian artery occlusive disease need not be treated other than in the occasional patient that requires normalization of subclavian artery flow in order to support the use of an internal mammary bypass graft for coronary artery revascularization or in the difficult hemodialysis patient requiring placement of dialysis access in the extremity supplied by the stenotic subclavian artery. In the patient with asymptomatic severe proximal common carotid artery occlusive disease, it seems intuitive that intervention should be considered for a preocclusive or critical stenosis at its origin in order to preserve patency of the common carotid artery and consequently reduce long-term risk for stroke.

Prior to the routine use of endovascular techniques in the cerebrovascular circulation, treatment of tandem carotid disease presented a quandary for the treating physician. In the symptomatic patient, it was often unclear whether the symptoms were related to a carotid bifurcation lesion or to a more proximally located common carotid or innominate lesion. Prioritization of which lesion to treat first could be quite problematic. The currently favored strategy involves a combined approach with open carotid endarterectomy and retrograde angioplasty and stenting of the proximal common carotid artery or innominate lesion. To be clear, the proximal disease need only be intervened upon for a severe, flow-limiting stenosis. Mild or moderate proximal lesions need not be treated concomitant to carotid endarterectomy and should simply be observed prospectively. In patients with nonatherosclerotic conditions affecting the brachiocephalic vessels, again, the indications for treatment should be reserved for the symptomatic patient. In the patient with inflammatory arteritis such as Takayasu's arteritis, the acute inflammatory phase should be treated medically to quiescence, and intervention should be reserved for resultant fibrotic stenosis in the affected vessels based on symptoms and severity as is done with atherosclerotic lesions (Figure 3).

Treatment Options

A number of therapeutic modalities are currently available for the treatment of brachiocephalic disease. The treatment options are categorized into two groups: open surgical reconstruction or endovascular intervention. These two general approaches are not mutually exclusive, and as mentioned previously, certain clinical situations may require combined treatment with both modalities to best treat more complex disease. Open surgical approaches may be further categorized as direct, or anatomic, reconstruction and indirect, or extraanatomic, reconstruction. The direct approach requires a median sternotomy for treatment of innominate or left common carotid artery lesions or a left posterior lateral thoracotomy for treatment of proximal left subclavian disease. The anatomic reconstruction maintains antegrade laminar flow accomplished through a bypass arising from the ascending aorta to the innominate and/or left common carotid artery. In the setting of isolated focal lesions localized to the innominate artery alone, endarterectomy may provide a suitable treatment option. Open repair may be preferred in suitable risk patients with extensive severe calcific atherosclerotic disease at the origin of the vessel to be treated. If severe brachiocephalic disease is identified in a patient being considered for coronary artery bypass grafting, the coronary revascularization may be performed concomitant with the brachiocephalic revascularization safely.

In patients with severe calcific disease in the ascending aorta and aortic arch, where cross-clamping the aorta would be impossible or extremely hazardous and construction of a graft anastomosis would be difficult, or in patients deemed to be poor candidates for median sternotomy due to advanced age, prior sternotomy or mediastinal radiotherapy, or multiple comorbidities, the indirect approach is preferable. This procedure is performed through supraclavicular or cervical incisions and involves bypass grafting or arterial transposition. Extraanatomic procedures are very well tolerated, with inherently low morbidity and mortality rates, and excellent long-term patency rates have been reported. The choice between performing a direct or indirect vascular procedure for brachiocephalic disease is also dependent on a number of other anatomic/pathologic factors, including the number of vessels involved, the location and distribution of the occlusive lesions in the involved vessel, the underlying pathogenesis and nature of the symptoms (embolic vs hypoperfusion), and the status of the other vessels supplying the brain not requiring or amendable to intervention, such as total internal carotid artery occlusion.

Advances in guide wire, angioplasty balloon, and stent design, as well as the availability of covered stent grafts, have broadened the applicability of endovascular treatment of severe brachiocephalic disease. As the experience and skill of the interventionalist have grown with the technological advances and improved device availability, endovascular treatment of fairly complex brachiocephalic disease has gained wider acceptance and use. With appropriate careful technique, excellent outcomes have been achieved with low associated morbidity. As is true for intervention in any vascular bed,

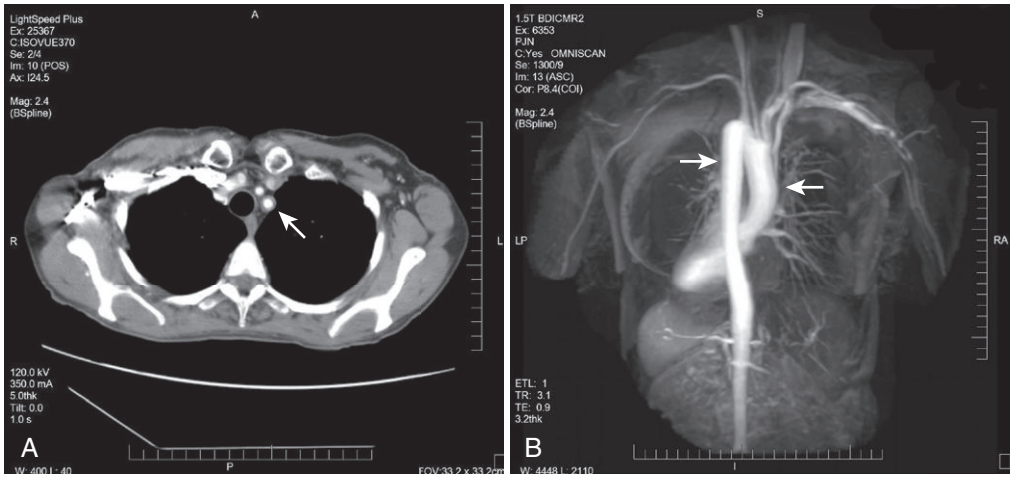

FIGURE 3 Axial images from CT angiogram **(A)** and 3-D reconstructed MRA **(B)** of a young woman with Takayasu's arteritis. Note the lucency surrounding the proximal brachiocephalic vessels on the CTA and the double contour of the ascending and descending thoracic aorta demonstrating wall thickening and inflammation.

close follow-up and regular surveillance is mandatory regardless of the type of intervention performed in the treatment of brachiocephalic disease.

ANATOMIC (DIRECT) REVASCULARIZATION

Endarterectomy

Endarterectomy may be considered for focal atherosclerotic lesions in the innominate artery. It should not be attempted in patients in whom the lesion is located at the ostium of the vessel because these lesions are an extension of severe atherosclerotic disease in the aortic arch. The calcific atherosclerotic disease involving the aortic arch could make placing a side-biting clamp on the arch just proximal to the takeoff of the innominate artery quite hazardous, and achieving a satisfactory end point of the endarterectomy into the aortic arch would be difficult with the associated risks for embolization, residual flap formation, or dissection. Additionally, innominate artery endarterectomy should not be considered in patients possessing a bovine configuration because this would require temporary disruption of flow into the right and left carotid systems simultaneously. Accomplishing a satisfactory end point in the left common carotid artery may also prove difficult with this anatomy.

Proper endarterectomy for innominate arterial atherosclerotic lesions requires placement of a side-biting clamp across the aortic arch at the level of the takeoff of the innominate artery. This allows extension of the endarterectomy proximally onto the aortic arch itself to remove all of the plaque that arises from the aorta. The endarterectomy is performed through a longitudinal arteriotomy that typically does not require patch closure due to the large caliber of the vessel. Distribution of plaque into the right subclavian and right common carotid artery may require extension of the median sternotomy incision up into the right side of the neck along the anterior border of the sternocleidomastoid. Again, achievement of satisfactory end points with this extent of disease may prove difficult, and bypass from the ascending aorta in these situations is probably more prudent.

Endarterectomy for isolated atherosclerotic lesions in the proximal left common carotid artery and left subclavian artery may be performed; however, these procedures require a median sternotomy in the case of the left common carotid lesions and left thoracotomy in the setting of left subclavian origin disease and are more appropriately treated with extraanatomic approaches, which have proven to be better tolerated with excellent patency rates. Endovascular approach to these lesions either through an antegrade transfemoral approach or a retrograde cervical approach for the left common carotid artery lesions or retrograde left brachial approach for the left subclavian lesions has been successfully performed with excellent technical success and patency rates. These techniques are discussed more fully in a later section.

Bypass Graft

Bypass grafts constructed in an antegrade configuration are performed through a median sternotomy incision, with the origin of the bypass graft arising from the anterolateral aspect of the ascending aorta. Careful palpation of the ascending aorta should be performed to avoid placement of the partially occluding side-biting clamp in an area of significant atherosclerotic disease. Careful sizing and positioning of the graft is mandatory to avoid kinking or graft compression in the retrosternal space when the sternum is closed. Additionally, the grafts are tunneled posterior to the innominate vein. A bulky graft may cause compression of the innominate vein, leading to left brachiocephalic vein occlusion and left arm swelling post procedure. Therefore, in the clinical setting where both the innominate artery and the left common carotid artery are to be bypassed, use of a bifurcated graft should be avoided due to the large volume and bulky nature of these grafts in this limited space.

Following systemic heparinization, a partially occluding clamp is applied on the ascending aorta as previously described and a 10- to 12-mm woven Dacron tube graft is anastomosed to the ascending aorta in an end-to-side fashion with 4-0 Prolene (Ethicon, Piscataway, NJ). suture. The graft is then clamped and distended with blood to assess hemostasis of the suture line and proper length of the graft prior to trimming. The distal anastomosis to the innominate artery is then performed either in an end-to-end or end-to-side fashion, depending on the clinical situation. When concomitant bypass to the left common carotid artery is required, an 8-mm knitted Dacron graft is taken off the innominate bypass graft in an end-to-side fashion above the thoracic inlet and left brachiocephalic vein to avoid graft kinking or compression. The distal anastomosis to the left common carotid artery may then be performed in an end-to-end or end-to-side configuration with 5-0 Prolene suture—again, depending on the clinical situation. Proximal occlusive lesions of the left subclavian artery are rarely symptomatic, and therefore, a "triple bypass" of all three brachiocephalic vessels is rarely, if ever, indicated. As noted previously, isolated left subclavian disease, when symptomatic, is best treated with endovascular treatment or extraanatomic bypass.

Brachiocephalic reconstruction may be performed safely with excellent outcomes. Multiple series have historically reported 30-day mortality rates of 4% to 7%, perioperative stroke rates ranging from 2% to 5%, and 5-year and 10-year patency rates exceeding 90%. As in the case of patients undergoing carotid endarterectomy, these patients must be followed closely with annual physical exam and surveillance duplex ultrasound for assessment of graft patency.

EXTRAANATOMIC (INDIRECT) REVASCULARIZATION

Isolated unilateral proximal common carotid artery or proximal subclavian artery lesions are readily treatable with extraanatomic reconstructions. These indirect methods of revascularization are performed through supraclavicular and/or cervical incisions and are better tolerated, with less perioperative morbidity and mortality, and they achieve patency rates similar to those of direct reconstruction. The most common form of revascularization is for construction of a prosthetic bypass between the ipsilateral carotid and subclavian arteries. The prosthetic graft utilized is usually a 7-mm or 8-mm knitted Dacron or polytetrafluoroethylene (PTFE) conduit. For treatment of proximal lesions, the procedure is performed through a single transverse supraclavicular incision at the base of the neck. The clavicular head of the sternocleidomastoid muscle is divided, and the scalene fat pad is reflected cephalad, taking care to identify and protect the phrenic nerve coursing anterior to the anterior scalene muscle. The anterior scalene muscle is then transected off its insertion to the first rib, exposing the underlying subclavian artery. The internal jugular vein is identified at the medial aspect of the supraclavicular incision and is mobilized laterally, exposing the underlying common carotid artery at the base of the neck. Care is taken to identify and protect the vagus nerve, which should be gently retracted laterally with the internal jugular vein. A short tunnel through the scalene fat pad is then made carefully behind the internal jugular vein and the vagus nerve. On the left side, great care should also be taken to avoid injury to the thoracic duct. In this exposure, a short bypass graft is constructed between the proximal common carotid artery and midsubclavian artery in end-to-side fashion with 5-0 or 6-0 Prolene sutures. It is not necessary to consider placement of a shunt during cross-clamping of the common

carotid artery for performance of a carotid to subclavian bypass, and obviously a shunt is not necessary for a subclavian to common carotid artery revascularization.

In the performance of a subclavian to carotid bypass, it may at times be necessary to perform a concomitant carotid endarterectomy. In this setting, the procedure is performed through a supraclavicular incision at the base of the neck, as well as an additional incision higher up the neck along the anterior border of the sternocleidomastoid muscle, as is typically performed in standard carotid exposure for endarterectomy. End-to-side anastomosis to the subclavian artery is constructed, and the bypass graft is then tunneled and brought up distally to the carotid bifurcation to the endarterectomy arteriotomy site with the distal subclavian to carotid anastomosis serving as a patch closure. This type of reconstruction is particularly required in situations where the entire common carotid artery is occluded up to the level of the carotid bifurcation and internal carotid artery patency has been preserved via retrograde filling through the external carotid artery and its branches. Our current preference in the treatment of coexistent focal hemodynamically significant stenosis of the proximal carotid artery with severe carotid bifurcation disease is performance of retrograde angioplasty and stenting of the proximal common carotid lesion with open carotid endarterectomy and patch angioplasty. The technique for retrograde angioplasty is discussed in a later section.

In settings for which the subclavian artery is not suitable for use, as in flow for ipsilateral subclavian to carotid bypass, a carotid to carotid bypass may be considered. The contralateral carotid artery is used as the inflow vessel for revascularization. The common carotid arteries are exposed through longitudinal incisions at the base of the neck along the anterior border of the sternocleidomastoid muscle. The common carotid arteries are then dissected free and exposed in a standard fashion, and the pharynx is identified medially. A short retropharyngeal tunnel is then made between the pharynx and the anterior spinal ligament with a combination of sharp and blunt digital dissection. It is helpful to have a nasopharyngeal tube or temperature probe in place to facilitate palpitation of the pharynx and ensure dissection in the proper plane. The retropharyngeal tunneling facilitates a shorter bypass graft and avoids the possibilities of skin erosion and the feeling of strangulation that sometimes occur with subcutaneous tunneling of these grafts in the anterior neck. The grafts also pose a cosmetic issue in patients with a very slender neck when tunneled anteriorly. The prosthetic graft utilized is a 7- or 8-mm knitted Dacron or PTFE graft anastomosed in end-to-side fashion at both common carotid arteries with 5-0 and 6-0 Prolene sutures. The common carotid arteries are not cross-clamped simultaneously, and therefore placement of a shunt is typically not required.

In rare instances, subclavian-subclavian or axillary-axillary bypasses have been utilized to restore pulsatile flow into the subclavian and vertebral arteries for symptomatic vertebral basilar disease, or in the presence of a total occlusion of the innominate artery, they may restore pulsatile flow to the right common carotid artery as well. The subclavian arteries are approached through supraclavicular incisions as described previously. The grafts are constructed in end-to-side fashion and are tunneled across the suprasternal notch. The axillary-axillary bypass grafts are constructed through bilateral infraclavicular incisions. The pectoralis major muscle is split along the length of its fibers, and the clavipectoral fascia is incised. The axillary vein will be encountered initially during the dissection with the axillary artery located just posterior and slightly superior to the vein. The axillary vein is completely mobilized with ligation and division of side branches to facilitate exposure to the axillary artery. The prosthetic graft is then anastomosed in an end-to-side fashion to the axillary artery and is tunneled subcutaneously across the front of the manubrium sterni. The subclavian-subclavian and axillary-axillary grafts are utilized in high-risk patients, usually those with hostile anatomy that would be encountered with the more standard direct or extraanatomic procedures.

ARTERIAL TRANSPOSITION

Subclavian-carotid or carotid-subclavian transposition has the advantage of avoiding prosthetic material and the small attendant risk of infection. The transposition procedure is more technically challenging than utilization of a bypass due to the requirement of a more extensive dissection and mobilization of the vessels. The dissection requires more retrosternal exposure of the proximal portion of the vessels, and particular attention must be paid to visualization and exposure of the internal mammary and vertebral arteries for transposition of the subclavian artery. The procedures are performed through a transverse supraclavicular incision. The dissection then proceeds along the anterior border or between the heads of the sternocleidomastoid muscle down to the internal jugular vein. The internal jugular vein and vagus nerve are then mobilized and gently retracted, laterally exposing the proximal common carotid artery. The subclavian artery is then exposed after identification and ligation/division of the vertebral vein. The subclavian artery is carefully dissected sharply, with dissection carried proximal to the takeoff of the internal mammary and vertebral artery. In the subclavian to carotid transposition, the proximal subclavian artery is clamped with a Cooley-Darra clamp, transected, and carefully sutured. Great care must be taken to avoid loss of control of this proximal stump because the stump is placed with tension to facilitate exposure in the upper mediastinum, and loss of this stump into the thoracic cavity prior to satisfactory suture ligation would be disastrous. The common carotid artery is then cross-clamped proximally and distally, and the subclavian artery is transposed and sewn in an end-to-side fashion with 5-0 or 6-0 Prolene suture. Care is taken to avoid kinking of the vertebral artery with the transposition. The indication and clinical situation requiring a carotid to subclavian transposition is much less common but is performed in a nearly identical fashion with the transection and suturing of the common carotid artery in the upper mediastinum and transposition of the common carotid artery to the subclavian artery just beyond the takeoff of the vertebral and internal mammary arteries. Subclavian to carotid transposition is our preferred technique in the event that debranching is required in the performance of thoracic aortic endograft treatment for aneurysm or dissection (Figure 4).

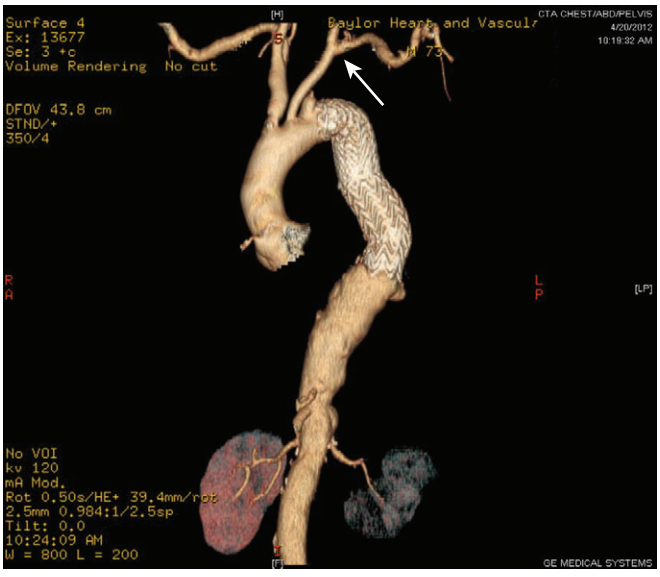

FIGURE 4 CTA of follow-up surveillance endovascular thoracic aneurysm repair in which debranching of the left subclavian artery with subclavian to left common carotid artery transposition *(arrow)* had been performed preoperatively.

Outcomes for extraanatomic brachiocephalic reconstructions are excellent. Multiple series have shown low incidences of paraprocedural stroke, and 30-day mortality is less than 3%. Five-year and 10-year patency rates exceed 90% in most series, and the patency rates of arterial transposition approach 100%.

ENDOVASCULAR TREATMENT

Numerous reports have demonstrated excellent results with open surgical revascularization in the setting of brachiocephalic disease with acceptably low 30-day mortality, stroke, perioperative stroke, and achievement of superb long-term patency of the reconstruction. However, as is true for all vascular beds, pursuit of minimally invasive procedures to treat brachiocephalic disease has been inevitable. Early reports of endovascular intervention in the arch vessels consisted mainly of lesions treated with angioplasty alone, and follow-up was limited. These studies revealed that endovascular intervention was feasible, and, as expected, utilization of endovascular techniques has increased with improvements in balloon and stent technology and maturation of technical skills in the treatment of cerebrovascular disease. In skilled hands, excellent outcomes with low morbidity and acceptable patency rates have been demonstrated.

Anatomic considerations are important in the planning of any treatment of brachiocephalic disease, but especially so if endovascular therapy is being considered. The anatomic characteristics of the lesions to be treated are key in the assessment for feasibility of treatment with catheter-based therapy. Endovascular intervention is preferable for stenosis rather than total occlusion and for nonostial, nonulcerative, and minimally calcified concentric lesions. Endovascular treatment is less favorable for severely eccentric lesions and lesions that extend contiguous to or into a major branch vessel, such as the vertebral artery arising off the subclavian artery, the left common carotid artery arising off the innominate artery in the Bovine configuration, or minimal separation of the origins of the innominate and left common carotid artery off the arch. These configurations carry the added risk of the compromise of the origin of one vessel in the treatment of another. Additionally, rotation of the vessel origin around the arch downward toward the ascending aorta for severe atherosclerotic disease affecting the aortic arch may make access and intervention of the brachiocephalic vessels much more challenging, and in these instances, open surgical treatment may be preferable.

INNOMINATE ARTERY INTERVENTIONS

Endovascular treatment of innominate lesions exposes the patient to potential embolization to both the right carotid and right vertebral artery distributions and therefore must be performed with great precision. Documentation of the position of the origins of the right common carotid and right subclavian artery branches in relation to the disease process is imperative. A kissing balloon technique is necessary to treat innominate lesions that extend directly proximate to or into the primary branches and to ensure proper distal stent placement. It is also important to ensure that the origin of the left common carotid is not compromised by angioplasty and stenting of a proximal calcific lesion in the innominate artery (Figure 5).

The innominate artery has the most challenging angulation extending off the aortic arch for cannulation through an antegrade transfemoral approach. Prolonged attempts at cannulation should not be pursued from this approach due to the risk of trauma and consequent embolization from the associated atherosclerotic disease in the aorta. In this situation, a retrograde brachial access may be performed and safe traversal of the innominate lesion accomplished. The innominate lesion may then be treated over the wire placed from the retrograde brachial approach, or the retrograde brachial wire can be snared from below and brought down with a through-and-through technique for greater stability for passage of the sheath and angioplasty system.

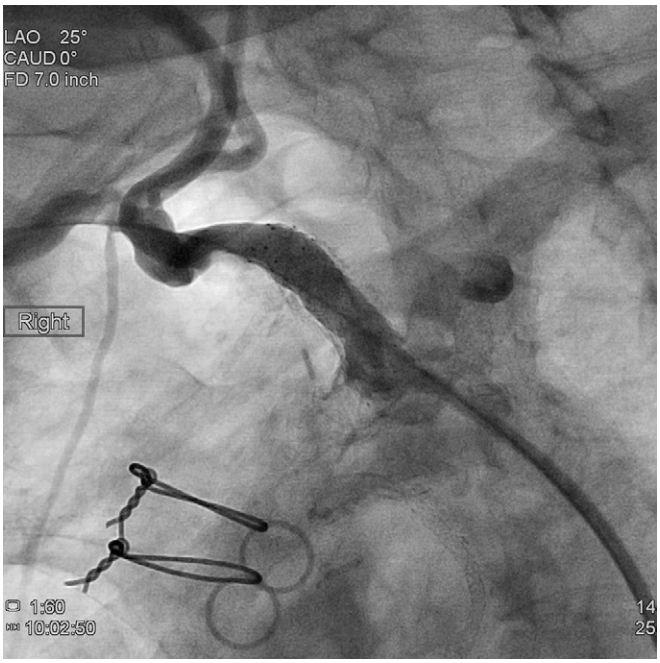

FIGURE 5 Innominate artery following PTA and stenting. Note sternal wires from previous coronary artery bypass which would have made an open innominate artery revascularization technically challenging.

For ostial lesions, 1 to 2 mm of the stent should protrude into the aortic lumen. If the angioplasty and stent are being performed through the retrograde right brachial approach, it may be difficult to inject adequate contrast to visualize the exact position of the innominate orifice relative to the aortic arch. It is helpful to have an angiographic pigtail catheter in place for arteriography and facilitation of better imaging. The transfemoral guide wire or angiographic catheter itself can act as a marker as it curves around the arch abutting the innominate orifice. With the brachial approach, the guide wire should be directed into the ascending aorta rather than making the sharp curve into the descending thoracic aorta because this facilitates in-line alignment for deployment of the stent.

The risk of embolization with primary angioplasty and stenting of innominate lesions appears to be low, and therefore the requirement for cerebral protection in these procedures remains unclear. In most instances, the simplest, most straightforward approach without protection is best unless a "high-risk" lesion with a worrisome potential for embolization is to be treated.

Left Common Carotid Artery

Endovascular treatment of left common carotid artery lesions at the level of the arch is feasible and safe and may be performed in an antegrade transfemoral approach similar to that described with the innominate artery intervention. In the situation of an angulated takeoff of the left common carotid artery from the arch and when better stability of the angioplasty system is required, a "buddy wire" may be positioned in the external carotid artery to facilitate maintenance of the guide wire and sheath position at the origin of the vessel, as is done in the treatment of more distal carotid disease. A protection device is frequently used with the antegrade transfemoral approach for endovascular interventions on "high-risk" lesions.

Again, when transfemoral access to the origin of the vessel proves difficult, a retrograde approach from the distal common carotid artery may be performed, particularly in situations where a concomitant ipsilateral carotid endarterectomy is to be performed. The carotid branches are thus readily controlled with application of a distal clamp, and cerebral protection is ensured.

Left Subclavian Artery

Antegrade transfemoral access to the left subclavian artery off the arch is the easiest of the three vessels to obtain. After accessing the origin of the vessel, a 0.035 guide wire is passed across the lesion into the distal subclavian artery. The guide wire may then be exchanged for a stiffer wire if deemed necessary. A long 6 French or 7 French sheath is then positioned just across the origin of the vessel at the level of disease. Predilatation with a 4-mm angioplasty balloon may be necessary to facilitate passage of the stent. Correct sizing of the stent is essential to ensure that the area of disease is covered fully and that the vertebral artery origin is not "jailed." For ostial lesions, the stent should extend 1 to 2 mm into the aorticlumen (Figure 6).

If the subclavian lesion approaches the origin of the vertebral artery, it may be important to protect the vertebral artery origin. This may be accomplished after placement of a larger sheath into the origin of the subclavian artery and exchange of the 0.035 wire for two separate 0.014 wires, one placed antegrade out into the axillary artery and the other placed antegrade in the vertebral artery. A balloon expandable stent may be accurately placed over both 0.014 wires immediately at the takeoff of the vertebral artery. In another approach where both antegrade transfemoral access and retrograde brachial access into the subclavian artery are obtained, the 0.014 wire is placed through the retrograde transbrachial sheath into the vertebral artery, and the angioplasty and stenting are performed across the 0.035 wire from the antegrade transfemoral approach. The retrograde transbrachial sheath also facilitates the imaging of the vertebral artery at the time of the intervention. Embolic protection of the vertebral artery has been described, but its routine use cannot be advocated due to the exceedingly low risk of emboli to the vertebral basilar system during subclavian artery intervention, as well as the risk of dissection of the vertebral artery with instrumentation. Again, for emphasis, the simplest, most straightforward approach with the least guide wire and catheter manipulation is generally best.

SUMMARY

The treatment of symptomatic disease affecting the brachiocephalic vessels is safe, effective, and durable. Younger, low-risk patients are suitable candidates for direct anatomic reconstruction performed through a median sternotomy, particularly those patients with multivessel involvement. The direct anatomic reconstructions include a bypass arising from the ascending aorta or innominate arterial endarterectomy. Older patients with multiple comorbidities or those individuals with prior median sternotomies or a hostile mediastinum due to other reasons are better treated with an indirect extraanatomic approach or should be considered for endovascular intervention. Extraanatomic surgical reconstructions are performed with various types of prosthetic bypasses or arterial transposition. Endovascular therapy is performed via an antegrade transfemoral approach, a retrograde brachial approach, or, at times, a combination of both. Selection of the mode of treatment in each individual patient is based on various patient, anatomic, or pathologic factors in which one approach may be safer and more effective than another. The requirements for brachiocephalic reconstruction have increased with the ever-expanding treatment of aortic aneurysmal disease and aortic dissection for the purposes of debranching and expansion of the applicability and appropriateness for endovascular treatment of aortic arch and descending thoracic aortic disease.

Upper Extremity Arterial Occlusive Disease

Virginia L. Wong, MD, FACS, and Vikram S. Kashyap, MD, FACS

OVERVIEW

Upper extremity arterial occlusive disease and ischemia is much less common than in the lower extremity and can be caused by a wide variety of etiologies, including systemic inflammatory conditions. Due to extensive collateralization around the shoulder and elbow, patients may remain asymptomatic despite significant chronic obstruction. However, once ischemic symptoms manifest, they are poorly tolerated and result in significant disability. Therefore, diagnosis and management of upper extremity ischemia can be considerably more challenging than for lower extremity disease.

ETIOLOGY

The causes of upper extremity ischemia are listed in (Box 1). Atherosclerosis and inflammatory arteritides tend to affect larger, more proximal arteries. Digital and small vessel disease is commonly seen with diabetes, chronic renal failure, and connective tissue disorders. The brachial artery is most commonly affected by embolism and trauma. Iatrogenic manipulation, such as for catheterization or hemoaccess procedures, may exacerbate the effects of underlying arterial disease and lead to new ischemic symptoms.

Systemic Disease

In the United States, atherosclerosis is the most common cause of subclavian artery obstruction, more commonly affecting the left side. Patients have risk factors typically associated with atherosclerosis (e.g., hypertension, hyperlipidemia, diabetes, smoking) and/or manifestations of the disease in other arterial beds (e.g., coronary artery disease, peripheral arterial disease). Takayasu's arteritis, typically described in young Asian females, frequently affects the supraaortic trunk vessels. Temporal (giant cell) arteritis, generally found in patients older than 60 years, affects the axillary to brachial arteries, as well as superficial temporal and ophthalmic arteries. Both diseases are associated with an initial inflammatory stage, characterized by fever, fatigue, myalgias, arthralgias, and elevated erythrocyte sedimentation rate. Both produce characteristic smooth, tapering arterial stenoses that differ in angiographic appearance from typical atherosclerotic disease (Figure 1). Superficial temporal artery biopsy may provide definitive diagnosis in cases of giant cell arteritis.

Occlusive disease of the more distal upper extremity arteries is associated with a number of autoimmune, inflammatory, and rheumatologic conditions. Scleroderma, CREST syndrome (calcinosis,

Blunt arterial injury
Penetrating arterial injury
Hypothenar hammer syndrome
Vibration

Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia), lupus, and rheumatoid arthritis are associated with small vessel disease, affecting palmar and digital arteries (Figure 2). Thromboangiitis obliterans (Buerger's disease) affects small distal arteries and is strongly associated with ongoing tobacco exposure.

Embolism

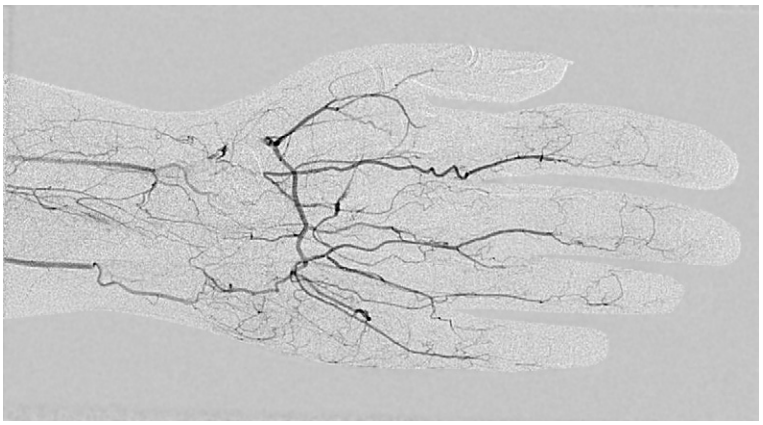
Embolism is a frequent cause of acute upper extremity ischemia. Cardiac emboli secondary to arrhythmia are most common, with the majority of these lodging in the brachial artery terminus or more proximally at the deep brachial artery origin (Figure 3). Other sources include proximal arterial aneurysm, ulcerated atherosclerotic plaque, and paradoxical embolus from deep venous thrombosis through a septal defect. Multiple emboli (embolic shower) affecting smaller, more distal arteries should prompt a search for a proximal arterial source, particularly in the absence of arrhythmia. Subclavian artery aneurysm or ulcerative lesion secondary to thoracic outlet obstruction is the most common scenario (Figure 4). Repetitive compression of the subclavian artery by myofascial and/or osseous structures at the thoracic outlet leads to poststenotic dilatation and embolization of mural thrombus. Posttraumatic and infectious aneurysms can also cause embolization.

FIGURE 1 Right upper extremity angiogram of a 57-year-old woman with temporal arteritis showing a classic, smooth, tapering stenosis in the proximal brachial artery. The patient's primary presenting complaint was forearm effort fatigue.

Trauma

Blunt and penetrating trauma involving the upper extremity can cause ischemia by arterial transection, intimal dissection, and thrombosis. Iatrogenic pseudoaneurysm and thrombosis after brachial artery manipulation (arterial lines, interventional procedures) are complications that may not be immediately recognized, due to rich collateral supply around the elbow. Effort fatigue in the hand and forearm may develop later.

Repetitive trauma can also cause arterial injury. Hypothenar hammer syndrome, which affects the terminal portion of the ulnar artery in Guyon's tunnel (formed by the pisiform, the hook of hamate, and the transverse carpal ligament), results from repeatedly striking objects with the base of the palm. Segmental ulnar artery occlusion or aneurysm formation with digital artery embolism can occur (Figure 5). Vibration-induced digital artery injury is associated with prolonged use of pneumatic tools (e.g., jackhammer) and chain saws.



EVALUATION

History and Physical Examination

A detailed history and physical examination are essential for diagnosing the correct etiology of upper extremity arterial disease. Symptoms may include color changes, coolness, numbness, weakness, effort-induced fatigue ("arm claudication"), rest pain, and tissue loss. Raynaud's phenomenon may represent benign vasospasm, but it can also manifest from fixed occlusive lesions, which must be ruled out. Effort-induced fatigue generally results from proximal or large vessel disease, while hand symptoms suggest involvement of small vessel disease as well. Digital tissue loss is nearly always associated with small vessel disease, with or without more proximal involvement. Posterior circulation symptoms (e.g., dizziness, ataxia, diplopia) or angina following coronary revascularization with right or left internal mammary artery (RIMA or LIMA) suggest occlusion of the subclavian or innominate artery proximal to the internal mammary and vertebral artery origins (subclavian steal syndrome). Atherosclerotic risk factors, occupational activities, personal and family history of autoimmune or connective tissue disorders, and history of upper extremity arterial intervention or trauma should be investigated. Renal failure and vascular procedures for hemodialysis access should be noted.

A complete examination of the neck and upper extremities should be performed, documenting pulses at superficial temporal, common carotid, subclavian, axillary, brachial, radial, and ulnar

FIGURE 2 Left-hand angiogram of a patient with scleroderma and small artery occlusive disease, producing multiple occlusions of the distal forearm, palmar, and digital arteries. The patient presented with severe Raynaud's syndrome and nonhealing fingertip ulcerations.

locations on both sides. Diminished or absent pulses indicate significant stenosis or occlusion proximal to that location; symmetric disease may suggest a systemic condition. Auscultation over the proximal arteries for bruit and inspection of hands and digits for color, temperature, trophic changes, and tissue loss are important. Electrocardiogram and echocardiogram evaluate for arrhythmia and atrioventricular thrombus, which predispose to cardioembolism. Chest and cervical spine radiographs evaluate for cervical ribs or osseous anomaly causing thoracic outlet obstruction. Computed tomographic scan or magnetic resonance imaging may be necessary to identify myofascial or ligamentous entrapment. Serum evaluation for erythrocyte sedimentation rate, connective tissue disorder (rheumatoid factor, antinuclear antibody, complement levels), hypercoagulable disorder (factor V Leiden, prothrombin gene mutation, antithrombin III, protein C and S deficiencies, antiphospholipid antibody, and hyperhomocysteinemia) may be helpful.

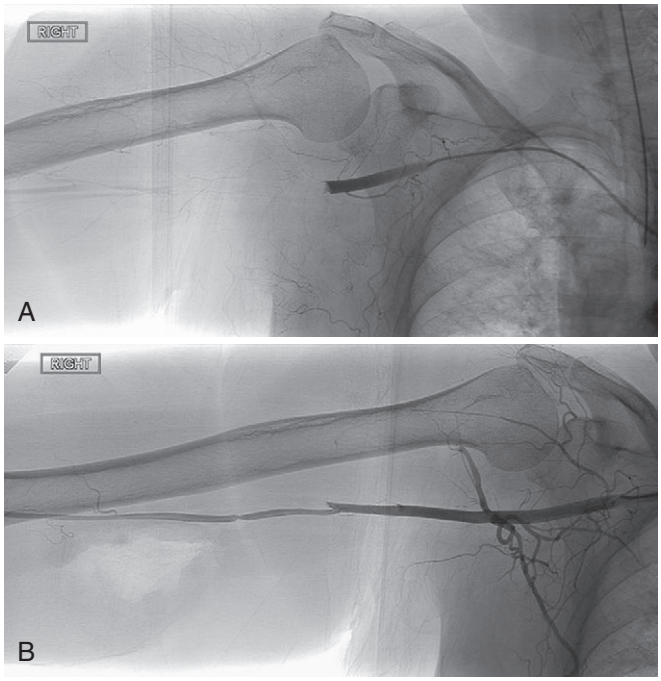


FIGURE 3 **A,** Embolic occlusion of right axillobrachial artery secondary to atrial fibrillation. **B,** Completion angiogram following surgical embolectomy.

Noninvasive Vascular Evaluation

Segmental arterial pressures, wrist-brachial index (WBI), absolute digit pressures, digital plethysmography, and arterial duplex are useful for evaluating upper extremity arterial disease and ischemia. Normal WBI with digital waveform dampening induced by cold exposure is helpful in diagnosing Raynaud's phenomenon and for ruling out more proximal fixed arterial lesions. Brachial artery pressure difference greater than 20 mm Hg between right and left sides suggests unilateral axillosubclavian arterial disease. Diminishment greater than 15 mm Hg between ipsilateral arm segments suggests intervening hemodynamically significant disease. Absolute digit pressure less than 50 mm Hg suggests significant ischemia. Arterial calcification due to diabetes or longstanding renal failure may falsely elevate pressures. Duplex provides detailed anatomic information but is less useful for evaluation of intrathoracic arterial lesions, due to lack of sufficient visualization.

Computed tomographic angiography (CTA) and magnetic resonance angiography (MRA) are important noninvasive modalities for evaluating upper extremity arterial supply. Visualization of aortic arch and large proximal arteries is superb, and three-dimensional reconstruction and other postprocessing techniques are valuable for identification of thoracic outlet obstruction and planning surgical release and revascularization of these lesions (Figure 6). Imaging of smaller forearm and hand arteries is less useful with these modalities,

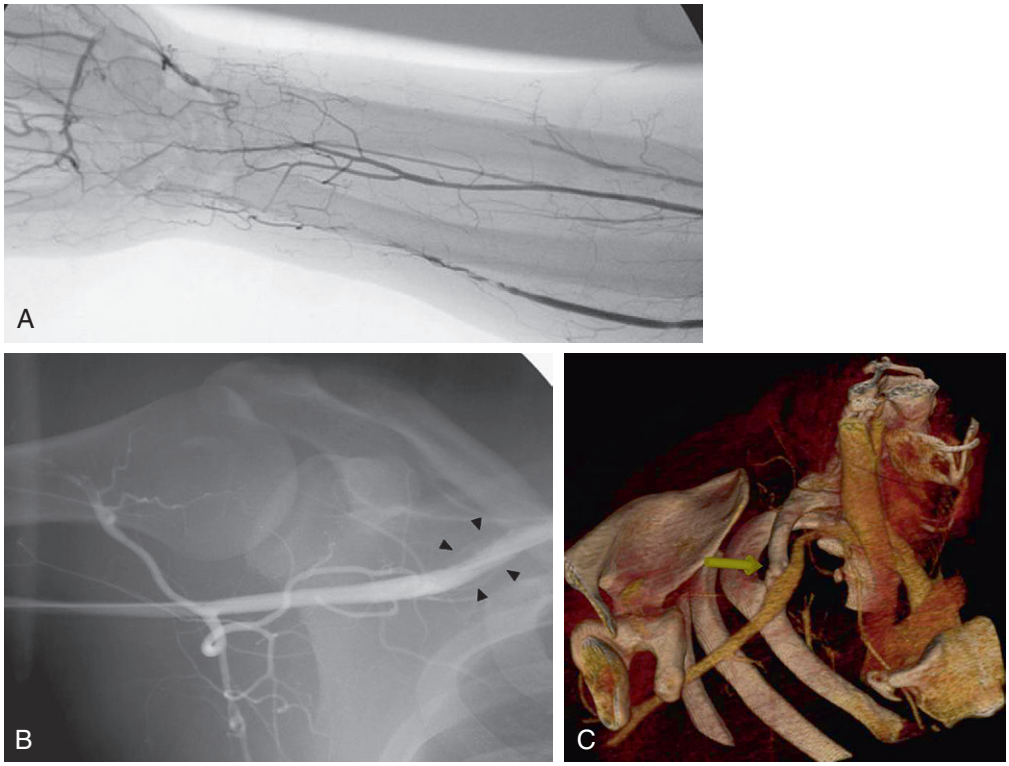

FIGURE 4 **A,** Right upper extremity angiogram in a 28-year-old, showing embolic shower to right forearm and hand arteries. **B,** Right subclavian artery aneurysm with mural thrombus (arrowheads). **C,** Three-dimensional reconstruction of CT angiogram showing right subclavian artery pressed downward by overlying clavicle (removed from image for arterial visualization) onto bony exostosis between first and second ribs *(arrow)*.

although advances in equipment and imaging techniques are providing more and more detailed distal evaluation. Artifact from heavy arterial calcification, metallic stents, or orthopedic hardware may obscure detail. Risk of contrast-induced nephropathy must be considered with CTA in patients with severe renal dysfunction. Risk of nephrogenic systemic fibrosis in end-stage renal disease (ESRD) patients may preclude use of MRA.

Catheter angiography remains a standard diagnostic imaging modality that may also offer the opportunity for endovascular treatment of selected upper extremity arterial lesions. Higher-quality images of smaller forearm and palmar arteries can be obtained with selective administration of contrast into the distal brachial artery. Provocative or diagnostic maneuvers such as catheter-directed vasodilator administration, pull-back intraarterial pressure measurement, and compression of flow through a patent ipsilateral arteriovenous access (e.g., during evaluation for arterial steal) can be performed for diagnosis and better visualization of distal arteries. Evaluation of the aorta and proximal upper extremity arteries requires aortic arch catheterization, usually from a transfemoral approach, while focal evaluation of distal brachial and forearm arteries can be accomplished via a transfemoral approach or by antegrade/retrograde brachial arterial catheterization above the level of disease involvement.

MANAGEMENT

Medical therapy represents the first line of treatment for many patients with upper extremity arterial disease and is the preferred management during the acute phase of inflammatory arteritides. Interventional treatment is generally reserved for patients with acute traumatic or embolic disease, or those with debilitating symptoms or significant ischemia. Endovascular techniques provide an opportunity for less invasive revascularization and have become the preferred option for treatment of focal proximal lesions that would otherwise require thoracotomy or sternotomy for proximal vascular control. Catheter directed thrombolysis may be more effective than surgical techniques, particularly for acute small vessel occlusion.

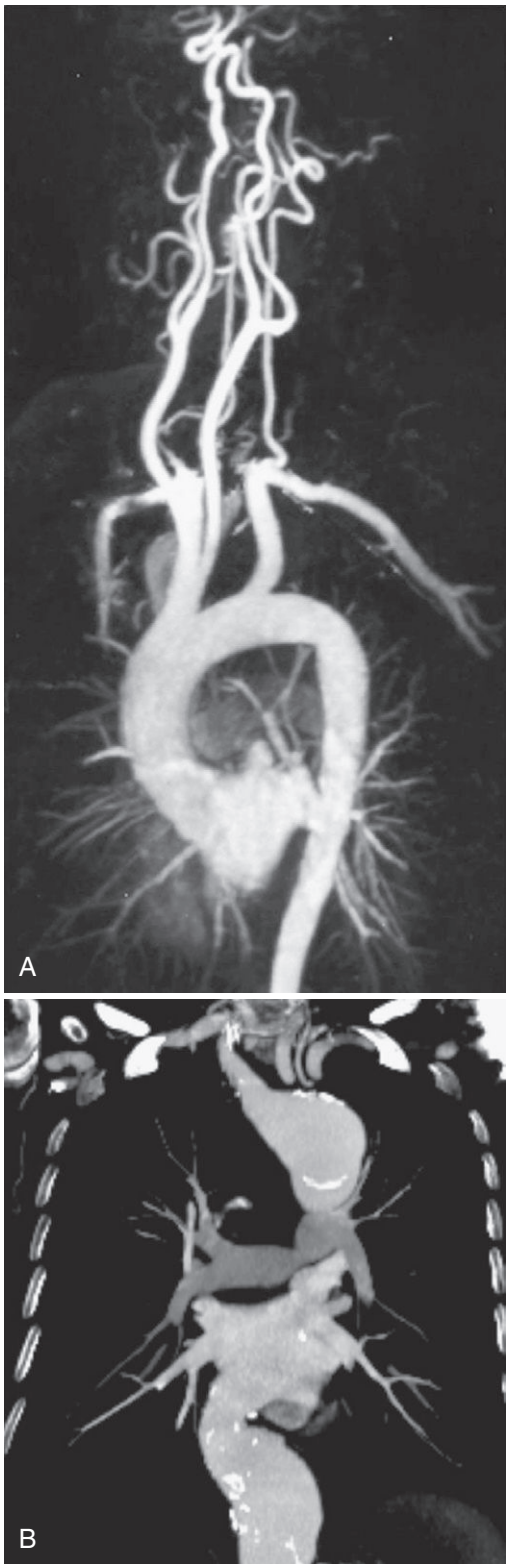

FIGURE 6 **A,** MRA of the aortic arch and supraaortic vessels. **B,** Coronal reconstruction CT angiogram demonstrating aberrant right subclavian artery origin from distal posterior aortic arch, beyond innominate and left common carotid artery origins.

However, the utility and durability of endovascular treatment is limited for more extensive and more distal arterial lesions, where surgical reconstruction is preferred.

Medical Therapy

Risk factor modification, including abstinence from tobacco and the use of lipid-lowering and antiplatelet therapy, is indicated for atherosclerotic disease. Cold avoidance and calcium channel blockade with nifedipine may be useful for treatment of Raynaud's symptoms. The acute inflammatory stage of Takayasu's and giant cell arteritis is treated with corticosteroids or other antiinflammatory agents such as cyclophosphamide, methotrexate, azathioprine, infliximab, or mycophenolate mofetil. Intervention on these lesions with endovascular or surgical techniques should be avoided during the acute inflammatory stage, due to poor results and high restenosis rates.

Endovascular Therapy

Endovascular techniques are particularly suited for short, focal obstructive lesions in the innominate, subclavian, and axillobrachial arteries. A transfemoral approach allows antegrade aortography and selective angiography through a long, supportive sheath. Retrograde access from the ipsilateral brachial artery affords the most direct access to orificial supraaortic trunk lesions, but passage of large sheaths and device delivery profiles may be limited by brachial artery diameter or may require cutdown and surgical repair to prevent access site complications. Anticoagulation during the procedure and monitoring afterward for hand ischemia and median nerve compression symptoms from brachial sheath hematoma are routine.

Once wire access across the lesion has been achieved, balloon angioplasty alone may provide sufficient treatment. Self-expanding bare metal stents are used for significant residual stenosis (>20% luminal diameter or persistent pressure gradient >20 mm Hg), immediate elastic recoil, or dissection following angioplasty. Balloon-expandable stents are useful for treatment of calcific focal lesions at the innominate, carotid, or left subclavian artery orifice, where obstruction is due to spillover aortic plaque, requiring higher radial force and precise stent deployment for treatment (Figure 7). Covered stents can be used for traumatic arterial pseudoaneurysm or for rupture following balloon angioplasty. Deployment of stents in the subclavian artery at the thoracic outlet should be considered with care, as repeated compression during arm movement can crush or fracture them. Endovascular treatment of lesions in this area may be considered following surgical decompression of underlying thoracic outlet obstruction.

For patients with severe, acute ischemia due to thrombosis or embolism, surgical catheter embolectomy provides the most rapid restoration of inflow, but access to smaller arteries of the hand and digits is not possible in this manner. Catheter-directed thrombolysis can be very useful for involvement of distal forearm, palmar, and digital arteries. The transfemoral approach using a long, supportive sheath is preferred for delivery of thrombolytic agent via an infusion wire or catheter advanced into thrombus, or positioned to allow the agent access to affected vessels. Continuous thrombolytic infusion is continued for 24 to 72 hours, monitoring for signs of hemorrhage and for a decrease in the serum fibrinogen level. Angiography through the existing catheter takes place at regular intervals during therapy to assess thrombolytic progress or adjust catheter position for maximum gain. Return to angiography occurs 12 to 24 hours following initial catheter placement, and then every 12 to 24 hours thereafter. Therapy is complete when an acceptable clinical or angiographic result is obtained or is terminated when no further progress is made or if bleeding or a critical drop in the serum fibrinogen level occurs. Risk of bleeding complications increases with duration of therapy and total amount of lytic agent delivered. Forearm or hand fasciotomy may be required for release of compartment syndrome following revascularization in patients with severe ischemia lasting more than 6 hours or in those who exhibit compromised neuromotor function.

AbuRahma and colleagues (AbuRahma A, et al., 2007) compared results of subclavian artery balloon angioplasty/stent with carotid-subclavian bypass for symptomatic lesions. Over a 10-year period, 121 patients were treated with balloon angioplasty/stent, while 51 patients were treated with bypass. There was no difference in survival between the two groups. Primary patency at 1 year was 93% for angioplasty/stent and 100% for bypass. Superior primary patency was noted at 5 years in the surgery group (96%), compared to the endovascular group (70%).

Surgical Therapy

Exposure techniques, revascularization options, and procedural success vary depending on the etiology and extent of arterial disease, as well as anatomic location of the lesion.

Operative Exposure of the Subclavian Artery

Due to the oblique and posterior course of the aortic arch, access to proximal right and left subclavian arteries requires different approaches. The origin of the right subclavian artery is best exposed through median sternotomy. Mobilization of the left brachiocephalic vein allows complete visualization of the innominate artery and its bifurcation into right subclavian and common carotid arteries. Cervical extension of the incision allows access to the right carotid sheath. Care must be taken to avoid injury to the right recurrent

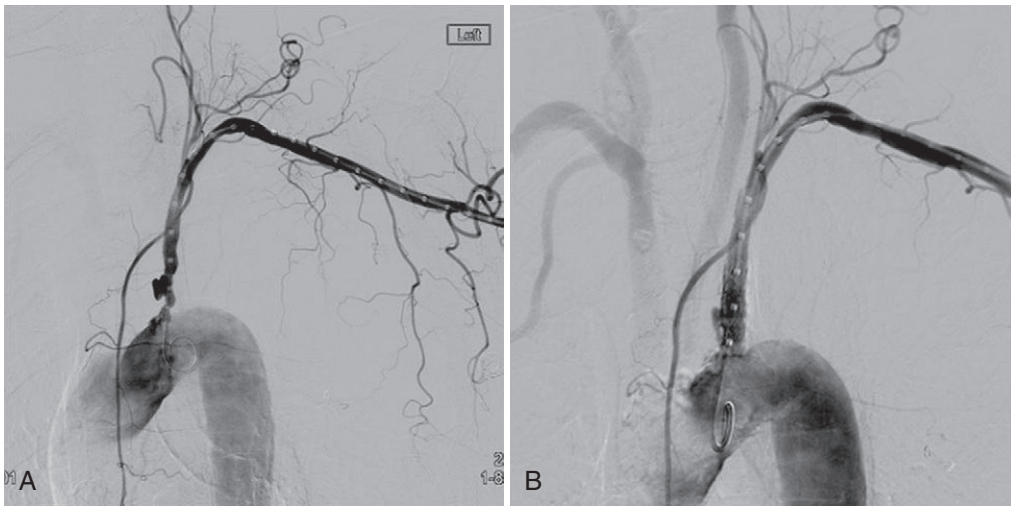

FIGURE 7 **A,** Aortogram from retrograde left brachial artery approach showing orificial subclavian artery stenosis. **B,** Aortogram following deployment of a balloon-expandable bare metal stent across the lesion.

laryngeal nerve, which courses inferiorly around the proximal right subclavian artery and ascends medially between the esophagus and trachea. The preferred approach to the more posteriorly positioned left subclavian artery origin is through left lateral thoracotomy, sited between the fourth and fifth ribs. Following entry into the pleural cavity, inferior retraction of the left upper lobe will reveal the aortic arch, visible through the mediastinal pleura. The vagus nerve passes anterolateral to the left subclavian artery, and the thoracic duct lies posteromedial to the artery. Care must be taken to avoid injury to either of these important structures. Limited exposure of either right or left proximal subclavian artery can be achieved via supraclavicular cervical incision, as described below.

Surgical Reconstruction for Proximal Subclavian Artery Lesions

Carotid-subclavian artery bypass and subclavian artery transposition have both been described extensively for operative treatment of proximal subclavian artery obstruction, with 75% to 90% patency at 5 years and acceptable morbidity. Preoperative evaluation should include carotid duplex to determine whether common carotid and/or bifurcation disease also requires treatment and to evaluate the vertebral arteries. Advantages of transposition include completely autogenous reconstruction and the need to perform only one anastomosis. Bypass avoids the need to obtain very proximal subclavian artery control deep in the incision, and it is better suited for extensive lesions beyond the orifice. Bypass is also preferred for preservation of a patent internal mammary artery to coronary artery bypass graft.

Subclavian Artery Transposition

The patient is positioned supine, with the head turned away from the operative side. A small roll placed under the shoulders helps provide better neck extension. A short, transverse cervical incision is made 2 cm above the clavicle and parallel to it, from the sternoclavicular joint toward midclavicle. The platysma is divided, and then the clavicular head of the sternocleidomastoid muscle is divided for better visualization. The scalene fat pad is mobilized superiorly, exposing the anterior scalene. The phrenic nerve, which runs from lateral to medial across the anterior scalene on its way into the chest, must be identified and preserved. The anterior scalene is divided from its attachment to the first rib. The internal jugular vein is mobilized and retracted laterally to allow access to the common carotid artery. The vagus nerve should be identified and preserved. On the left, the thoracic duct may require ligation; inadvertent injury will cause serious lymphatic leak. The subclavian artery is skeletonized, obtaining control of the thyrocervical trunk, vertebral, and internal mammary arteries. Following heparinization, branch vessels are occluded first to prevent embolism. The subclavian artery is clamped and divided as far proximal as safely possible. The proximal arterial stump is oversewn immediately with stay sutures to prevent retraction of the artery back into the chest before secure closure. The common carotid artery is clamped; shunting is usually not required as long as the carotid bifurcation remains open. The common carotid artery is opened longitudinally on its posterolateral surface, and end-to-side anastomosis is performed between the transected subclavian artery and the common carotid artery (Figure 8). If the subclavian artery is too short to reach, mobilization of the common carotid artery may bring it farther laterally. Division of the internal mammary artery may provide more length as well. The incision is closed over a closed suction drain, left in place for 24 hours, and removed when sanguinous and/or lymphatic drainage has diminished.

Carotid-Subclavian Bypass

Patient positioning and initial exposure is as above for subclavian artery transposition. For bypass, only a short segment of the subclavian artery need be exposed. The usual site is just distal to the thyrocervical trunk. As such, most of the dissection takes place lateral to the clavicular head of the sternocleidomastoid muscle. Phrenic nerve injury is more common during this more lateral approach. A short polytetrafluoroethylene (PTFE) graft is tunneled beneath the internal jugular vein, and an end-to-side anastomosis is performed to the common carotid and subclavian arteries (Figure 9). Beveling the carotid end of the graft 20 to 30 degrees is necessary to direct the bypass graft downward toward the subclavian artery.

Ziomek and colleagues reported that prosthetic graft is the conduit of choice for these short-length carotid-subclavian bypasses, with superior long-term patency than for autogenous vein bypass (94% vs 58% at 5 years). However, they and others conclude that subclavian transposition may yield slightly better results. Systematic review by Cina and colleagues (Cina C, et al., 2002) suggests higher mean 1-year patency and symptomatic freedom rates with subclavian transposition (98% and 99%) compared to carotid-subclavian bypass (84% and 88%).

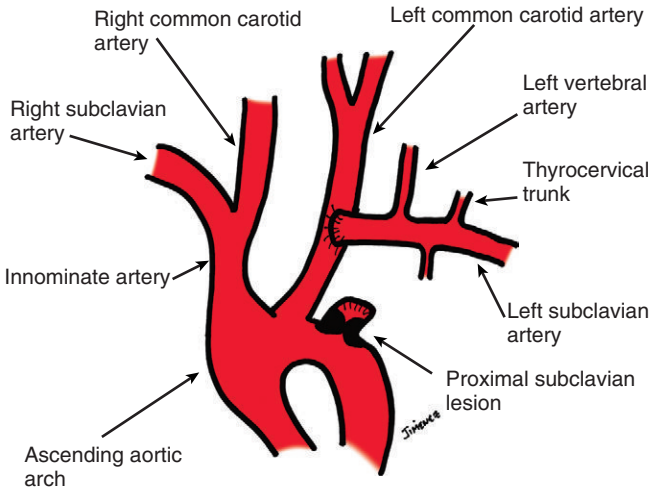

FIGURE 8 Left subclavian transition.

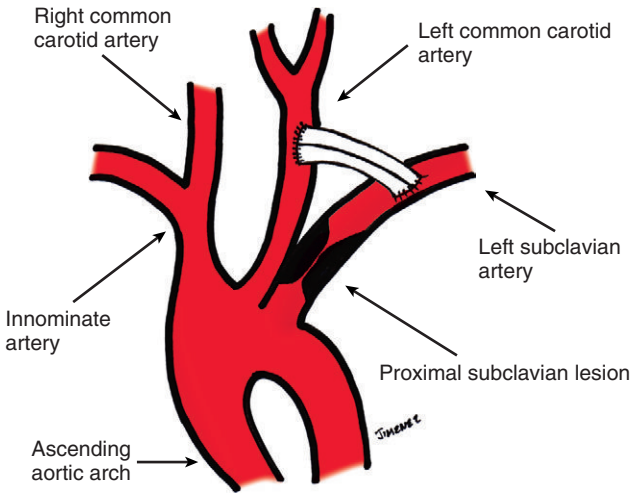

FIGURE 9 Carotid-subclavian bypass.

Axillary Artery

Occlusive lesions of the axillary artery are rare. Exposure may be required for trauma or for proximal anastomosis of axillofemoral bypass. The ipsilateral arm is abducted onto an arm board. An infraclavicular incision is made two fingerbreadths below the midclavicle

and extended to the deltopectoral groove. Fibers of the pectoralis major muscle are split, and the underlying clavipectoral fascia is opened. The pectoralis minor muscle is divided near its tendinous insertion onto the acromion for better visualization. The axillary vein lies slightly anterior and inferior to the artery; overlying venous branches may require division for full exposure of the artery. Care must be taken to avoid transection of the lateral pectoral nerves, which may cause postoperative pectoralis muscle atrophy.

Surgical revascularization of the axillary artery for occlusive disease is required infrequently. Carotid-axillary, carotid-brachial, subclavian-brachial, and axillobrachial bypasses have been described and may be required for extensive subclavian artery lesions, trauma, or revascularization of failed, less-extensive bypasses. Autogenous vein appears to be the preferred conduit in this location, likely due to the length of graft required for revascularization.

Brachial Artery

The ipsilateral arm is abducted onto an arm board or table. Exposure can be achieved through a longitudinal incision anywhere along the bicipital groove, medially between the biceps and triceps muscles. The basilic vein will be medial and superficial to the brachial sheath. The median nerve lies immediately adjacent to the brachial artery and is usually encountered first upon opening the brachial sheath. Great care must be taken with the use of cautery to avoid injury to this large sensorimotor nerve. Mobilization over several centimeters will allow enough slack for gentle vessel loop retraction of the nerve away from the underlying brachial artery. Crossing branches from paired brachial veins may require division for full exposure of the artery. Exposure of the terminal brachial artery and its bifurcation into radial and common ulnar interosseus arteries can be achieved by extension of the incision onto the anterior forearm in "lazy S" fashion so as to avoid longitudinal scar contracture across the antecubital crease. Division of the bicipital aponeurosis will allow contiguous exposure of the artery across the antecubital space. In 15% of patients, a separate and high takeoff of the radial artery will be identified (brachioradial artery variant). Its origin may be located anywhere between the axillary artery and the brachial artery terminus. This artery is usually encountered as a smaller-caliber, more superficial artery, not in immediate proximity to the median nerve. It is the most commonly identified upper extremity arterial variation, and it is distinct from the rare superficial brachial artery or truly duplicated brachial artery variations. Definitive identification of the high radial artery requires either extensive proximal exposure or angiography, but the persistence of the radial pulse at the wrist following brachial artery cross-clamp should confirm the anatomy.

For localized brachial artery trauma or for catheter retrieval of embolus, exposure and mobilization of a relatively short distance of the brachial artery will suffice. Control of uninvolved proximal and distal artery should be obtained. Primary suture repair or anastomosis can be considered if adequate length and sufficient vessel circumference remain after débridement of devitalized tissue. Patch angioplasty or interposition graft may be required for repair or bypass of more extensive lesions. Saphenous vein is the preferred conduit for brachial artery bypass, due to size match and improved patency over PTFE. Prosthetic material should be avoided in contaminated traumatic fields. Penetrating or extensive blunt trauma may also be associated with nerve injury; detailed sensory and motor exam should be performed before and after revascularization.

Radial and Ulnar Arteries

Exposure of the radial artery in the forearm is achieved via a longitudinal incision oriented along a line extending from the antecubital crease to the styloid process of the radius. The fascia is opened along the medial border of the brachioradialis muscle. Proximally, the artery lies beneath the muscle. More distally, the artery lies deep to the antebrachial fascia, between the brachioradialis and flexor carpi radialis tendons. At the wrist, the radial artery is quite superficial, lying just beneath the antebrachial fascia and medial to the radius. Exposure of the ulnar artery in the forearm is achieved by following a plane between the flexor carpi ulnaris and flexor digitorum superficialis muscles. In the midforearm, the artery lies beneath the flexor carpi ulnaris muscle and adjacent to the ulnar nerve. Distally, the artery lies just beneath the antebrachial fascia.

Bypass to the forearm arteries is rarely used and is most often required for trauma or neglected embolic occlusion. Mesh and colleagues (Mesh C, et al., 1993) performed 95 upper extremity arterial bypass procedures over a 15-year period. Overall 5-year patency was 63%, with autogenous conduit demonstrating superior patency at all anatomic sites compared with prosthetic material (71% vs 38%). All far distal forearm prosthetic grafts failed within 1 year. A series by Spinelli and colleagues (Spinelli F, et al., 2009) reported on 23 upper extremity bypasses performed over a 10-year period in patients primarily with critical limb ischemia. They achieved 83% primary 3-year patency, using autogenous conduit in 83% of cases. Thus, the surgical literature supports using arterial bypass with autogenous conduit for upper extremity arterial disease, with acceptable patency rates.

Angioaccess-Induced Arterial Steal Syndrome

Hand ischemia following creation of ipsilateral arteriovenous (AV) access for hemodialysis is an infrequent, but potentially debilitating, complication. Given the increasing incidence of renal failure requiring dialysis in the United States, AV access–induced steal may be the most common hand ischemia syndrome seen by most practitioners. Distal ischemia results from an imbalance in perfusion hemodynamics, where arterial occlusive disease proximal or distal to the AV anastomosis restricts supply to the hand or where high-volume flow through the AV anastomosis literally steals blood from the distal supply, reversing direction of arterial flow in the parent artery distal to the AV anastomosis. Predicting which patients will develop steal is challenging. Several factors may increase the risk of steal, including diabetes, advanced age, female sex, and use of proximal (brachioaxillary) inflow rather than forearm (radial) inflow. Symptoms of arterial steal may be mild, moderate, or severe and include persistent digital numbness, tingling, pallor, hand and finger motor weakness, and digital ulceration or gangrene. Many patients develop transient symptoms immediately following AV access creation, possibly due to local sensory neuropraxia after surgical manipulation or until arterial collateral accommodation takes place. Persistent mild symptoms that are well tolerated may be observed. More severe symptoms that affect daily activities, particularly in the dominant hand, require further evaluation and treatment. Rapidly progressive or severe ischemia and tissue loss mandate prompt evaluation and treatment to avoid limb loss or permanent devastating disability.

Arterial steal is diagnosed by a combination of clinical examination, duplex ultrasound and plethysmography, and catheter angiography. Arterial occlusive disease located proximal or distal to the AV anastomosis must be identified and addressed, if present; these can often be treated with balloon angioplasty during angiographic evaluation. In severely ischemic patients, or in those who are poor surgical candidates, simple ligation and sacrifice of the AV access are definitive and acceptable treatments for limb salvage. High-flow steal can be treated by operative flow-restriction techniques, such as fistula banding or plication. However, therapeutic failure and access thrombosis rates are high with these procedures, due to inability to accurately determine intraoperatively how severely to restrict flow for optimal results. Revascularization for relief of steal symptoms while preserving a functioning AV access can be considered in patients who are good surgical candidates.

The distal revascularization with interval ligation (DRIL) procedure is effective, with acceptable results. Arterial bypass, preferably saphenous vein, is routed around the AV anastomosis, from the

proximal brachial or axillary artery to the distal brachial, radial, or ulnar artery. The proximal bypass anastomosis is placed at least 6 cm proximal to the AV anastomosis, and the interval brachial artery is ligated just beyond the AV anastomosis, eliminating reversal of flow (Figure 10). The major disadvantage of DRIL is ligation of the native brachial artery, which eliminates some brachial collateral flow to the forearm and hand and could place the hand in jeopardy, should the DRIL bypass fail. However, devastating ischemic consequences of failed DRIL bypass are seldom reported, possibly due to the relatively short life expectancy in this patient population. Huber and colleagues reported 64 DRIL procedures, where operative mortality was 3% and complication rate was 22% (14% of which were wound complications). Bypass patency at 5 years was 71%. While the majority of patients (78%) experienced relief of ischemic symptoms, 5-year mortality was 33%, reflecting the severity of comorbid conditions in this subset of dialysis patients. These results are similar to other reported series.

Revision of inflow into the AV access can be achieved using proximalization of arterial inflow (PAI procedure, described by Zanow, 2006) or revision using distal inflow (RUDI procedure, described by Minion, 2005). PAI uses a small-diameter PTFE feeder conduit (4 or 5 mm) from a large proximal artery (usually axillary) to supply the AV access (Figure 11). The more proximal artery has higher perfusion pressure and is better able to collateralize, providing better perfusion to both the AV access and the distal extremity. RUDI achieves inflow restriction to the AV access by bringing an extension conduit from a smaller forearm artery, usually the proximal radial or ulnar artery (Figure 12). This alters the perfusion imbalance and improves distal extremity supply. In either case, severe flow restriction to the AV access can result in access loss. However, unlike DRIL, both PAI and RUDI preserve continuity of flow through the native brachial artery, avoiding the need to ligate an axial artery. Failure of revascularization places only the AV access in jeopardy. Thermann and colleagues (Thermann F, et al., 2010) reported results of 40 PAI procedures over a 5-year period. High clinical success was achieved, with primary patency 62% at 1 year and secondary patency 75% at 18 months.

SUMMARY

Upper extremity arterial occlusive disease and ischemia are less common than in the lower extremity, but when symptomatic, they cause significant disability. The etiology is diverse and may include systemic conditions, necessitating a thorough clinical evaluation before deciding upon treatment strategy. Medical management is useful for optimizing and controlling systemic disease. Endovascular therapy is emerging as an effective, less invasive treatment option, particularly for less extensive or intrathoracic lesions. Surgical revascularization remains the standard therapy for more extensive and distal lesions, with acceptable results for most upper extremity bypass procedures. Hand ischemia caused by AV access–induced arterial steal syndrome is a potentially devastating condition. Surgical revascularization in appropriate patients may offer symptom relief while preserving access function in these very challenging patients.

Aortoiliac Occlusive Disease

Shant M. Vartanian, MD, and Michael S. Conte, MD

INTRODUCTION

Aortoiliac occlusive disease (AIOD) is a common cause of lower extremity ischemia. The spectrum of clinical presentations is broad—from asymptomatic peripheral arterial disease (PAD) to limb-threatening critical limb ischemia (CLI). Even moderate ischemia, which manifests as intermittent claudication (IC), can be significantly disabling. By limiting the patients' ability to perform their primary occupation or carry out activities of daily living, IC can have a profoundly negative impact on quality of life. Because the risk of progression from claudication to major limb amputation is low—5% over 5 years—and the overall mortality is close to 20% over that same time period, the indication for intervention in IC is to improve the quality of life. In contrast, CLI should generally be treated with revascularization to reduce ischemic pain, heal wounds, and avoid major limb amputation.

INITIAL EVALUATION AND INDICATIONS FOR INTERVENTION

The initial evaluation for all patients with PAD starts with a detailed history and physical examination. Symptomatic patients with AIOD often present with claudication symptoms that involve the proximal muscles of the thigh, hip, buttocks, and calf. Depending on the location of the occlusive disease, pelvic ischemia can present with buttock claudication and erectile dysfunction. The syndrome of IC, impotence in males, and reduced femoral pulses due to AIOD was first recognized by the French surgeon René Leriche and bears his name. CLI symptoms manifest in the lower leg or foot with ischemic rest pain, nonhealing wounds, or gangrenous changes.

AIOD can be well collateralized with reconstitution of the infrainguinal circulation from the upper torso through the inferior epigastric artery and through the abdomen via mesenteric, retroperitoneal, and pelvic collaterals. Many patients have palpable femoral pulses, even in the setting of significant occlusive disease. In contrast, patients that present with rest pain or tissue loss often have extensive occlusions or multilevel disease. Diminished femoral pulses can be confirmed with noninvasive vascular lab studies, which should be performed as part of the initial evaluation. Segmental Doppler pressures or pulse volume recordings are useful for demonstrating the physiologic significance of disease and can help to localize hemodynamically significant lesions or suggest the presence of multilevel disease.

There are distinct anatomic patterns of AIOD. Typically, focal lesions present with lower extremity claudication. AIOD secondary to atherosclerosis is largely a disease of smokers, although advanced age, hypercholesterolemia, hypertension, and diabetes are also common risk factors. Ethnic variation in the anatomic pattern of AIOD has also been noted. Arteriopathies other than atherosclerosis can also involve the aortoiliac system, such as Takayasu's disease and radiation arteritis. Because of the unique pathophysiology of these entities, these nonatherosclerotic etiologies require alternative management approaches that are not further considered here.

The goals of therapy for patients with IC are secondary prevention of cardiovascular events and improvement in walking ability. Initial interventions should include management of risk factors, such as smoking cessation, hypertension, and glycemic control, and it should be coupled with a 3- to 6-month trial of exercise. There is mounting evidence that exercise therapy may be as effective as revascularization procedures in some patients with IC. The CLEVER trial, a randomized controlled study comparing supervised exercise therapy versus endovascular treatment of aortoiliac occlusive disease, showed greater objective short-term improvements in walking performance for the exercise therapy group but higher patient-reported satisfaction outcomes for iliac stenting. Similar results have been reported from randomized trials comparing exercise therapy to endovascular treatment of infrainguinal occlusive disease. Therefore, vascular interventions for IC, either open or endovascular, should be reserved for patients with disabling symptoms despite optimal medical therapy, for whom the risk to benefit ratio is low and a durable result is expected.

The treatment algorithm is altered for patients presenting with CLI. Though these patients have a shorter life expectancy than patients with IC, they are also at much higher risk for major amputation. The goal of therapy in CLI is healing of wounds, relief of pain, and prevention of limb loss. Revascularization, whether through direct surgical or endovascular means, is more aggressively pursued because medical management alone is in general a poor option.

In patients who are candidates for intervention, imaging studies are paramount for developing a treatment strategy. Though ultrasound can identify areas of stenosis, its utility in the setting of AIOD is limited by the presence of bowel gas, the patient's habitus, and heavily calcified vessels. Computed tomographic (CT) or magnetic resonance (MR) angiography are excellent at evaluating the aortoiliac segment, and the CTA in particular informs the operator about the location and distribution of calcified lesions, which is an important consideration in operative planning (Figure 1). The optimal and most cost-effective approach to imaging is debatable. Whereas in the past diagnostic angiography was a routine part of the workup, unless the patient is a candidate for an endovascular intervention, surgeons can often proceed directly to open surgical revascularization with the quality of the imaging seen on contemporary CT and MR angiograms. However, diagnostic catheter-based angiography may still be preferred in some cases, such as in the presence of prior stenting or spine hardware artifact, which can render CT or MR less accurate. In some cases, when the physical exam and noninvasive studies point to a high likelihood of an endovascular intervention and access appears straightforward, the value of a preliminary CT in terms of both cost and contrast exposure is questionable. However, our preferred approach is to obtain a cross-sectional imaging study to outline the options and to develop the strategy for intervention.

The patient's comorbid conditions, functional status, and life expectancy help frame the risks of intervention, but the underlying anatomic pattern of disease is supremely important in determining the safety, benefit, and durability of the procedure. The most commonly used anatomic classification system was presented by a multidisciplinary, multisociety consensus statement in 2000 and revised in 2007: the Trans-Atlantic Inter-Society Consensus (TASC) guidelines (Figure 2). Because endovascular interventions have a comparatively lower procedural morbidity than open surgical revascularization for AIOD, it is generally agreed upon that claudicants with focal and discrete lesions (TASC A or B) should be preferentially treated with endovascular interventions first. More advanced patterns of disease (TASC D) should be treated with surgical revascularization, unless the operative risk is prohibitive. In either case, immediate procedural success is high, but optimal management should carefully consider the long-term implications of the intervention because the disease is chronic and frequently progressive.

FIGURE 1 Preprocedure imaging. Computed tomographic (CT) angiography is an excellent imaging modality for evaluating aortoiliac occlusive disease. Not only is it informative regarding the degree and length of stenosis or occlusions, but the location and distribution of calcified atheroma are also revealed. Understanding both is important in selecting the appropriate revascularization strategy. In this maximum intensity projection, heavy calcification of the aortoiliac segment is evident, with occlusion of the right external iliac artery.

DIRECT SURGICAL REVASCULARIZATION

Direct surgical revascularization of AIOD is considered the "gold standard" treatment for durable vascular interventions. Ten-year patency rates of 85% for both aortofemoral bypass and aortoiliac endarterectomy are unmatched by endovascular procedures (Figure 3). For those patients with unilateral disease, the 3-year patency rate for iliofemoral bypasses exceeds 90% in most reports. Despite advances in patient selection, anesthetic care, and postoperative management—all of which have made the conduct of the operation much safer—direct revascularization today is reserved for patients with advanced aortoiliac occlusive disease for whom the risks of surgery are low and a durable result is expected.

The degree and distribution of atherosclerosis helps dictate which revascularization strategy will be most successful. The TASC II aortoiliac classification scheme helps serve as a framework for stratifying which patterns of disease are more likely to respond well to endovascular interventions (Types A and B) and which are more likely to have a durable result with direct revascularization (Type D). Examples of disease patterns that are served well with direct surgical revascularization include diffuse aortic or bilateral iliac disease, long segment chronic total occlusions, concordant aneurysmal disease of the aorta, patients with early and aggressive recurrence after a previous endovascular intervention, or those that have had atheroembolic events related to aortoiliac atheroma.

In patients with extensive comorbid conditions, such as uncorrectable coronary artery disease, poor ventricular function, advanced pulmonary disease, renal failure, or hostile abdominal anatomy, the increased risks of open surgery may make direct revascularization prohibitive, even in the setting of Type D lesions. Aggressive

Type A lesions

- Unilateral or bilateral stenoses of CIA
- Unilateral or bilateral single short (≤3 cm) stenosis of EIA

Type B lesions

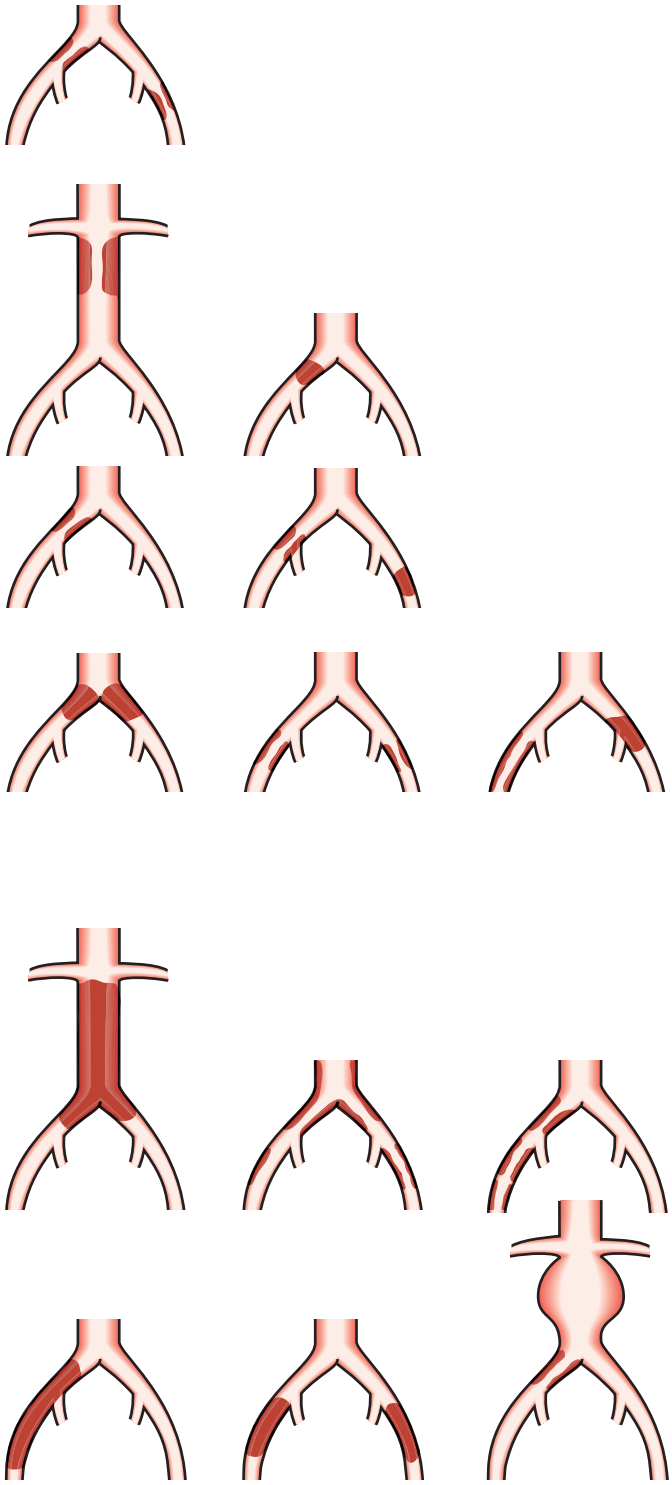
- Short (≤3 cm) stenosis of infrarenal aorta
- Unilateral CIA occlusion
- Single or multiple stenosis totaling 3-10 cm involving the EIA not extending into the CFA
- Unilateral EIA occlusion not involving the origins of internal iliac of CFA

Type C lesions

- Bilateral CIA occlusions
- Bilateral EIA stenoses 3-10 cm long not extending into the CFA
- Unilateral EIA stenosis extending into the CFA
- Unilateral EIA occlusion that involves the origins of internal iliac and/or CFA
- Heavily calcified unilateral EIA occlusion with or without involvement of origins of internal iliac and/or CFA

Type D lesions

- Infrarenal aortoiliac occlusion
- Diffuse disease involving the aorta and both iliac arteries requiring treatment
- Diffuse multiple stenoses involving the unilateral CIA, EIA, and CFA
- Unilateral occlusions of both CIA and EIA
- Bilateral occlusion of EIA
- Iliac stenoses in patients with AAA requiring treatment and not amenable to endograft placement or other lesions requiring open aortic or iliac surgery



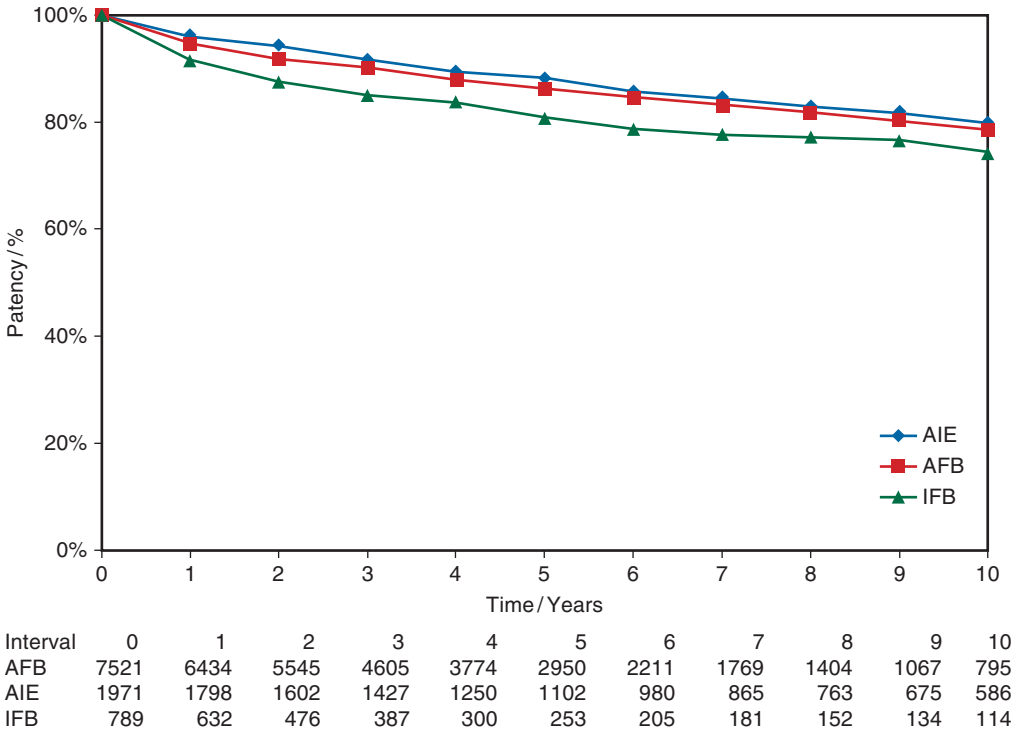


FIGURE 2 TASC II classification of aortoiliac occlusive disease. The TASC II classification scheme characterizes the location and morphology of aortoiliac occlusive disease. Anatomy alone does not dictate surgical approach, but rather the synthesis of surgical risk, comorbid conditions, functional status, and life expectancy help weigh the risks and benefits of each intervention. *(Norgren L, Hiatt WR, Dormandy JA, et al: Inter-society consensus for the management of peripheral arterial disease (TASC II). TASC II working group,* Eur J Vasc Endovasc Surg *33 (Suppl 1):S1-S75, 2007.)*

endovascular techniques, which can achieve high levels of technical success in experienced centers, may be appropriate despite the absence of long-term outcome data. Conversely, extraanatomic bypasses are an alternative approach in such patients, particularly when the indication for intervention is limb-threatening ischemia.

In addition to direct and extraanatomic bypass options in treating bilateral AIOD, unilateral iliac occlusive disease presents additional revascularization options, including the unilateral aortofemoral bypass, the iliofemoral bypass, the femoral-femoral bypass, and the axillary-femoral bypass. Choosing between an aortofemoral bypass

FIGURE 3 Long-term patency for direct revascularization. A review of 51 studies of direct surgical revascularization spanning 4 decades of compiled long-term patency data from 8006 patients. Durability of each type of procedure was excellent. *AIE,* aortoiliac endarterectomy; *AFB,* aortofemoral bypass; *IFB,* iliofemoral bypass. *(Adapted from Chiu KW, Davies RS, Nightingale PG, et al: Review of direct anatomical open surgical management of atherosclerotic aorto-iliac occlusive disease,* Eur J Vasc Endovasc Surg *39(4):460-471, 2010.)*

and an iliofemoral bypass is largely dependent on the distribution of atherosclerosis and whether the inflow artery can be safely controlled and the graft anastomosed at the level of the common iliac or distal aorta. Cross-sectional imaging is particularly helpful for examining the degree of calcification in these vessels, which may preclude this approach if extensive. Progression of atherosclerosis in the nonaffected limb is possible, but concern about future obstructive disease should not preclude a unilateral bypass. By basing the graft distally on the aorta and not mobilizing the infrarenal aorta extensively, the option to return for direct revascularization of the contralateral side remains viable. Crossover femoral-femoral bypass grafts are a useful approach in unilateral disease, particularly for patients who are higher risk, have had extensive prior abdominal surgeries, or have had failure of a prior graft limb. Unilateral axillary-femoral grafts are rarely indicated in elective scenarios, as the long-term results are inferior to direct revascularization or axillary-bifemoral bypasses. Clinical scenarios that may warrant such a reconstruction include presentation with acute or subacute ischemia with absent femoral pulses in a high-risk patient or when the contralateral groin is either septic or has soft tissue compromise in a patient that otherwise needs an extraanatomic bypass.

Although the long-term outcomes for direct revascularization with aortobifemoral or iliofemoral bypasses set the mark for durable outcomes, certain demographic features bear careful consideration. Female patients consistently have lower patency rates, in part due to the smaller size of their native vessels. Patients with multilevel disease also have worse long-term outcomes. A particular note of caution concerns the young patient (age <50) with AIOD, as several reports have highlighted markedly inferior outcomes in these patients with premature PAD. This likely reflects the presence of poorly controlled risk factors, particularly smoking, or an aggressive vascular disease phenotype. Even a seemingly straightforward endovascular procedure in these patients can have reduced durability and can accelerate the progression of disease toward complex reconstruction at an early age. We strongly advocate conservative management for the majority of younger patients and reserve intervention for severely progressive or limb-threatening symptoms.

The most common cause of failure of surgical reconstructions for AIOD is progression of atherosclerosis or neointimal hyperplasia at the distal anastomosis. Appropriate management of femoral disease at the time of the index operation is the key to maximizing the benefit and durability of any revascularization for AIOD. Unobstructed outflow through the profunda femoris is adequate runoff to maintain graft patency. A careful inspection of the profunda orifice following femoral arteriotomy should always be performed, and if there is any suspicion of obstructive disease at this level, a femoral endarterectomy with or without a formal profundaplasty should follow. Specific details on managing the femoral artery can be found in the section on aortofemoral bypass that follows.

AORTOBIFEMORAL BYPASS

Careful preoperative planning is essential in direct aortoiliac reconstruction. Body habitus, prior surgical history, presence of stomas, and skin conditions are important factors to consider in choosing an approach. Vascular imaging studies are critical for determining the level of aortic and iliac artery control, presence of concomitant renal or visceral artery disease, extent of common femoral and outflow disease, and the presence of concomitant aneurysmal degeneration of the aorta or iliac arteries. The location of the left renal vein should also be identified on cross-sectional imaging, as a retroaortic renal vein is not uncommon and may be inadvertently damaged during aortic mobilization or clamping if not anticipated.

Determining the level and configuration of the proximal and distal anastomoses is central to the preoperative strategy and should include careful consideration of the pelvic circulation. The proximal anastomosis to the aorta may be created in either an end-to-end or end-to-side fashion, with the former being preferred in most cases. With the end-to-end anastomosis, pelvic perfusion is maintained via retrograde flow from the external iliac arteries and proximal lumbar and mesenteric collaterals. In the presence of severe bilateral external iliac artery disease, an end-to-side configuration may be preferred. Alternatively, reimplantation of a patent inferior mesenteric artery

may be performed regardless of the proximal configuration, particularly if there is suggestion of significant superior mesenteric artery disease or both hypogastric arteries are either occluded or will be excluded. An absolute indication for end-to-end reconstruction is the presence of concomitant aneurysmal degeneration of the abdominal aorta, which must then be fully excluded. Because the end-to-side aortic anastomosis requires a longer disease-free segment of infrarenal aorta, extensive atherosclerotic changes may also preclude it. In general, the immediate infrarenal aorta is more disease free and less likely to progress over time, which is an important reason to favor the end-to-end configuration.

The aortobifemoral bypass (AFB) procedure begins with exposing the femoral arteries. Minimizing the duration of time the abdomen is open limits insensible fluid losses, hypothermia, and inevitably blood loss. The common femoral artery is exposed through a longitudinal incision in standard fashion. The extent of exposure is predicated upon the extent of disease within the femoral artery. Proximally, exposure of the external iliac just above the inguinal ligament is often necessary to identify a soft, disease-free segment of artery that is amenable to clamping. The ligament may either be mobilized and retracted or partially divided to achieve the appropriate exposure. The inferior epigastric artery and circumflex iliac arteries should be identified and controlled because these are major collateral pathways in the setting of aortoiliac occlusive disease. Uncontrolled, these arteries will be a source of formidable back bleeding into the surgical field. The overlying deep circumflex iliac vein, which traverses anterior to the external iliac artery, deep to the inguinal ligament, should also be divided. Tunnels for the graft limbs are initiated from the groin by gentle finger dissection in the plane just anterior to the external iliac artery. Inadvertent injury to the crossing veins is avoided by ligating the vein before developing the tunnel.

The distal extent of exposure depends on whether an adjunctive femoral endarterectomy or profundaplasty is necessary. In all cases, the proximal superficial and deep femoral arteries are exposed for at least 2 to 3 cm beyond their origins. Assessment of these vessels by direct palpation, in addition to the preoperative imaging, is important to determine if they can be safely clamped or whether more extensive disease should be addressed by endarterectomy or patch angioplasty. This determination is most critical for the profunda femoris artery (PFA), the critical collateral pathway for the entire lower limb. If disease is present in the proximal PFA, more distal exposure of the secondary branches of the artery is necessary, and this often requires division of the overlying lateral circumflex femoral vein. After completing the groin exposures, these incisions are packed with antibiotic-soaked gauze sponges, and attention is turned to the abdomen.

The abdominal aorta is usually exposed via a transperitoneal approach through a midline incision. Though transverse exposures allow for generous access to the abdominal aorta, this incision requires division of the inferior epigastric arteries, which are major collateral pathways in the setting of AIOD. In the event of graft thrombosis, preserving the native collateral circulation can protect against the development of severe ischemia. The retroperitoneal approach via a left flank or a left paramedian incision may be desirable in select cases, such as those patients with "hostile" abdomens; however, it is slightly more challenging to develop the tunnel for the right limb of the bypass graft.

For transabdominal exposures, after exploring the abdomen and ensuring the appropriate placement of the nasogastric tube, an inframesocolic approach is used to enter the retroperitoneum. The ligament of Trietz is taken down, mobilizing the duodenum to the patient's right, until the vena cava is visualized. The anterior surface of the aorta is exposed from the inferior mesenteric artery up to the renal vein. Numerous lymphatics are encountered during this portion of the exposure, and they should be ligated to prevent a postoperative chyle leak. The renal vein is then mobilized from the vena cava medially to the adrenal and gonadal branches laterally. With adequate mobilization, including ligating the adrenal and lumbar branches, it is generally unnecessary to divide the renal vein, even if a suprarenal clamp is planned. If an aortic or renal artery endarterectomy is anticipated, or suprarenal clamping of the aorta is necessary for control, the renal arteries should be individually controlled. If an end-to-side anastomosis is planned, more extensive aortic mobilization is required to control or ligate lumbar arteries that would otherwise back bleed.

The distal extent of exposure is predicated upon the location of atheromatous disease. Palpation of the distal aorta, common iliac, and external iliac arteries will help identify a soft spot that is amenable to clamping. The peritoneum overlying the segment of artery is incised and the artery is exposed. Circumferential control is not necessary, and limiting dissection can minimize the chance of adjacent iliac vein injury. When exposing sites of distal control, be mindful of the location of the hypogastric plexus and the presacral nerves, which course anterior to the aorta and travel caudally over the aortic bifurcation. Injury to the plexus, which controls the autonomic functions of the pelvis, can result in impotence and retrograde ejaculation in men. To avoid this complication, approach the common iliac arteries laterally, and sweep up the peritoneum and the underlying nervous plexus toward the midline.

Deciding how and where to clamp the aorta is not trivial. Heavily calcified atheroma can be incompressible, or its irregular contour may prevent adequate hemostasis. The aorta is carefully palpated to identify a soft spot that is compressible. Atraumatic vascular clamps are applied in either a side-to-side or front-to-back fashion to ensure adequate apposition of the aortic walls. Clamping calcified atheroma can result in intimal tears, and the resulting clamp site injury can be a formidable challenge from which to recover. Side-biting or partial occlusion clamps are not recommended for an end-to-side anastomosis, as occasionally an endarterectomy of the aortic arteriotomy is necessary, and the partial occlusion clamps prevent adequate exposure and visualization of the lumen.

Tunnels for the graft limbs are then completed from the abdomen with careful blunt dissection directly over the external iliac artery. The graft limbs should be tunneled posterior to the ureter under direct visualization to prevent late upper urinary tract obstruction (Figure 4). Working from both the peritoneal cavity and the femoral exposure, a length of plasma tubing or a Penrose drain is passed with a curved aortic clamp to mark the tunnel. On the patient's left side, the tunnel is created deep to the mesentery of the sigmoid colon.

A bifurcated graft is selected—typically a collagen-coated or presealed knitted Dacron prosthesis. Generally, the graft is sized according the diameter of the aortic cuff. However, it may be advantageous to err in favor of a larger size if the graft limbs appear too small to maintain adequate outflow (i.e., <7 mm). Heparin sodium is then given as a bolus dose of 70 mg/kg and allowed to circulate for 3 minutes. Maintaining an activated clotting time of 250 to 300 seconds prevents lower extremity thrombus formation. Because atheromatous or thrombotic debris may break free and embolize in the process of applying vascular clamps, the distal clamps are applied first.

As noted previously, although there are advantages and disadvantages of each approach, most proximal anastomosis should be fashioned end-to-end. The in-line flow patterns result in less turbulent flow than an end-to-side anastomosis. After excising a portion of the aorta, the graft lies flat in the retroperitoneum, making for closure of the retroperitoneum over the graft simpler and theoretically resulting in a lower incidence of enteric erosions and graft infections (Figure 5). If planning an end-to-end anastomosis, the aorta is transected 2 cm distal to the proximal aortic clamp. Excising a short segment of aorta (2-4 cm), stopping short of the IMA, gives the main body of the graft space to lie within the retroperitoneum and allows for retrograde flow to perfuse the IMA if patent. The distal segment of aorta is oversewn or stapled, and if heavily diseased, it may require an endarterectomy first.

The proximal aortic cuff may also require an endarterectomy or may be lined with laminar thrombus or loose plaque that should be

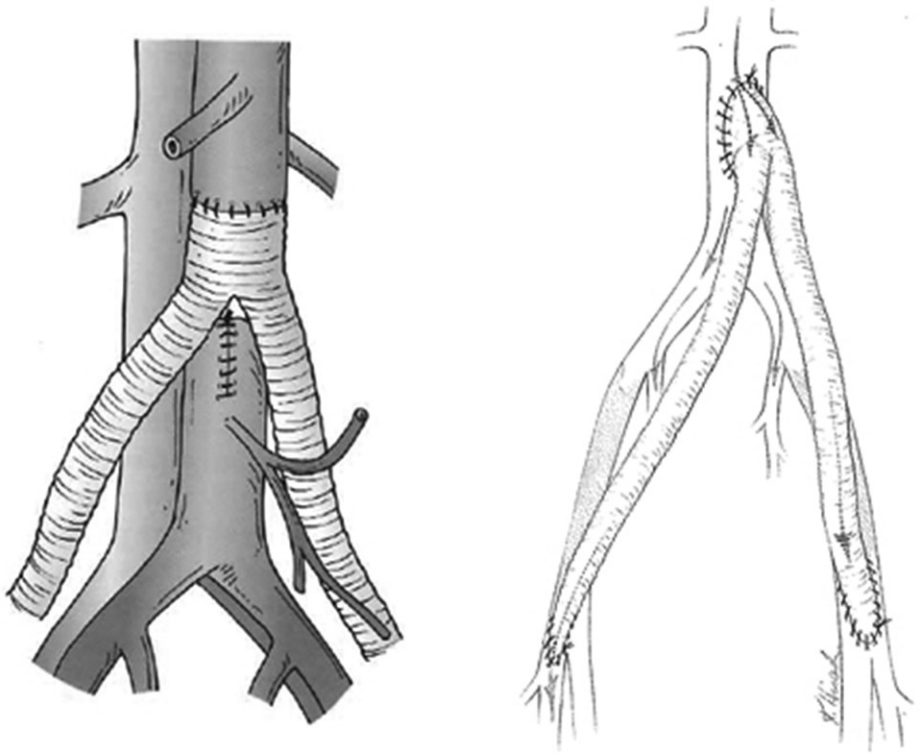

FIGURE 4 The proximal anastomosis. By resecting a short segment of aorta, the end-to-end proximal anastomosis lies flat along the retroperitoneum. This configuration ensures nonturbulent flow at the proximal anastomosis and simplifies the retroperitoneal closure at the completion of the reconstruction. In situations where antegrade flow to the pelvis needs to be preserved, an end-to-side anastomosis is favored. *(Adapted from Cronenwett JL, Johnston, KW:* Rutherford's vascular surgery, *ed 7, Philadelphia, 2010, Saunders; and from Zarins CK, Gewertz BL:* Atlas of vascular surgery, *St. Louis, 2005, Elsevier.)*

cleared prior to fashioning the anastomosis. This should be done with great care as to limit debris entering the lumen of the renal arteries or inadvertently developing a deep endarterectomy plane with resulting thin adventitia that may tear easily during suturing. If this is anticipated, the proximal anastomosis should be buttressed with a felt strip or sewn with interrupted pledgeted mattress sutures. The body of the graft is then shortened to less than 4 cm in length so the graft limbs straddle the oversewn aortic stump rather than lie over them. The proximal aorta is flushed to clear remaining debris, and the anastomosis is then created with 3-0 monofilament polypropylene suture. The graft limbs are then individually flushed, rinsed with heparinized saline, clamped, and then passed through the previously made tunnel with a curved aortic clamp.

One key to maintaining durability of the AFB graft is ensuring adequate outflow. In some cases, AIOD exists without significant femoral or infrainguinal occlusive disease. In these situations a simple end-to-side anastomosis to the common femoral artery is adequate. Very rarely, as in the case of truly isolated Type I disease, the distal anastomosis may be to the intraabdominal external iliac artery. However, due to the high frequency of disease progression in the external iliac and common femoral arteries, this should be done cautiously. The graft limb is beveled and sewn to the distal artery with continuous 5-0 monofilament polypropylene suture.

More commonly, however, multilevel or common femoral disease is also present. Unobstructed flow into PFA is sufficient outflow to maintain graft patency. Even in the setting of a complete SFA occlusion, a well-collateralized profunda system is adequate runoff for an AFB graft and will often alone result in significant hemodynamic improvement of the limb distally. After creating the longitudinal arteriotomy, the orifice of the profunda should be visually inspected and interrogated with a series of dilators, and it should easily accommodate at least a 4-mm probe.

When orificial disease of the PFA is present, a limited endarterectomy is indicated, and the arteriotomy can be extended onto the profunda so a profundaplasty is created with the hood of the graft (Figure 6). When more extensive PFA disease is present, a longer endarterectomy and patch angioplasty may be required. If the distal endpoint of the endarterectomy is not firmly secure, it should be reinforced with interrupted sutures. The arteriotomy and patch closure should be extended to just beyond this transition zone. The graft limb is then flushed, the arteries are back bled, and the clamps are released sequentially so that residual debris preferentially flows into the pelvis. The anesthetist should be advised prior to unclamping that significant hypotension may result from perfusing the ischemic limb.

With appropriately managed outflow disease, a sequential bypass to the lower extremity is rarely needed. These adjunctive procedures add to blood loss and operating time, and they expose the patient to the complications of infrainguinal bypass without necessarily improving the long-term patency of the AFB. They are largely reserved for limbs with severe limb-threatening ischemia, such as those with extensive tissue loss in the setting of complete SFA occlusion, which cannot wait for a staged infrainguinal procedure.

After completion, an assessment of distal perfusion is made by palpating the artery in the field and by listening with Doppler intonation to both the target artery and the pedal arteries. When outflow is limited to the PFA, improvement in pedal Doppler signals may not be immediately appreciated in the operating room due to the patient's hemodynamic status and peripheral vasoconstriction. If content with the technical result, hemostasis is achieved, and the retroperitoneum overlying the graft is closed with absorbable suture. Inadequate coverage of the graft may lead to a graft-enteric fistula. In the setting of end-to-side anastomosis, it may not be possible to close the retroperitoneum over the graft directly. In these situations, a tongue of omentum can be mobilized and secured to the retroperitoneum between the graft and the overlying bowel.

ILIOFEMORAL BYPASS

Just as in the AFB, the iliofemoral bypass (IFB) procedure begins with the femoral exposure. There are no significant differences in the conduct of this portion of the operation. The degree of exposure is

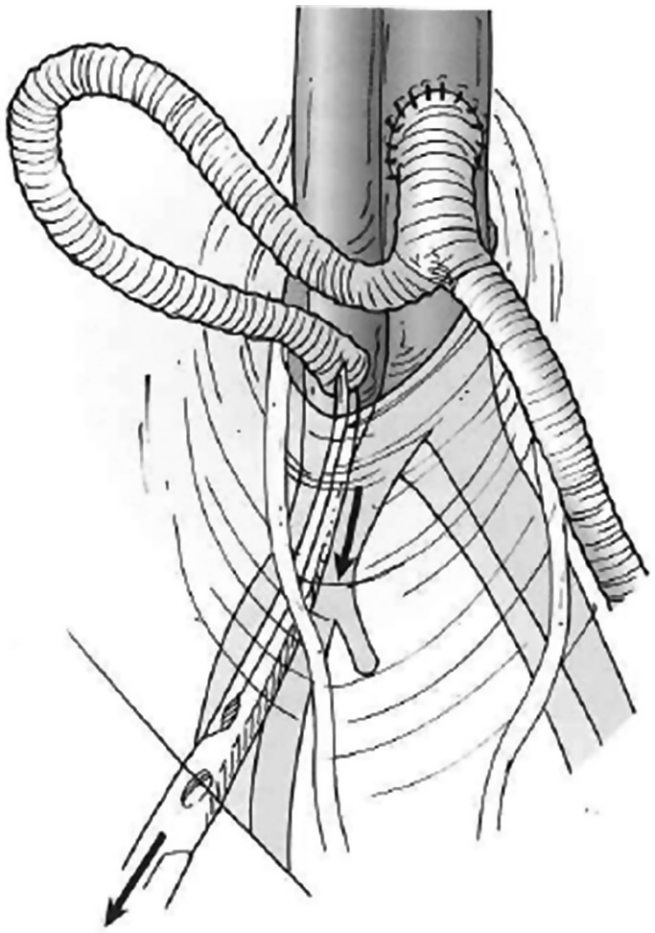

FIGURE 5 Tunneling of the graft limbs. The retroperitoneal tunnel is developed by blunt manual dissection under direct vision, taking care to establish a plane posterior to the ureter. After completion of the proximal anastomosis, the graft limb is passed through the tunnel with a curved aortic clamp. *(Adapted from Cronenwett JL, Johnston, KW:* Rutherford's vascular surgery, *ed 7, Philadelphia, 2010, Saunders.*)

a function of the extent of atherosclerotic disease in the femoral artery. If anticipating a femoral endarterectomy, generous exposure of the profunda femoris artery should be performed.

Unlike in AFB, where a transperitoneal or retroperitoneal exposure to the abdominal aorta is an option, in treating unilateral disease, the retroperitoneal exposure is particularly suitable. Advantages include avoiding potential trauma to the hypogastric plexus and presacral nerves, avoiding adhesions if the patient has had previous abdominal surgery, and theoretically minimizing the postoperative ileus because the peritoneal space is not entered. Either an oblique lower abdominal or a paramedian incision may be used for iliac artery exposure. Regardless, the surgical field extends from the costal margins to the knees in case more proximal exposure is required.

The location of the inflow is dependent on the distribution of atherosclerotic disease. Anticipate the need for extending the arteriotomy or performing a local endarterectomy when choosing a location for the vascular clamps. Often, this means being prepared to clamp the distal abdominal aorta and contralateral iliac artery even though the surgical plan calls for a common iliac artery anastomosis. Just as in the AFB, the prosthetic graft is then passed through the tunnel, and the remainder of the operation is completed.

EXTRAANATOMIC BYPASS

Although direct reconstruction of aortoiliac disease can be done with low morbidity and mortality in well-selected patients, those with significant coexistent cardiac and pulmonary disease—who are at high risk for open aortic surgery due to either physiologic or anatomic constraints—would be better served with extraanatomic reconstruction. These techniques, such as the femorofemoral bypass or the axillobifemoral bypass, limit the morbidity associated with major vascular surgery but come at the price of limited durability. These techniques are usually reserved for patients with critical limb ischemia and are generally not performed for intermittent claudication.

FEMOROFEMORAL BYPASS

The principle advantage of femorofemoral bypass (FFB) is that it can be done under local or regional anesthesia, minimizing pulmonary complications associated with direct reconstruction of the abdominal aorta. This procedure is well suited for patients who have iliac occlusive disease limited to one iliac system and a contralateral side that is free from hemodynamically significant stenosis. However, even this principle is in evolution. Multiple groups have reported satisfactory outcomes with hybrid procedures, where focal iliac lesions of the donor iliac system are treated first with endovascular techniques, before completion of the femorofemoral bypass graft.

The technique is performed through bilateral longitudinal incisions exposing the femoral arteries. Oblique incisions, though common when placing cross-femoral grafts during endovascular treatment of aortic aneurysms, are less versatile when treating occlusive disease. However, it may be advantageous in obese patients to help reduce the risk of wound complications related to crossing skin folds. Following adequate exposure of the inflow and outflow arteries, the graft tunnel is made in the subcutaneous tissue directly overlying the pubis, immediately anterior to the fascia of the abdominal wall, by blunt finger dissection or with the assistance of a curved clamp. The choice of graft material, whether supported or unsupported PTFE or polyester, has been well studied and does not appear to have significant effect on outcomes. Multiple configurations of the graft have been described, but the most common is the inverted C orientation. Following heparinization and clamping, an end-to-side anastomosis is fashioned with the beveled end of the graft to the common femoral artery at a slightly oblique angle, oriented from medial to lateral. In obese patients, the inguinal ligament can descend significantly when the patient moves from the supine to the standing position. Grafts sewn too proximally on the common femoral artery may undergo kinking at the heel of the graft. To avoid this complication, place the graft distally on the common femoral artery. The graft is then passed through the tunnel, ensuring that the course the graft takes is a gentle turn into the contralateral groin. The graft is then distended to ensure accurate measurement of length, trimmed to size, and then sewn end-to-side to the target femoral artery.

AXILLOBIFEMORAL BYPASS

The axillobifemoral bypass (AxBF) graft is well suited for frail patients with aortic or proximal iliac occlusive disease with advanced lower extremity ischemia, such as tissue loss or rest pain. Other indications are patients with a "hostile" abdomen, including previous radiation therapy, intestinal stomas, or intraabdominal sepsis. Unlike the FFB, the AxBF usually requires general anesthesia (though the original report describes the procedure under local anesthesia). Due to the limited inflow the axillary artery can provide, the procedure is typically reserved for patients with limb-threatening ischemia, not IC alone.

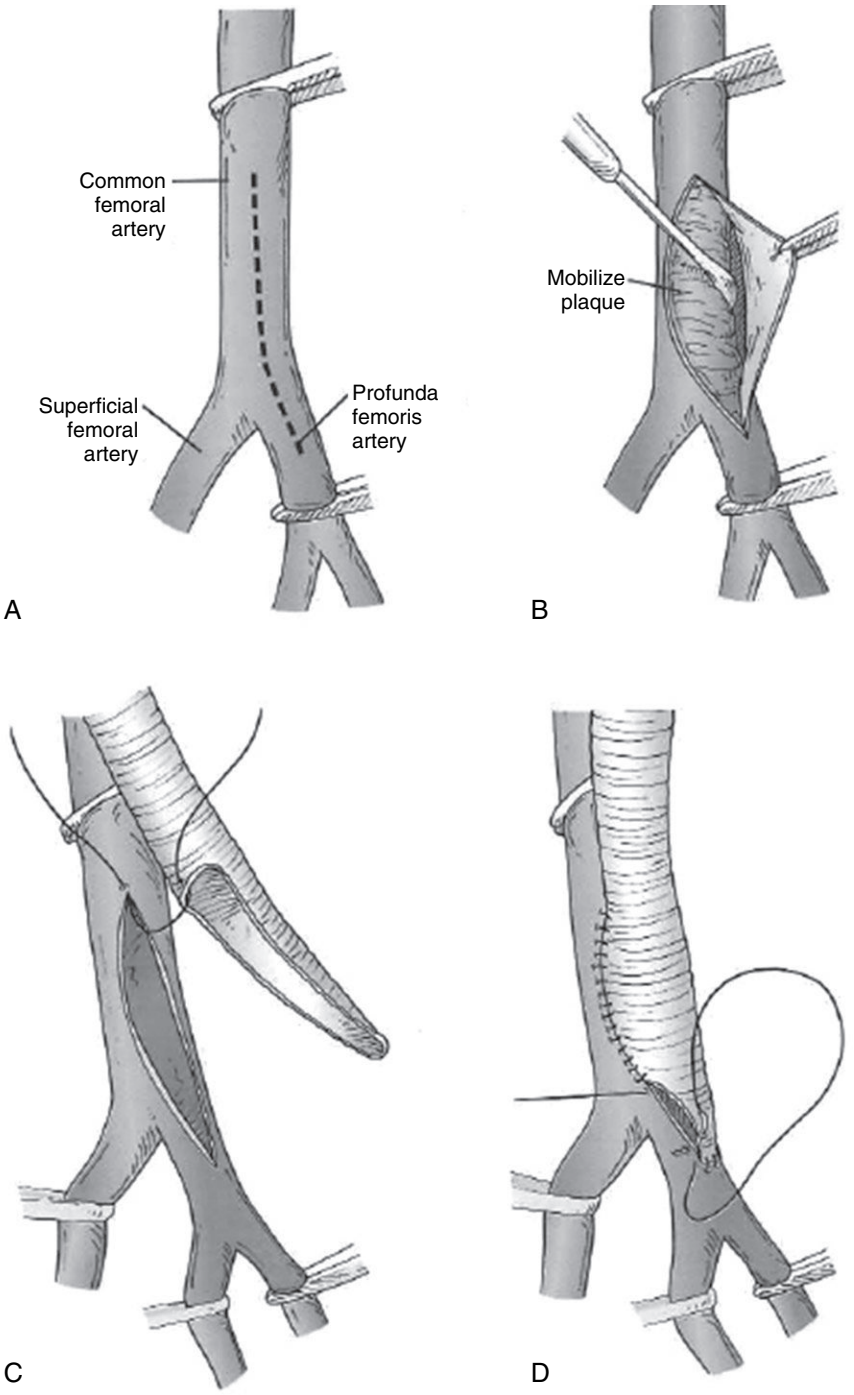

FIGURE 6 Adjunctive profundaplasty. Graft patency is optimized by maximizing the graft limb outflow. Concomitant disease of the profunda femoris orifice should be treated with limited endarterectomy and a profundaplasty using the toe of the aortofemoral graft limb. *(Adapted from Cronenwett JL, Johnston, KW:* Rutherford's vascular surgery, *ed 7, Philadelphia, 2010, Saunders.)*

Outflow plays a particularly important role in the midterm durability of this procedure. A long prosthetic bypass graft based upon the axillary artery is at risk for thrombosis. Providing outflow via both femoral arteries rather than upon the ipsilateral femoral artery alone has been shown to increase flow within the graft at the axillary artery and improve the long-term patency of the bypass. Preoperatively, blood pressure measurements in both arms dictate whether to use the right or left side for inflow. Typically, the left subclavian artery is atheroprone, and the right axillary artery is the source of inflow. The patient is positioned supine on the operating table, a shoulder roll is placed behind the patient, and the arm is tucked to the side. The skin is prepped widely, and the patient is draped low to the bed should there develop the need for a counterincision or if there is a mishap during the tunneling of the graft.

An infraclavicular incision overlying the insertion of pectoralis minor is used to expose the axillary artery. The clavipectoral fascia is divided, and a muscle-splitting technique is used to dissect through the pectoralis major into the deep pectoral fascia. The pectoralis minor is divided to expose the second portion of the axillary artery. The axillary artery is fragile in comparison to the femoral artery and should be handled with care to prevent inadvertent laceration or dissection. Mobilizing a generous length of artery without traumatizing the closely associated brachial plexus allows for delivering the artery up into the surgical field, simplifying the anastomosis.

This maneuver is facilitated by dividing the deep thoracic artery (Figure 7).

The femoral exposure is performed as in FFB—a longitudinal incision to expose the common femoral artery—and the cross-femoral graft is tunneled in a similar manner. The graft tunnel from the axillary artery to the femoral artery should traverse anterior to the anterior superior iliac spine, along the fascia of the abdominal wall, posterior to the breast in women, and deep to the pectoralis major. An externally supported prosthetic graft (i.e., ringed PTFE) is used, because the graft can be compressed and will thrombose while the patient lies on his or her side while sleeping. The graft should be trimmed with the artery in its native position, with enough redundancy to allow for shoulder abduction postoperatively without placing tension on the anastomosis. Following heparinization and clamping, the beveled graft is anastomosed end-to-side along the anteroinferior portion of the axillary artery to minimize the possibility of graft kinking as it passes into the tunnel.

A variety of configurations for the distal anastomoses have been described. As in the femorofemoral graft, we prefer an inverted C orientation, with the cross-femoral graft based upon the axillofemoral graft rather than the native artery. Inverted S configurations, graft flow dividers, or other manipulations to limit competitive flow in the iliac artery have been described but do not appear to significantly affect the quality of the procedure.

OTHER SURGICAL REVASCULARIZATION OPTIONS

Prior to the popularization of prosthetic grafts, the standard treatment for aortoiliac occlusive disease was the endarterectomy. The open, eversion, and semiclosed methods have all been described with excellent patency. The advantage of the endarterectomy is avoidance of complications related to prosthetics grafts (infection, pseudoaneurysm formation, etc.) and potentially improved inflow into the hypogastric arteries. However, the excellent result with AFB and endovascular techniques has limited the number of patients who are candidates for this type of intervention. Currently, the ideal candidate for endarterectomy is the younger patient who has focal (e.g., Type I) disease in a large-caliber vessel, who is not better served with endovascular interventions. The high success rates of angioplasty and stenting for these more limited disease patterns have essentially rendered aortoiliac endarterectomy obsolete in current practice.

Rarely, there will be patients who are candidates for direct surgical revascularization but may not have an accessible abdominal aorta. This may be because of abdominal radiation, proximal aortic disease above the renal arteries that prevent aortic clamp application, or a failed previous aortic operation. In these cases, an alternative source of inflow is the distal thoracic aorta. This requires exposure through either a lateral thoracotomy, high retroperitoneal or thoracoretroperitoneal approach. The latter simplifies tunneling of the graft limbs through the retroperitoneum, posterior to the kidney. A transperitoneal approach with medial visceral rotation may also be used, though more commonly this is necessary when the initial plan for an infrarenal anastomosis is abandoned due to unanticipated disease severity or calcification. The durability of this procedure rivals that of the AFB.

COMPLICATIONS OF SURGICAL REVASCULARIZATION

Aortobifemoral grafting is considered the "gold standard" for durable AIOD treatment. Improvements in patient selection, intraoperative anesthetic care, surgical proficiency, and postoperative management have made the procedure safe for most. In multiple contemporary series, AFB can be performed with a less than 1% in-hospital mortality (Table 1). The overall morbidity rate approaches 20% to 35% when using a composite endpoint that includes both major and minor complications. Postoperative cardiac events occur in less than 5% of patients and can be minimized with appropriate use of medications such as beta-blockers, aspirin, and statins in accordance with current practice guidelines. Pulmonary complications are not infrequent, occurring in up to 7% of patients. Adequate pain control with

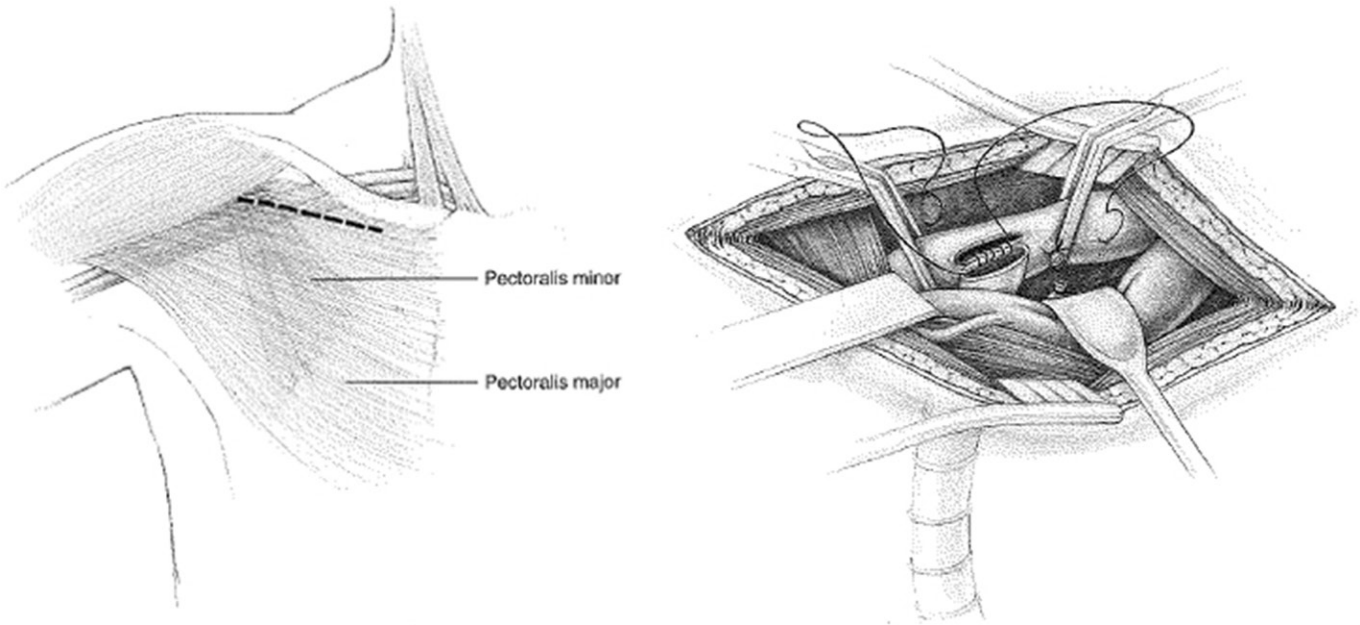

FIGURE 7 Axillofemoral bypass. An infraclavicular incision overlying the insertion of pectoralis minor is used to expose the axillary artery. The pectoralis minor is divided, exposing the second portion of the axillary artery. Dividing the deep thoracic artery allows for a generous mobilization and helps deliver the artery up into the surgical field, simplifying the anastomosis. *(Adapted from Zarins CK, Gewertz BL:* Atlas of vascular surgery, *St. Louis, 2005, Elsevier.)*

TABLE 1: Results of direct surgical revascularization

Procedure	5-year patency	Perioperative morbidity	Operative mortality
Aortofemoral bypass	80% to 95%	10% to 30%	2% to 4%
Iliofemoral bypass	80% to 90%	10% to 25%	1% to 3%
Femorofemoral bypass	55% to 85%	10% to 25%	1% to 3%
Axillobifemoral bypass	50% to 75%	10% to 40%	1% to 4%
Axillofemoral bypass	45% to 70%	10% to 40%	1% to 4%
Iliac endarterectomy	80% to 90%	10% to 20%	1% to 3%

epidural anesthesia to facilitate pulmonary toilet and avoidance of volume overload can help prevent these complications. Atheroemboli can be liberated during the procedure, manifesting as end organ ischemia in the skin, pelvis, spinal cord, and bowel. Attention to detail during clamping and flushing can minimize this complication. Ischemic colitis and pelvic ischemia are rare and can be avoided by planning a procedure that maintains pelvic perfusion. Other complications include renal failure from ischemia secondary to prolonged clamp times or embolization during aortic cuff endarterectomy; wound complications, particularly in the groin (lymphocele, lymphocutaneous fistula, wound infections); and postoperative hemorrhage.

The most frequent late complication of the aortobifemoral bypass graft is thrombosis, typically involving a single graft limb. The 10-year patency of this bypass is approximately 85%. A classic mistake is to base the graft too far distal on the abdominal aorta. Disease progression proximal to the graft presents as bilateral limb thrombosis. Unilateral graft limb thrombosis is invariably a result of outflow obstruction from either neointimal hyperplasia in the anastomotic area or progression of native disease in the femoral artery. This can be managed with a thrombectomy through a femoral exposure and revision of the distal anastomosis.

Pseudoaneurysm formation secondary to material fatigue or suture fracture is not as frequent as it once was and may also result from either degeneration of the native femoral artery or occult graft infection. Nonvirulent species of bacteria can present with a pseudoaneurysm long after the index procedure. An index of suspicion for infection should be maintained when treating all pseudoaneurysms. Graft infection remains an uncommon but dreaded complication of AFB. Less subtle signs of a graft infection at the level of the groin include a draining sinus tract or evidence of cellulitis or induration. Infections involving the intraabdominal portion of the graft can present with abdominal tenderness with or without an ileus, sepsis, or a gastrointestinal bleed. Infrequently, a graft enteric fistula may develop when a loop of bowel, typically but not always the duodenum, erodes into the graft. This challenging complication is minimized by carefully closing the retroperitoneum over the graft or interposing a tongue of omentum at the time of the index operation.

Complications related to extraanatomic bypasses are similar to those of arterial surgery in general. There are risks of hemorrhage, wound complications, hematoma, graft infection, and pseudoaneurysm formation. Specific to the cross-femoral graft, complications of tunneling subfascial with subsequent bowel and bladder perforation have been reported. Specific to the axillary graft, trauma to the brachial plexus, atheroemboli to the hand, or graft avulsion have been reported. This last complication can be minimized by planning enough redundancy of the graft to allow for comfortable shoulder abduction postoperatively.

RESULTS OF SURGICAL REVASCULARIZATION

AFB grafting is the "gold standard" for treating aortoiliac occlusive disease. Irrespective of the surgical indication—be it claudication or critical limb ischemia—graft patency at 5 years is nearly 90% and at 10 years is about 85% (see Table 1). Although gender may affect the outcomes, transperitoneal or retroperitoneal exposure and end-to-end or end-to-side anastomosis do not appreciably alter the results. Results of IFB for unilateral disease are generally at least as good as AFB in reported series.

Extraanatomic bypasses do not fare as well but have acceptable midterm results. Though these interventions are typically reserved for patients with coexistent comorbid conditions that are not candidates for direct revascularization, and therefore have a higher expected mortality over the long term, many series have reported 5-year patency rates averaging approximately 70%. The long-term results with AxBF are more muddled. Often, these patients have shortened life expectancy, and survivors with less burden of disease bias long-term outcome data. Even so, stratifying results by indication shows results are inferior to aortobifemoral grafting, with an estimated 5-year patency of 50% to 70%.

ENDOVASCULAR INTERVENTIONS

Just as in open surgery, preprocedure planning sets the stage for a successful endovascular intervention. Noninvasive imaging, in particular with CT angiography, delineates the location and extent of disease, as well as the degree of calcification. It also helps assess the quality of the access vessels and whether an ipsilateral retrograde, contralateral antegrade, brachial approach, or concomitant open femoral exposure will be necessary. In general, CIA disease is treated through an ipsilateral retrograde approach, and EIA disease is treated with a contralateral antegrade approach. If the CIA is occluded, bilateral punctures of the femoral arteries will be necessary to perform an aortogram proximal to the lesion.

Access is gained in the CFA using the Seldinger technique under ultrasound guidance. Inspection of the anterior surface of the CFA not only identifies segments of artery that are disease free and likely to be receptive to puncture but also a segment of artery that is favorable for maintaining hemostasis during sheath removal. This maneuver can circumvent common complications related to endovascular interventions, such as retroperitoneal hematomas, pseudoaneurysm formation, and iatrogenic arteriovenous fistulas.

In situations where there is significant femoral disease but limited AIOD (i.e., TASC A or B), a hybrid approach utilizing an open femoral endarterectomy with endovascular treatment of the aortoiliac system is preferred. In these cases, carefully weigh the option of a formal AFB versus the reduced morbidity and durability of the hybrid procedure. The hybrid approach can be executed in a number of ways. We favor performing the endarterectomy first, as it allows for the possibility of stenting the external iliac artery right down to, or even into, the endarterectomy site without having to achieve inflow occlusion of the stent. After endarterectomy and patch angioplasty, the patch can be punctured directly, or the sheath can be introduced between the patch suture line prior to tying down the patch. It can sometimes be difficult to stay out of the dissection plane when passing the wire retrograde. Securing the proximal edge of the endarterectomy with suture minimizes this risk. Alternatively, puncturing the artery and leaving the wire across the true lumen of the iliac artery during the endarterectomy eliminates problems with wire passage. However, even with soft insert clamps, bleeding around the

wire may be a persistent nuisance. Otherwise, an "up-and-over" wire can be passed from a contralateral antegrade approach into the surgical field.

With either technique, a 5 French sheath is used at the access site, and a hydrophilic guidewire with an angled tip catheter is used to access the aorta. The patient is heparinized to maintain an activated clotting time of 250 to 300 seconds, and a power injector is used to perform flush aortography with a multisidehole catheter (Figure 8). The AP projection is ideal for evaluating the aortic bifurcation, and oblique views of the pelvis are needed to open the iliac bifurcation. In general, a 50% stenosis is considered hemodynamically significant. If the significance of the lesion is in doubt, direct pressure measurements or intravascular ultrasound can be used to more accurately estimate the degree of stenosis. A resting pressure gradient of over 10 mm Hg when pulling back an end-hole catheter through the lesion or an enhanced gradient of over 20 mm Hg when infusing a vasodilator distally (e.g., nitroglycerin or tolazoline) is considered hemodynamically significant.

Stenosis can usually be crossed with a hydrophilic guidewire and catheter combination with relative ease. Chronic total occlusions are technically more challenging. Finding a serviceable plane depends on plaque morphology. Crossing occlusions retrograde has the mechanical advantage of "push ability," as the wire and catheter combination is not working around a curve. However, it can be difficult to precisely reenter the lumen once subintimal, and this can be particularly problematic if inadvertently extending the plane up along the aorta. Reentry catheters have been developed to facilitate this process. The antegrade approach from the contralateral iliac artery eliminates worries about reentry into the aorta, but it can be difficult to engage a subintimal plane because push ability is lost at the bifurcation. This is particularly true with flush iliac occlusions. The brachial approach is another option, but larger sheath sizes needed for iliac stenting typically mean starting with an open brachial exposure. In addition, a long catheter passed around the aortic arch also has its own set of mechanical disadvantages.

Lesion length, location, and degree of calcification dictate whether angioplasty alone, a balloon-expanding stent, or a self-expanding stent should be used. Occlusive disease of the terminal aorta, or orificial disease of the common iliac artery, should be treated with balloon-expanding "kissing" stents (Figure 9). Balloon-expanding stents can be deployed accurately and have greater radial strength. Theoretically, treating only one iliac artery orifice can result in plaque shift during angioplasty, obstructing the contralateral lumen. Treating both sides simultaneously avoids this complication. Covered balloon-expanding stents may have improved patency in long-term follow-up because covered stents prevent the development of neointimal hyperplasia through the interstices of the stent. They may also be safer in the setting of small, heavily calcified, or tortuous iliac arteries that are more prone to rupture with balloon inflation.

The external iliac artery is more mobile than the common iliac artery, and as such, the treatment algorithm is slightly different. Balloon angioplasty alone is reasonable for TASC A and B lesions in the external iliac artery. Based upon the degree of recoil or the presence of a dissection flap, the external iliac artery is selectively treated with self-expanding stents. As these devices tend to be more flexible than the stiff balloon-expanding stents, they handle the mobility of the external iliac artery better and are less likely to get crushed if deployed in close proximity to the inguinal ligament. As noted above, heavily calcified lesions that are likely to rupture should be treated with covered self-expanding stents so that aggressive angioplasty does not result in rupture with active extravasation into the retroperitoneum.

Complications of Endovascular Interventions

In appropriately selected patients, the procedural complication rate for endovascular intervention in AIOD is low. Access site complications are the most common and total less than 2% in most series. Pseudoaneurysms, retroperitoneal bleeding, dissection, and atheroembolism can be avoided by using ultrasound guidance to access the femoral artery. A femoral angiogram will inform the operator if an inadvertently high puncture was performed. Though percutaneous closure devices have not been shown to unequivocally decrease access site complication rates, this is one situation where they may be useful.

The most serious intraoperative complication is arterial rupture during angioplasty. In the presence of active extravasation, quickly reinflating the balloon can maintain hemodynamic control until an appropriately sized stent graft can be deployed to cover the disruption. Other intraoperative complications include dissection, vessel spasm, thrombosis, and atheroembolism. Another common postprocedure complication includes contrast-induced nephropathy, particularly in patients with preexisting renal insufficiency. Though there are no absolute contraindications for endovascular interventions, patients with renal insufficiency should be pretreated with hydration to minimize the effect of contrast exposure. In patients who are at risk for contrast-induced nephropathy, contrast should be used sparingly, and consideration should be given to CO_2 angiography, which works reasonably well within the aortoiliac segment.

RESULTS OF ENDOVASCULAR INTERVENTIONS

The technical success rate of iliac angioplasty and stenting is quite high, on the order of 98% in many reports. Though this translates into hemodynamic improvement, maintaining long-term patency

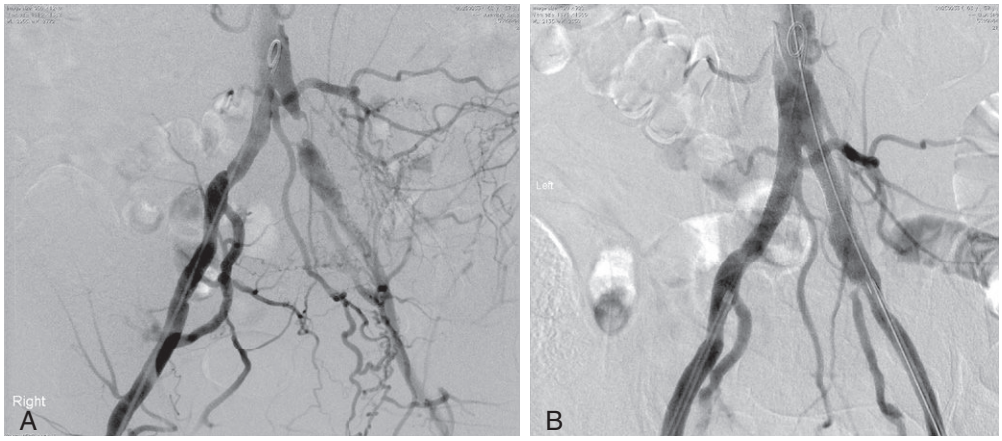

FIGURE 8 Diagnostic angiography and percutaneous intervention. A diagnostic angiogram shows a left common iliac stenosis, with extensive collateralization from the middle sacral and segmental lumbar arteries. **A,** Focal lesions, are excellent candidates for endovascular interventions. **B,** Note the absence of collateralized vessels after the left common iliac lesion is treated with a stent.

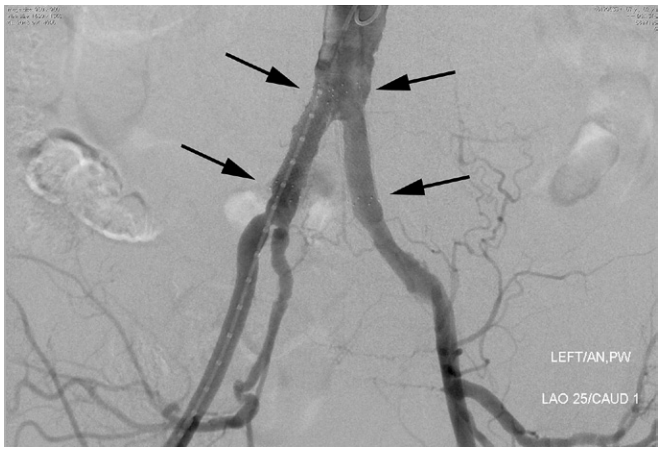

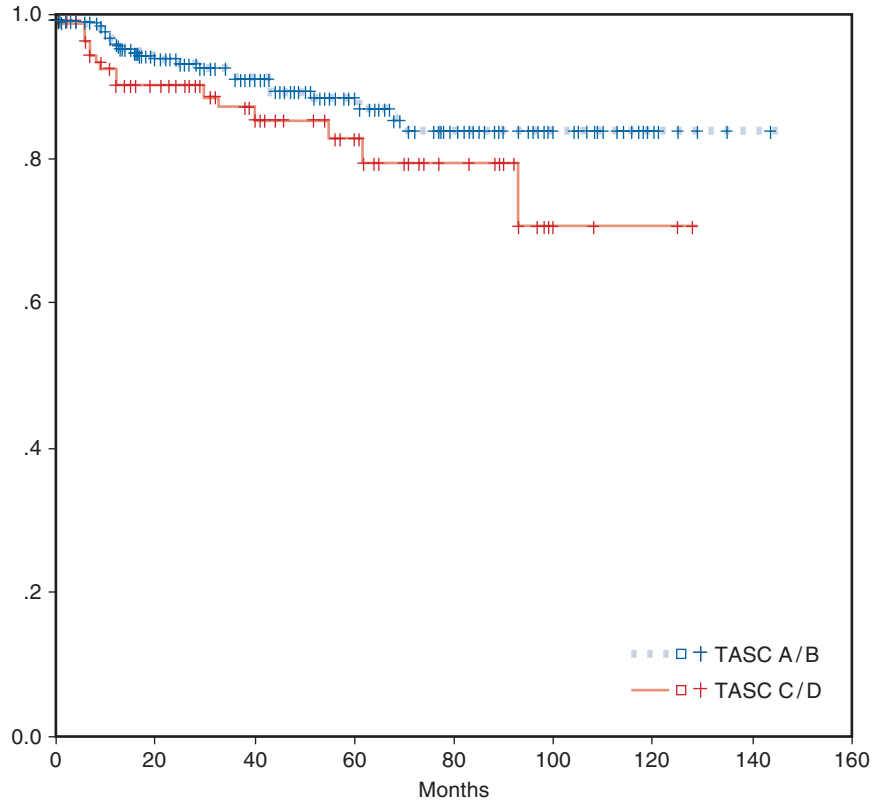

FIGURE 9 "Kissing" stents. Endovascular treatment of bilateral common iliac disease originating at or near the aortic bifurcation requires "kissing" stents. Simultaneous deployment of balloon-expanding stents avoids complications related to plaque shift during angioplasty. Well-positioned and appropriately sized stents do not encroach upon the distal abdominal aorta or the contralateral limb.

requires dedication to surveillance and often requires multiple reinterventions (Figure 10). Most lesions will need to be treated with primary stenting, but in lesions amenable to angioplasty alone, primary stenting is less likely to have an early recurrence or need reintervention, and it may be more cost effective to treat with primary stenting at the index procedure. Surveillance with ankle brachial indices, and possibly ultrasound if the patient's habitus is amenable, is necessary because as a group, the primary patency of iliac stenting is approximately 70% at 5 years (Table 2). Maintaining patency with reinterventions can improve this rate to about 85%. All patients should be maintained on antiplatelet therapy indefinitely. Although there is little literature addressing this specifically for iliac angioplasty and stenting, extrapolating from the experience of percutaneous cardiac interventions, antiplatelet therapy will help prevent early thrombosis.

Although a variety of factors that affect outcomes have been reported, including renal failure, diabetes, and the diameter of the treated vessel, the most important determinant of long-term outcomes is the underlying burden of disease. The TASC classification captures this relatively well, and long-term outcomes are far better with TASC A or B lesions than with TASC C or D lesions. As it currently stands, the TASC working group has recommended endovascular interventions for TASC A and B lesions and direct surgical revascularization for TASC D lesions. Treatment of TASC C lesions is individualized for each patient, though given the high degrees of technical success, endovascular interventions are often opted for first.

TASC, Trans-Atlantic Inter-Society Consensus.

SUMMARY

AIOD is a common cause of lower extremity ischemia syndromes. For claudicants, the decision to intervene must include a careful assessment of procedural risks and expected benefits. The success, safety, and reasonable durability of endovascular interventions have made the application of this technique the intervention of choice for those with localized disease. However, direct surgical revascularization still plays an important role in treating patients with a more advanced burden of disease and also serves as a means of salvaging failed endovascular interventions. Even in high-risk patients, extraanatomic bypass procedures can prove useful to treating lower extremity ischemia in AIOD. As with all vascular interventions, long-term outcomes are optimized by aggressive postprocedural medical management, risk factor reduction, and surveillance.

Femoropopliteal Occlusive Disease

Natalia O. Glebova, MD, PhD, and Thomas Reifsnyder, MD, FACS

INTRODUCTION

Peripheral arterial disease (PAD) has a prevalence rate of up to 10% in the general population and of nearly 20% in people over the age of 70 years. With the aging population and the increasing prevalence of PAD risk factors such as diabetes mellitus, hypertension, and dyslipidemia, the societal burden of PAD continues to grow. Vascular surgeons need to be knowledgeable and proficient with the wide variety of treatment modalities. As a subset of PAD, femoropopliteal occlusive disease affects the vasculature between the inguinal ligament and the tibial vessels and is a pattern of disease frequently seen in cigarette smokers. The most frequently obstructed vessels are the superficial femoral (SFA) and popliteal arteries. The decreased blood flow leads to tissue ischemia of the calf and foot. Atherosclerosis is the culprit in the overwhelming majority of patients, although occasional patients with fibromuscular dysplasia, giant cell arteritis, Takayasu's arteritis, or other arteriopathies may present similarly.

EVALUATION

Patient evaluation begins with a history and physical examination. The identification and modification of risk factors such as cigarette smoking, diabetes, hypertension, dyslipidemia, and dietary habits is paramount. The patient's symptom complex combined with a thorough pulse examination usually reveals the level of the arterial lesion and guides the subsequent treatment regimen.

Patients with femoropopliteal occlusive disease present in one of three ways: incidentally found asymptomatic disease, intermittent claudication, or limb-threatening ischemia. Claudication (from the Latin *claudicare* meaning "to limp") manifests as crampy achy calf pain with walking that occurs at a reproducible distance and is relieved with rest. Although it is a strong risk factor for other atherosclerotic problems, the natural history of intermittent claudication is relatively benign with less than 3% of patients needing a major amputation within 5 years. However, patients with significant claudication have functional limitations that affect lifestyle and employment. In these patients and in those who present with limb-threatening ischemia, further workup and revascularization are warranted.

The noninvasive vascular laboratory is a useful tool; however, its indiscriminate use should be discouraged, particularly as a screening method. The most common tests are the ankle-brachial index (ABI) and color duplex scan. The former is determined with calculation of the ratio of the higher systolic pressure at the ankle (either at the dorsalis pedis or posterior tibial artery) to the higher systolic brachial pressure in either arm. In general, an ABI greater than 0.97 is

considered normal, and values less than 0.4 are often associated with critical limb ischemia. The best use of the ABI is to discriminate between vasculogenic and neurogenic claudication. Only in patients with vasculogenic claudication does the ABI drop significantly when the patient walks to the point of calf pain (this test requires a treadmill in the vascular laboratory). The presence of femoropopliteal occlusive disease usually can be determined with physical examination, so unless there is a diagnostic dilemma, confirmation of the presence of disease with a vascular laboratory ABI is not warranted. Not infrequently, ABIs cannot be calculated because of the incompressibility of diabetic calcified vessels. Noninvasive alternatives include digital or toe pressures, pulse volume recordings, or transcutaneous oxygen measurements.

Duplex ultrasound scan arterial mapping is also available from the vascular laboratory. In this era of endovascular intervention, distinguishing patients that have TASC II (see subsequent) A and B lesions from C and D lesions helps with decision making. If the patient is not a good open surgery candidate, preintervention duplex scan arterial mapping can minimize the number of patients who undergo purely diagnostic arteriography.

After the decision is made for invasive treatment of femoropopliteal occlusive disease, the next step is digital subtraction angiography with possible synchronous angioplasty or stenting. Angiography also allows the identification and treatment of an unsuspected inflow problem, and the delineation of the best outflow option. Although surgical decisions can be based on computed tomographic angiography (CTA) or magnetic resonance angiography (MRA), contrast arteriography remains the gold standard.

TREATMENT

Treatment of femoropopliteal occlusive disease is based on a careful weighing of the patient's symptoms, intervention required, expected durability of the intervention, and the risks of the procedure.

Medical

Patients with mild claudication should be treated nonoperatively with medical optimization and an exercise program. This includes risk factor modification: cessation of cigarette smoking, dietary and pharmacologic (statin) reduction in low-density lipoprotein (LDL) cholesterol and triglyceride levels, treatment of hypertension with thiazide diuretics and angiotensin-converting enzyme (ACE) inhibitors, and control of diabetes. All patients with demonstrable PAD should take aspirin to reduce the risk of cardiovascular morbidity and mortality. Although technically cilostazol (Pletal, which is expensive) and pentoxifylline (Trental, which requires thrice daily dosing) have been shown to statistically improve walking distance, the authors have not found them to be particularly effective.

A crucial part of nonoperative management of PAD is a walking regimen. Although supervised programs work the best, these frequently are not available. Instead, an explicit instruction sheet outlining how to do a walking program should be given to the patient. This structured program consists of at least 3 weekly walking sessions of 30 minutes. Patients walk until they experience calf pain; they then stop and rest until the pain goes away and then repeat until the half hour is over. The old adage "no pain, no gain" does not apply to claudication, and patients should be advised not to try and push through the pain. If strictly followed, such exercise programs along with risk factor modification and medical optimization usually improve walking distance to the point of patient satisfaction.

For patients with critical limb ischemia, noninterventional treatment is not the first line of therapy, although risk factor modification is mandatory for the patient's overall health.

Interventional

Many options are available for treatment of femoropopliteal occlusive disease, but few high-quality clinical trials are available to guide decision making. For intermittent claudication, the goal of treatment is symptom relief and improvement in patient's functional status. For critical limb ischemia, interventions aim at relief of pain and prevention of limb loss.

Endovascular treatment options include plain or cutting balloon angioplasty, stenting, and atherectomy. Surgical options are autogenous or synthetic bypass grafts, profundaplasty, and endarterectomy. Hybrid procedures may be used. Bear in mind that there must be adequate inflow before any interventional treatment of infrainguinal occlusive disease.

A classification of arterial lesions established by the Trans-Atlantic Inter-Society Consensus for the Management of Peripheral Arterial Disease (TASC II) is helpful in choosing the right treatment option (Figure 1). Type A lesions are short and in general are successfully treated with endovascular means. Type B lesions are intermediate in length and complexity; endovascular techniques are thought to provide excellent results and should be used, unless open revascularization is indicated for other associated lesions. The treatment of type C lesions is evolving. At the time TASC II was published, type C lesions were thought to be best treated with open revascularization, with endovascular methods recommended only for patients with a prohibitive risk to open surgery (Figure 2). With improved endovascular techniques, the treatment of type C lesions really depends on the skill set of the surgeon. Type D lesions are long complex lesions that are best treated with surgical bypass.

Endovascular Treatment

Endovascular treatment of short isolated infrainguinal lesions has a high technical success rate. The optimal lesions for percutaneous interventions are located in proximal larger caliber arteries, are stenotic rather than occlusive, are short in length and focal rather than multiple, have good runoff, and are in the absence of multilevel disease. Results are better if the indication for endovascular intervention is claudication rather than critical limb ischemia.

The fundamental steps are: obtaining arterial access, identifying the lesion with diagnostic angiography, crossing the lesion with a guidewire, treating the lesion with balloon angioplasty or stent placement, and performing completion angiography to evaluate the result. Arterial access is usually obtained via the contralateral common femoral artery (CFA). Alternatively, in thin patients, the ipsilateral CFA may be used for antegrade access. The brachial artery may be used if the patient has had a prior aortobifemoral bypass. Next, a sheath is placed, and a catheter is used to perform an angiogram and delineate the lesion. The lesion is then crossed with a guidewire, and a balloon is placed over the wire, centered on the lesion, and inflated. The size of the balloon depends on the residual lumen size of the nearby more normal artery. Completion angiography is then performed. If a more than 30% residual stenosis exists or if the angioplasty has created a local dissection, then a self-expanding stent should be placed across the lesion. The authors do not advocate stenting in the popliteal artery because mechanical trauma from artery flexion may lead to stent occlusion. Heparin (~80 units/kg) is administered intravenously at the start of the procedure, and if stent placement is deemed likely, prophylactic antibiotics are given. All patients should already be on an aspirin regimen; after intervention, clopidogrel (Plavix) is prescribed for 6 weeks. Follow-up is routine. After a single postprocedure ABI, the patient is followed symptomatically. If symptoms recur, then a duplex scan is performed to see whether there is in-stent restenosis or a new lesion.

Stent placement should be strongly considered in percutaneous interventions for femoropopliteal occlusive disease because restenosis rates after angioplasty are high, especially for longer lesions. For

Type A lesions
- Single stenosis ≤10 cm in length
- Single occlusion ≤5 cm in length

Type B lesions
- Multiple lesions (stenoses or occlusions, each ≤5 cm)
- Single stenosis or occlusion ≤15 cm not involving the infrageniculate popliteal artery
- Single or multiple lesions in the absence of continuous tibial vessels to improve inflow for a distal bypass
- Heavily calcified occlusion ≤5 cm in length
- Single popliteal stenosis

Type C lesions
- Multiple stenosis or occlusions totaling >15 cm with or without heavy calcification
- Recurrent stenoses or occlusions that need treatment after two endovascular interventions

Type D lesions
- Chronic total occlusions of CFA or SFA (>20 cm, involving the popliteal artery)
- Chronic total occlusion of popliteal artery and proximal trifurcation vessels

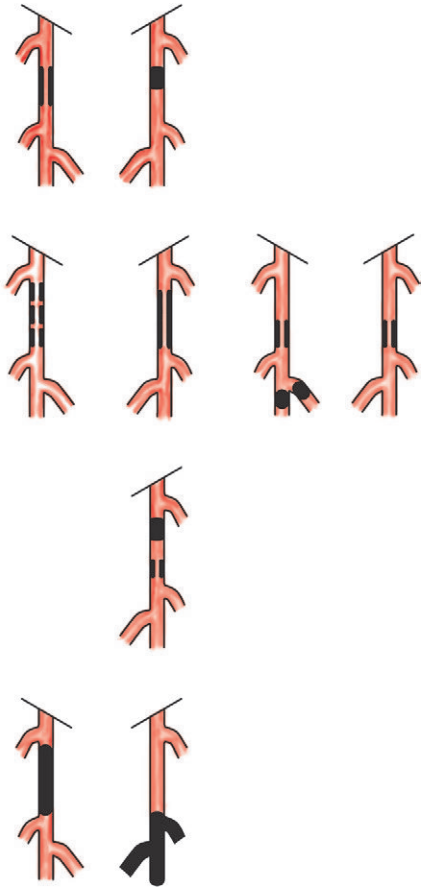

FIGURE 1 Trans-Atlantic Inter-Society Consensus (TASC) classification of femoral popliteal lesions. *CFA,* Common femoral artery; *SFA,* superficial femoral artery. *(From Norgren L, Hiatt WR, Dormandy JA, et al: Inter-Society Consensus for the Management of Peripheral Arterial Disease [TASC II], J Vasc Surg 45[Suppl 1]:S5-S67, 2007.)*

example, the ABSOLUTE trial is a randomized prospective trial that compared implantation of self-expanding nitinol stents with angioplasty in 10-cm SFA stenotic lesions. At 6 months, the rate of restenosis was 24% in the stent group and 43% in the angioplasty group ($P = 0.05$); at 12 months, the rates were 37% and 63%, respectively ($P = 0.01$). At 2 years, restenosis rates were 46% versus 69% in favor of primary stenting compared with balloon angioplasty, with optional secondary stenting with an intention-to-treat analysis ($P = 0.031$). Consistently, stenting (whether primary or secondary) was superior to plain balloon angioplasty in this study.

As technology develops, endovascular options for treatment of femoropopliteal occlusive disease will undoubtedly improve. Drug eluting and absorbable stents are currently being evaluated.

Surgical Treatment

Surgery for femoropopliteal occlusive disease usually entails a bypass operation and occasionally endarterectomy of calcified CFA lesions. Long-term patency rates are superior to those of endovascular interventions. Infrainguinal bypass requires the presence of adequate inflow and outflow. The distal target should be the least diseased artery with the best continuous runoff to the foot. Grafts constructed with autogenous vein have superior patency to those made of prosthetic material. The bypass may originate from the common, deep, or superficial femoral arteries, although use of the proximal SFA in a patient with femoropopliteal occlusive disease should be done with caution. The distal target site may be the above-knee or below-knee popliteal or tibial vessels.

Other than surgeon skill, the major determinant of bypass patency is the conduit. Autogenous vein has always been and continues to be the superior conduit for all infrainguinal bypasses. The greater saphenous vein is the preferred conduit and should be evaluated and mapped with a preoperative duplex scan. Lesser saphenous, contralateral greater saphenous, basilic, and cephalic arm veins are other possible conduits. Nondiseased vein at least 3 mm in diameter can be used; if the bypass is for claudication, smaller veins may be flow limiting and only partially relieve symptoms. Vein bypasses may be placed in a reversed, nonreversed, or in situ configuration. If used in a reversed fashion, the vein should be of similar size throughout. The in situ technique should be reserved for bypasses distal to the knee joint. Cryopreserved vein and human umbilical vein have patency rates similar to prosthetic grafts but are more expensive. However, they can be helpful in situations where infection is present. Prosthetic conduit options are Dacron, expanded polytetrafluoroethylene (ePTFE), and ePTFE bonded with heparin. No clear superiority of one prosthetic over another has been shown.

The conduct of a bypass operation begins with planning the incisions. Unless the bypass is combined with an extensive groin reconstruction, the incisions should not cross the groin crease. Exposure of the common femoral artery is through an oblique skin line incision several centimeters above the crease (Figure 3). If a CFA endarterectomy/profundaplasty may be necessary, one may start with a vertical incision, but kept above the groin crease and only extended distally if necessary. Exposures of the popliteal, posterior tibial, and peroneal arteries are through the medial leg incision used to harvest the greater saphenous vein.

The greater saphenous vein harvest begins just below the groin crease (see Figure 3). The incision is then extended distally along the path delineated and marked at the time of preoperative vein mapping. Alternatively, the vein is marked at the beginning of the case with a bedside ultrasound scan machine. Before the incision is made, use the backside of a #15 scalpel to crosshatch the incision. This makes reapproximating the skin much easier at the time of closure (see

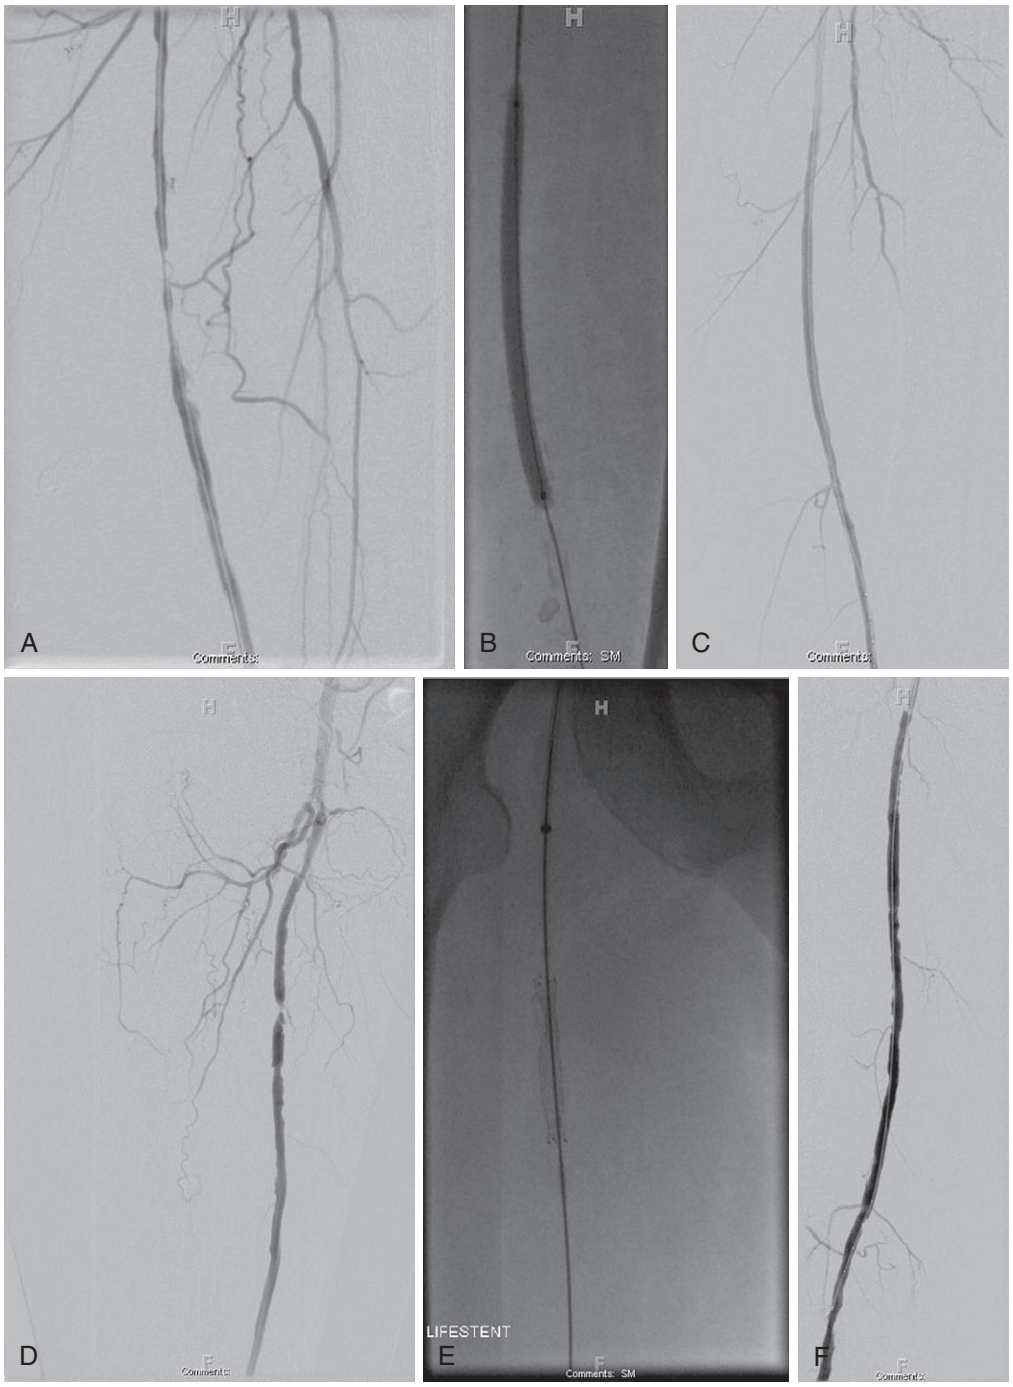

FIGURE 2 Endovascular treatment of Trans-Atlantic Inter-Society Consensus (TASC) A lesions with percutaneous transluminal angioplasty/stent. **A,** Occlusive disease in superficial femoral artery (SFA) of a patient with claudication. **B,** Balloon angioplasty of SFA lesion. **C,** Postangioplasty angiogram showing resolution of lesion. **D,** Another example of occlusive SFA disease in a different patient with claudication. **E,** Stent deployment. **F,** Poststent angiogram showing improvement in flow.

Figure 3). Meticulous technique must be used to avoid damage to the vein. Use a vessel loop around the vein to retract it side to side while dissecting. Ligate all side branches 1 to 2 mm away from the vein so when the vein is distended the ties do not bind. Although veins may be harvested endoscopically or through small interrupted incisions, the authors believe that a long continuous incision affords the best opportunity to harvest an undamaged vein. Lastly, it is always better to have an extra inch of vein than to fall an inch short.

Once the vein is removed, gently distend it with heparinized saline solution. After the administration of systemic heparin, a longitudinal arteriotomy is made in the inflow artery. A local endarterectomy of the posterior plaque is always tempting, but this should be avoided unless a formal endarterectomy/profundaplasty is planned. The end of the vein is spatulated, and if a nonreversed or in situ configuration is to be used, the most proximal valve is excised with direct vision. Alternatively, Leather Karmody valve scissors (Medline Industries, Inc., Mundelein, Ill) can be used to cut the first valve or two. The end-to-side anastomosis is created with a running 5-0 or 6-0 polypropylene suture. Flow is then restored into the bypass and native circulation. With arterial pressure distending the vein, a valvotome (the authors prefer the Mills retrograde valvulotome; Pilling) is inserted from the distal end. The remaining valves are then gently cut. If an in situ technique is used, then the valvotome is inserted through side branches. Once all the valves have been cut, there should

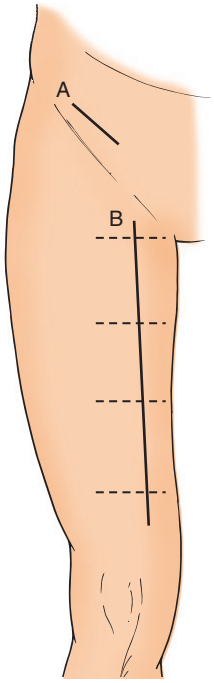

FIGURE 3 Incisions for exposure of common femoral artery *(solid line A)* and greater saphenous vein *(solid line B)*. Crosshatch markings are indicated with *dashed lines*.

be strong continuous flow from the distal end of the bypass. Alternative valvotomes (LeMaitre) may be used, but because of cost concerns, the authors prefer the easy to use and reusable Mills.

Unless the bypass is in situ, it is now tunneled anatomically to the distal anastomotic site. The authors have found that the Jenkner (Aesculap) tunneler is easy to use. For an above-knee bypass, the tunneler is passed just deep to the sartorius muscle and superficial to the SFA. Care must be taken not to pass the tunneler through some of the sartorius fibers. For the below-knee popliteal artery, pass the graft to the above-knee area. With the index fingers from above and below the knee, create a tunnel between the heads of the gastrocnemius muscle and gently pass an aortic clamp from distal to proximal. Gently grasp the end of the vein graft and pull it to the below-knee position.

After each step, check that the bypass is not twisted and that there is still strong continuous blood flow. Mark the distal end of the vein to help maintain orientation and then perform an end-to-side distal anastomosis. If one of the tibial vessels is the distal target, use a pneumatic tourniquet instead of clamps to control bleeding.

After completion of the bypass, confirm bypass patency with palpation of distal pulses. In addition, augmentation of flow distal to the distal anastomosis should be found when checked with a continuous wave Doppler scan. Completion contrast angiography or intraoperative duplex imaging should be used liberally if there is any question concerning the technical result. The most important part of the operation begins once the bypass is in place. Most bypass operations involve lengthy incisions, and closure must be meticulous and not left to the intern. The groin is closed with multiple layers of absorbable 2-0 suture in the femoral sheath, fascia, and subcutaneous layers. The skin closure depends on the incision. If the incision is a skin line, then absorbable 4-0 subcuticular closure may be used. If the incision is vertical, then the skin should be closed with interrupted 3-0 nylon vertical mattress sutures. The long saphenous vein harvest incision is closed with a single layer of running 2-0 absorbable suture in the fascia. The skin is closed with vertical mattress 3-0 nylon sutures, making sure to reapproximate the hash marks made at the beginning of the case. There is no place for stapled closures during lower extremity bypass.

Although solid data confirming its benefit are lacking, the authors start dextran-40 at 25 mL/h during the operation and continue it until a total of 500 mL has been infused. After surgery, the patients are managed in a regular surgical unit. Home medications, particularly beta blockers, statin, and aspirin, are administered. On postoperative day 1, either a soft cast or compression garment is applied from the knee down. The physical therapy department then evaluates the patient, and ambulation is begun. Once patients are off parenteral narcotics, can void, and can ambulate safely, they are discharged to home. In uncomplicated cases, discharge is on postoperative day 2 or 3.

Strong evidence shows that a graft surveillance program leads to higher assisted primary patency. If a nonspliced greater saphenous vein was used as conduit, the first follow-up duplex scan is at the time of suture removal. If the bypass is normal, then the patient should be rechecked every 4 to 6 months for 24 months and then yearly thereafter. If the bypass was constructed of alternative autogenous vein or spliced vein or an abnormality is found on the initial scan, then surveillance should be more rigorous.

DISCUSSION

The treatment of femoropopliteal occlusive disease is evolving, with many available options but a dearth of high-quality evidence to guide the physician. Clearly, should a bypass operation be performed, every effort should be made to use autogenous vein and not prosthetic for the conduit. Patency rates up to 90% at 5 years for saphenous vein femoropopliteal bypasses can be attained. Graft patency is superior for autogenous vein conduits as compared with prosthetic materials (Table 1).

The debate of open versus endovascular for femoropopliteal occlusive disease has no easy answer. The TASC II guidelines are helpful, but presenting symptoms, patient characteristics, and surgeon training and skill outweigh the guidelines.

Two recent studies compared bypass operations with endovascular treatments, one for claudication and one for critical limb ischemia. Siracuse and colleagues in 2012 made a retrospective comparison of bypass operations with percutaneous transluminal angioplasty with and without stent (PTA/S) as first-time intervention for claudication from SFA occlusive disease. This study showed that PTA/S resulted in significantly higher rates of restenosis and recurrent symptoms when compared with bypass. Operations were associated with a greater length of stay and an increased wound infection rate. Stratified by TASC class, no significant differences were found in restenosis between PTA/S and bypass in TASC A and B lesions. However, C and D lesions had a significantly lower restenosis rate with bypass versus PTA/S. Incidentally, statins also improved freedom from restenosis and symptom recurrence. The study does have the limitation of being retrospective.

The Bypass versus Angioplasty in Severe Ischaemia of the Leg (BASIL) trial is the only randomized controlled trial that compared open surgical bypass with endovascular therapy as the initial treatment strategy for severe limb ischemia. At 2 years, the main clinical outcomes of overall survival and amputation-free survival were similar between the two arms of the trial. An extended analysis showed that beyond 2 years, patients who were initially randomized to bypass had improved overall survival and amputation-free survival rates. Patients who received a prosthetic bypass had worse outcomes than those who received a vein bypass. In addition, patients who underwent bypass after failed angioplasty had worse outcomes than those who underwent a bypass first. The overall conclusion of this trial is that patients with severe leg ischemia should preferably undergo a bypass operation with vein as the initial procedure. Endovascular treatment in these patients comes with a higher risk of failure and a subsequent increased risk of failure with bypass surgery.

TABLE 1: Graft patency, aggregate of multiple studies

	Suprageniculate femoropopliteal bypass			Infrageniculate femoropopliteal bypass			Femorotibial bypass		
Type of bypass	*1 y*	*3 y*	*5 y*	*1 y*	*3 y*	*5 y*	*1 y*	*3 y*	*5 y*
Saphenous Vein

The BASIL trial questions the argument for a percutaneous first approach proposed by some. According to that philosophy, patients who should undergo open bypass are those with failed endovascular therapy. In fact, it strongly argues that for severe limb ischemia, the best treatment is a bypass operation with autogenous vein.

SUMMARY

Femoropopliteal occlusive disease is a subset of peripheral arterial disease that involves the vasculature below the inguinal ligament and above the tibial vessels. Patients may present with symptoms of intermittent claudication, critical limb ischemia, or nonhealing wounds. Evaluation begins with a history and physical examination, and noninvasive studies such as ankle-brachial indices, toe pressures, and pulse volume recordings are used as adjuncts for diagnosis. Medical treatment and life style management should be the first line of treatment for mild claudication. Interventional therapy should be used for severe claudication that affects the patient's function and for critical limb ischemia. Endovascular therapy is probably best reserved for claudication with discrete stenoses or occlusions. For patients with severe limb ischemia, operative bypass with autogenous vein is preferred. Lastly, prosthetic grafts should be avoided if at all possible.

Tibioperoneal Arterial Occlusive Disease

Hari Kumar, MD, Raghu Motaganahalli, MD, FACS, and Michael Patrick Murphy, MD

It has been estimated that 8 to 10 million people suffer from peripheral arterial disease (PAD); this prevalence approximates the prevalence of coronary artery disease in the United States. PAD is a systemic inflammatory process that affects the entire arterial tree; however, anatomic patterns of distribution are associated with specific patient demographics, medical risk factors, and symptoms. Symptoms of PAD are caused by ischemia of the skeletal muscle bed distal to the more proximal location of the flow-limiting arterial lesion. *Claudication* is defined as pain in the thigh or calf muscles with exercise that remits with rest and is indicative of disease in the iliac or femoral arteries, respectively. Critical limb ischemia (CLI) results from insufficient blood flow to meet the metabolic demands of the tissue in the leg and is characterized by pain at rest, ulceration, or gangrene, all heralding signs of eventual limb loss. Patients with a predominant distribution of atheroocclusive disease in the tibial and peroneal arteries are more likely to initially present with signs and symptoms of CLI than are patients with proximal femoropopliteal disease caused by absence of collateral vessel flow to the foot. In addition to recognized risk factors, patients with PAD and tibioperoneal occlusive disease (TPOD) have a higher frequency (>60%) of diabetes mellitus and renal insufficiency. These patients are also at significant risk for vascular disease of the coronary, cerebral, and renal arteries; thus when an intervention is planned, the vascular surgeon must consider these risk factors and always prioritize life before limb.

PATIENT ASSESSMENT

In the assessment of a patient with TPOD, a complete history and physical examination are critical for planning treatment. This evaluation should include an assessment of the patient's functional status with regard to current ability to ambulate, the patient's expectations of therapy, and risk stratification for major adverse cardiac events, with planning for possible intervention. Patients who are physically active, do not have cardiac symptoms, and have normal electrocardiographic findings do not need further workup. Patients with limited physical reserve (are unable to climb a flight of stairs), have had a recent myocardial infarction, or report symptoms consistent with exertional angina should undergo a myocardial stress test. Patients with claudication should be managed conservatively with risk factor modification that focuses on cessation of tobacco use and glycemic control, as fewer than 5% of such patients progress to CLI. A supervised exercise program and treatment with cilostazol have demonstrated efficacy in improving exercise tolerance in claudicants.

A thorough examination of the leg and foot helps determine the likelihood of functional salvage. The examiner should note the patient's ability to walk, evidence of flexion contractures, or other neuromuscular disabilities that may affect ambulation. The presence of local infection, soft tissue edema, venous disease, and prior surgical incisions influence the choice of intervention. The physical examination should also focus on arterial perfusion of the symptomatic limb; the examiner should note presence and quality of the femoral, popliteal, posterior tibial, and dorsalis pedal pulses. The quality of the femoral pulses is a crucial aspect of the examination because it reveals whether there is concomitant suprainguinal vascular disease and whether the common femoral artery (CFA) is suitable for a bypass graft to restore inflow. Inflow disease involving the common and external iliac arteries should be addressed before or during distal revascularization, as discussed elsewhere. Likewise, an atherosclerotic CFA can be reconstructed with endarterectomy at the time of bypass. A palpable pulse in the popliteal artery, felt in the posterior fossa of the knee, usually indicates absence of flow-limiting proximal stenosis or occlusion in the femoral artery and is a common finding in young diabetic patients who have disease predominantly in the tibial and peroneal arteries. Dorsalis pedis and posterior tibial pulses are often not palpable in patients with TPOD, and Doppler assessment with a handheld probe is most helpful. Triphasic signals indicate normal arterial wall transduction of systolic and diastolic pressures; transduction signals become attenuated to a biphasic pattern with mild to moderate disease and monophasic with severe disease. Absence of hair and shiny tone of the skin on the lower leg reflect chronic arterial insufficiency, and evidence of ulceration is a sign of severe ischemia and potential limb loss. A full set of laboratory tests is conducted, with particular attention to renal function, in anticipation of imaging studies with contrast materials that may be nephrotoxic.

In the vascular laboratory, arterial perfusion is estimated from absolute pressures measured at the upper thigh, midthigh, calf, and ankle. A pressure change greater than 20 to 30 mm Hg between each segment indicates intervening flow-limiting disease. Critical levels of ischemia are evidenced by (1) ankle pressures lower than 50 mm Hg for rest pain and lower than 70 mm Hg for tissue loss or (2) toe pressures lower than 30 mm Hg for rest pain and lower than 50 mm Hg for tissue loss. If a venous conduit is to be used for surgical bypass, the authors routinely use duplex ultrasonography to ensure that the proposed vein is adequate, with a diameter of at least 3.5 mm throughout its length. Preoperative marking of the venous conduit is also performed because incisions can be directly placed without creation of a flap, to avoid postoperative wound problems.

Once a patient is determined to have CLI, it is imperative to plan a revascularization procedure with endovascular techniques or surgical bypass because the risk of limb loss within a year of diagnosis is 40%. Although the perception that amputation is a less morbid procedure in the patient with CLI who is at high risk, current data reveal that the 30-day mortality rates for endovascular intervention (2% to 8%) and surgical bypass (2% to 6%) in CLI are similar, whereas the rate is generally higher for primary amputation (6% to 12%). High-resolution imaging is essential for planning revascularization, regardless of whether a surgical or endovascular approach is being considered, and digital subtraction angiography (DSA) with iodinated contrast material delivered via an intraarterial catheter is considered the "gold standard." DSA image quality is not compromised by calcification of the arterial wall, and selective catheter placement in the external iliac or femoral arteries can provide high-quality images of the tibial and peroneal arteries in the lower leg in the presence of multilevel disease. In diabetic patients and patients with renal insufficiency, nephrotoxicity of iodinated contrast material can be minimized with preprocedure and postprocedure hydration with normal saline, administration of acetylcysteine, and selection of a non-ionic contrast agent. Carbon dioxide gas can be used as a contrast agent; it produces excellent resolution and avoids any risk of renal injury.

Multiple-slice spiral computed tomographic angiography (CTA) is a noninvasive technique for imaging the entire arterial tree from the abdominal aorta to the level of the foot; it provides superb spatial and temporal resolution with a single-bolus infusion of contrast agent. The accuracy of CTA in visualizing lumen patency is restricted by calcification in the vessel wall, a frequent occurrence in the infrapopliteal arteries of diabetic patients. Gadolinium-enhanced

magnetic resonance angiography is highly accurate for detection of stenosis greater than 50% or occlusion within the entire lower extremity arterial tree. However, it is difficult to estimate luminal patency with calcifications, and gadolinium cannot be used in patients with renal failure because of the risk of nephrogenic systemic fibrosis. Time-resolved imaging of contrast kinetics is used to image the infrapopliteal vessels with greater accuracy, comparable with that of DSA.

In the initial planning for intervention in the patient with TPOD, the arterial tree should be imaged from the diaphragmatic hiatus of the abdominal aorta with continuous image acquisition through the lower extremities, with multiple dedicated views of the ankle and foot. In the setting of impending limb loss in a patient with renal insufficiency in whom duplex ultrasonography demonstrates no evidence of hemodynamically significant suprainguinal disease, selective imaging of the ischemic limb with DSA and adjunctive renal protective measures or CO_2 angiography should be performed immediately, with the intent to treat in the same setting. Furthermore, extensive calcification of the tibial arteries may preclude an accurate assessment of the infrapopliteal arteries; in this situation, DSA should be performed. In the planning of surgical bypass, the tibial or peroneal artery chosen for the distal anastomosis should have continuous unimpeded flow to the plantar arches of the foot, especially in patients with tissue loss. In many diabetic patients, the peroneal artery is the only remaining patent artery below the knee; however, either the anterior branch to the dorsalis pedal artery or the posterior branch to the posterior tibial artery (ideally both) must be intact to provide perfusion to the foot as the artery terminates above the ankle. In patients with occlusion of the tibial and peroneal arteries throughout the lower leg, the plantar and tarsal arteries should be examined as possible sites of a distal anastomosis for limb salvage.

SELECTION OF INTERVENTION

The primary objectives in treating patients with TPOD are to relieve pain, promote healing of ulcers, preserve a functional limb, and restore or maintain the ability to ambulate. These objectives must be tempered by the patient's general medical condition, current ambulatory status, and previous operations. In general, the success of surgical bypass is the availability of a single segment of autogenous vein of suitable diameter, whereas success of endovascular treatment is determined by extent of atherosclerotic disease, as quantified by the Trans-Atlantic Inter-Society Consensus (TASC) I Working Group in 2000. Infrapopliteal lesions are categorized in severity from classes A to D (Table 1). The Bypass versus Angioplasty in Severe Ischaemia of the Leg (BASIL) trial is the only randomized trial (452 patients) in which outcomes of surgical bypass and percutaneous transluminal angioplasty (PTA) were compared and provides level 1 evidence in the field. At 1 year, the amputation-free survival (AFS) rates were equivalent; however, at 2 years, AFS rates were better among the patients undergoing bypass. The BASIL authors concluded that bypass with autogenous vein is the best treatment for patients with severe limb ischemia expected to survive more than 2 years and that bypass with prosthetic grafts in patients without sufficient autogenous vein are associated with poor results. Thus endovascular interventions are the preferred option for TASC classes A, B, and single-level C lesions, whereas surgical bypass is recommended for multilevel TASC classes C and D lesions in a surgical patient with average risk. Bypass is the first choice with significant tissue loss (ulcer larger than 1 cm or gangrene involving the foot; Figure 1). The surgeon should be both flexible and creative. A patient with an open wound over the anticipated distal anastomosis site or without adequate single segment vein would best be served with PTA.

TABLE 1: Trans-Atlantic Inter-Society Consensus (TASC) classification for infrapopliteal lesions

Class	Lesion characteristics
A	Single stenosis <1 cm long
B	Multiple focal stenoses <1 cm long or one or two stenoses <1 cm involving the trifurcation
C	Stenoses 1 to 4 cm long, occlusion 1 to 2 cm long, or extensive stenosis involving the trifurcation
D	Occlusion >2 cm long or diffuse disease

SURGICAL BYPASS

All patients are maintained on an aspirin regimen before the surgical procedure. Unless it is contraindicated, warfarin (Coumadin) and clopidogrel therapy is stopped several days before elective open operations. However, if limb ischemia is acute, patients are admitted and undergo system anticoagulation with intravenous heparin. Patients are provided Hibiclens towelettes for a total body wash the evening before and the morning of surgery for same-day admissions to minimize risk of wound infections.

Anesthesia and Positioning

Options for anesthesia include local, epidural, and general anesthesia, and selection should be based on the patient's relative risk. Patients with chronic obstructive pulmonary disease and coronary artery disease are best served with local and epidural anesthetics; otherwise the authors prefer general anesthesia for patient comfort, as most surgical bypasses to the tibial or peroneal arteries require 4 to 6 hours. The patient is placed supine on the operating table, and any open wounds are covered with Ioban drape. Hair is clipped from the groin and over the area anticipated for exposure of the greater saphenous vein (GSV)—the authors leave the vein course marked on the skin with duplex ultrasonography before surgery—and the distal anastomosis. The skin of the lower abdomen, both sides of the groin, legs, and feet are painted with ChloraPrep. If the patient has evidence of methicillin-resistant *Staphylococcus aureus* colonization or infection, Hibiclens scrub is used. The authors prepare both legs in case the GSV in the ipsilateral leg is inadequate or inadvertently injured beyond repair during its harvest. Disposable paper drapes are placed to leave both sides of the groin exposed, and then the groin is covered

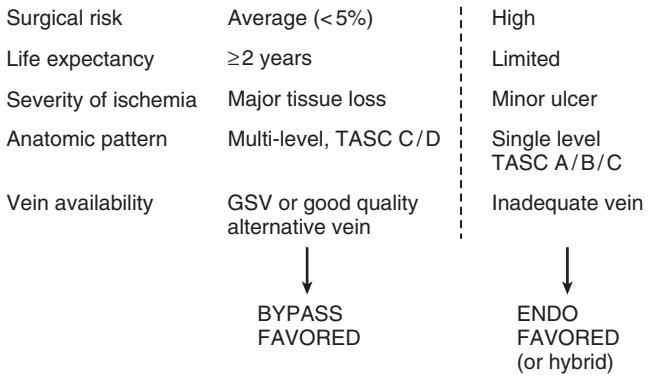

FIGURE 1 Schema for bypass or endovascular treatment (ENDO). *GSV,* Greater saphenous vein; *TASC,* Trans-Atlantic Inter-Society Consensus (class). *(From Conte MS: Critical appraisal of surgical revascularization for critical limb ischemia,* J Vasc Surg *57:2, 2013.)*

with Ioban drape pressed into the creases of the skin. Two Bovie electrocautery devices are used to enable simultaneous exposure of the inflow and outflow arteries.

Operative Exposures

Inflow Vessels

The CFA is the artery most commonly used for the proximal anastomosis and is easily exposed with either a tangential incision in the groin crease or a longitudinal incision centered over the femoral pulse. The tangential incision is used if preoperative imaging demonstrates a disease-free CFA and profunda femoral artery (PFA) and has fewer wound complications than the longitudinal incision. The authors use a longitudinal incision if concomitant disease in the CFA or PFA necessitates reconstruction with endarterectomy or patch angioplasty. This incision is started at the inferior border of the inguinal ligament and is extended distally for approximately 6 to 8 cm. The proximal CFA, PFA, and superficial femoral arteries (SFA) are circumferentially controlled with vessel loops. If there are no flow-limiting lesions in the SFA, alternative inflow sites for the proximal anastomosis include the middle and distal SFA at the adductor hiatus and the popliteal artery above and below the knee, which are invaluable when the length of the GSV is limited.

Outflow Vessels

The anterior or posterior tibial arteries are the first choice for the distal outflow anastomosis because they are more accessible and are in direct continuity with the arterial arches of the foot. The peroneal artery is selected if the anterior tibial and posterior tibial arteries are diffusely diseased. The target for the distal anastomosis must be free of calcified plaque because this may lead to dissection of the intima and compromise graft patency. If at the time of exposure the posterior tibial artery is found to have concentric calcifications throughout its length not seen on preoperative imaging, the authors expose the anterior tibial artery and use it, if it is less diseased, and vice versa.

Proximal Posterior Tibial and Peroneal Arteries

To expose the tibioperoneal trunk and the proximal segments of the posterior tibial and peroneal arteries, an incision is made approximately 2 cm posterior to the medial edge of the tibia, starting just proximal to the knee joint and extending distally as needed. If the ipsilateral GSV is being used as conduit, the authors make the incision directly over the course of the vein, which is marked on the skin preoperatively. The fascia of the gastrocnemius muscle is incised, and the medial head is retracted posteriorly with a Weitlaner retractor with dull prongs. The popliteal fossa is entered, and the popliteal vein is encountered medial and anterior to the artery and usually has several large tributary branches at the level of the tibioperoneal trunk that should be ligated and divided. The popliteal vein is then mobilized with sharp dissection and retracted posteriorly with a vessel loop, which exposes the distal popliteal artery. The soleus muscle is detached as close as possible to the tibia to prevent obstruction of view, and a second Weitlaner retractor is placed. Meticulous dissection with Metzenbaum scissors exposes the distal popliteal artery and is continued distally to expose the tibioperoneal trunk and then subsequently the proximal portions of the posterior tibial and peroneal arteries. Care must be taken because there are multiple vein branches that tear easily; thus these should be ligated and divided when encountered to avoid bleeding as the transected vein will retract into the muscle if inadvertently torn. The two concomitant veins that run parallel to each artery are equally friable and send branches that cross the arteries at frequent points that should be ligated as well.

The middle and distal portions of the posterior tibial artery are exposed with a longitudinal incision approximately 1 cm posterior to the medial edge of the tibia (Figure 2, *A*). The fascia is incised longitudinally, and the plane between the flexor digitorum longus muscle and posterior tibialis muscle is entered and expanded bluntly with the surgeon's fingers. The posterior tibial artery can be tracked between the two muscles by following the small muscular arterial branches in a retrograde direction. A Weitlaner retractor is placed for posterior retraction of the flexor digitorum longus (FDL) and gastrocnemius muscles, and the periadventitial fascia overlying the artery is opened with Metzenbaum scissors, again with care to ligate and divide venous branches that cross the artery anteriorly (see Figure 2, *B*). The surgeon exposes the bifurcation of the posterior tibial artery into the medial and lateral arteries by dividing the flexor retinaculum distally. The medial plantar branch continues in a straight course from the bifurcation along the medial portion of the sole of the foot. Division of the abductor hallucis muscle is usually necessary to facilitate exposure. The lateral plantar artery takes a slightly more inferior course to the medial plantar artery and is often larger. Usually a segment suitable for bypass can be exposed before it courses laterally across the sole of the foot.

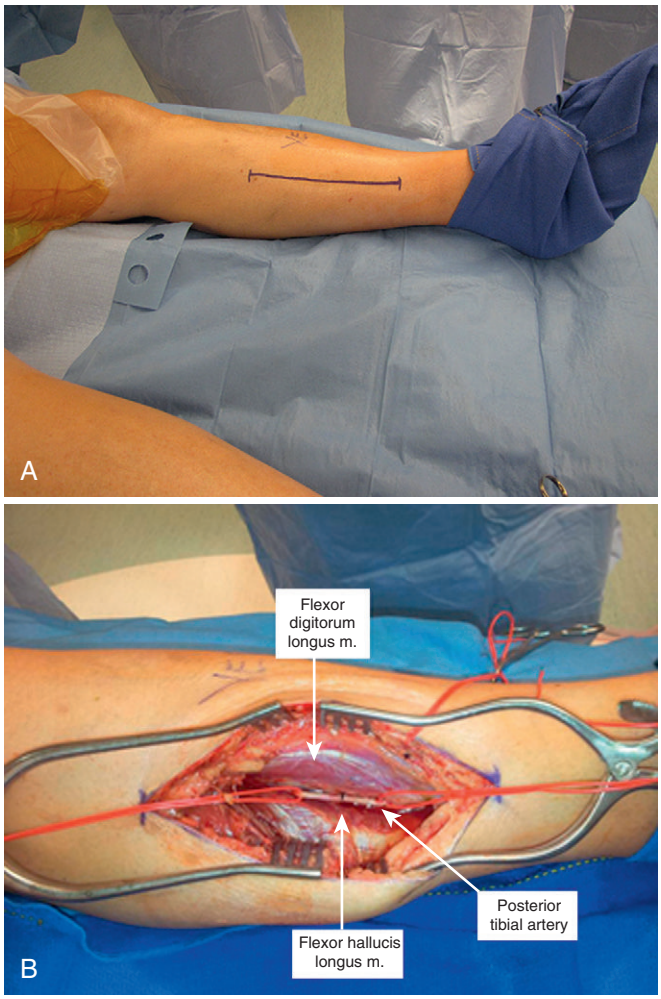

FIGURE 2 Exposure of the posterior tibial artery. **A,** An incision is made on the middle third of the medial portion of the leg. **B,** The posterior tibial artery lies between the flexor digitorum longus and flexor hallucis longus muscles, which are separated with sharp and blunt dissection.

The middle segment of the peroneal artery can be exposed through the same incision used to expose the posterior tibial artery, and the plane of dissection is carried more deeply. The tibial nerve is retracted anteriorly and the flexor hallucis longus muscle posteriorly to expose the peroneal artery and its terminal branches. The distal peroneal artery is exposed with an incision placed laterally over the fibula, and the bone is cleared of all muscular and tendinous attachments (Figure 3, *A* and *B*). The bone is then gently resected for a distance of at least 8 cm, and the peroneal artery lies medially on the flexor hallucis longus muscle (see Figure 3, *C* and *D*).

Anterior Tibial Artery and Dorsalis Pedis Artery

The anterior tibial artery is exposed through a longitudinal incision placed lateral to the anterior border of the tibia (Figure 4, *A*). The fascia overlying the tibialis anterior and the extensor digitorum longus muscles is opened, and the groove between the these two muscles is separated (see Figure 4, *B*), which exposes the anterior tibial artery, its concomitant veins, and the deep peroneal nerve (see Figure 4, *C*).The dorsalis pedal artery is the continuation of the anterior tibial artery onto the dorsum of the foot and is exposed by an incision made just lateral to the extensor hallucis longus tendon and not directly overlying the artery. Division of the inferior extensor retinaculum exposes the proximal dorsalis pedal artery and its lateral tarsal branch.

Conduit

For patients with TPOD, bypass grafting with single-segment GSV remains the "gold standard" of revascularization; 1-year and 5-year limb salvage rates exceed 90% and 80%, respectively. If the ipsilateral portion of the GSV is inadequate or previously used for bypass, then the GSV from the contralateral leg should be used. If the contralateral leg has extensive PAD that will eventually necessitate bypass, then an endovascular approach should be used in the ipsilateral limb. If no GSV is available and endovascular attempts for revascularization are unsuccessful, then the lesser saphenous vein or the basilic and cephalic veins from the arms are second options, if they are of adequate diameter. The basilic and cephalic veins, if not damaged by repeated venipuncture, can be harvested as a single continuous graft of significant length. In a retrospective analysis, heparin-bonded expanded polytetrafluoroethylene (ePTFE) bypass to the tibial

arteries had a 1-year primary patency rate of 75.4% and is thus an option in an otherwise young, previously active patient without infected wounds. Less optimal choices are composite segments of arm and leg veins and cryopreserved vein allografts; however, all are equivalent to prosthetic conduit in terms of graft patency and limb salvage but should be considered when a leg with a contaminated wound is treated.

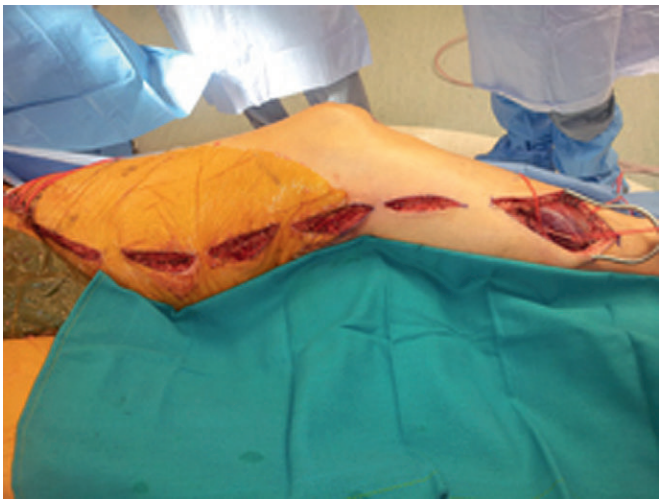

FIGURE 5 The greater saphenous vein is exposed with a series of incisions along its course on the medial aspect of the leg. Skin bridges are left in place to minimize tension on the incision closure and prevent wound dehiscence.

The GSV can be procured with either open or endoscopic techniques; patency rates and wound complication rates are equivalent. It is crucial that the GSV be exposed and extracted with meticulous technique because injury and repair may compromise patency. The authors use a series of skip incisions with 2- to 3-cm skin bridges to expose the vein (Figure 5), which provides adequate exposure of tributary branches and fewer wound complications than does a continuous incision. The authors ligate branches approximately 1 to 2 mm distal to their origin from the GSV to prevent crimping and luminal narrowing of the GSV. The authors begin harvesting after exposure of the proximal and distal arterial targets, which allows estimation of the length of conduit necessary and helps minimize ischemia of the vein. The GSV can be used in a reversed, nonreversed, or in situ manner. In the authors' experience with bypass to the tibial or peroneal arteries, the best lumen size match is with a nonreversed GSV. For the proximal anastomosis, the authors select the most disease-free segment of CFA and often must sew it to the distal external iliac artery if necessary; thus leaving the vein in situ compromises the ability to reach this far proximally.

Inflow Anastomosis

The distal external iliac artery, CFA, PFA, and SFA are exposed as previously described. Tunnels for the bypass graft are created, and the patient undergoes systemic anticoagulation with heparin at an initial dose of 80 to 100 U/kg, followed by periodic boluses of 1 to 2000 U of heparin to maintain an activated clotting time of 250 to 300 seconds throughout the operation. The CFA is palpated to determine the site that is most free of atherosclerosis. Atraumatic clamps are placed on the SFA, PFA, and proximal portion of the CFA, and an arteriotomy is created with a No. 11 scalpel blade. The arteriotomy is expanded to 25 to 35 mm, depending on the diameter of the GSV. The proximal portion of the GSV is cut with tenotomy scissors in a beveled manner, and the anastomosis is created with 5-0 monofilament suture in a continuous manner. In patients without flow-limiting lesions (<50%) in the proximal SFA, more distal sites can be used for the proximal anastomosis that include the SFA just proximal to the sartorius muscle.

Tunnels for Bypass Grafts

Before the patient receives heparin for the proximal anastomosis, tunnels for the bypass graft are created by advancing a Gore tunneling device or a large aortic clamp beneath the sartorius muscle from an incision at the level of the adductor hiatus, usually one already made for GSV harvest. Once the proximal anastomosis is completed, the vein graft is clamped distally and inflated with blood. The anterior aspect of the vein is marked longitudinally on its anterior surface to prevent twisting, and the distal aspect of the vein is dragged through the tunnel. To reach the proximal third of the posterior tibial and peroneal arteries, the graft is tunneled from the adductor hiatus thorough the popliteal fossa to maintain a straight path. To reach the distal segments of the posterior tibial and peroneal arteries, the vein graft is tunneled subcutaneously and medial to the knee. For the anterior tibial artery, the vein graft is tunneled on the lateral aspect of the leg subcutaneously. This approach avoids acute turns in the graft that occur with a medial path and is especially useful when the patient has had prior bypass surgery.

Outflow Anastomosis

Creation of the outflow anastomosis requires adherence to meticulous technique and gentle manipulation of arteries, many of which are calcified. Loupe magnification is essential. The vessels can be controlled with constricting vessel loops, vascular clamps, or a proximally placed pneumatic tourniquet. An arteriotomy is initiated with a No. 11 scalpel blade, with care not to lacerate the posterior wall of the artery. In general, the arteriotomy should be approximately 1.5 times the diameter of the vein graft because longer anastomoses tend to flatten the hood of the vein and create a sharp angle at the heel, which lead to flow turbulence and consequently a nidus for intimal hyperplasia. Monofilament suture (7-0) is used to create a running sutures line from the heel forward to a point two thirds from the toe. At this point, the authors use interrupted sutures beginning at the toe and proceeding in a retrograde direction, placing five to seven sutures (Figure 6) and tying the last to the running suture line. This technique allows direct visualization of the arterial lumen and precise placement of sutures at the most critical area of the anastomosis, the toe, with regard to flow into the distal artery. Furthermore, the series of interrupted sutures prevents constriction of the anastomosis, as may occur with a running suture line. When the surgeon encounters a patent but diffusely calcified artery, the creation of a distal arteriovenous fistula with vein patch, as described by Neville, may improve bypass graft patency. A common ostium is created between the tibial or peroneal artery and an adjacent vein. A section of GSV is used to place a patch over the common ostium, and the vein graft is then anastomosed to the patch.

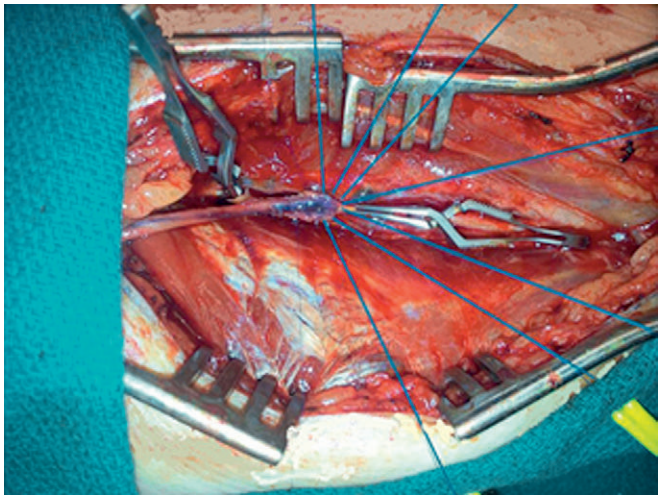

FIGURE 6 The distal anastomosis is created with a running suture of 7-0 monofilament, beginning at the heel and running continuously to the middle of the anastomosis. Interrupted sutures are then placed beginning at the toe and proceed back towards the running sutures. The interrupted sutures are not tied until after placement is complete, to enable visualization of the arterial lumen.

ENDOVASCULAR REVASCULARIZATION

Indications for Intervention

With lower rates of perioperative morbidity and mortality, high rates of technical success, and equivalent rates of limb salvage, PTA of the tibial and peroneal arteries is a critical skill of the vascular surgeon. Evidence of long-term efficacy was provided by the Beth Israel Deaconess Medical Center, which demonstrates that PTA of the tibial and peroneal arteries results in 1- and 5-year primary patency rates of 57% and 38% and limb salvage rates of 84% and 81%, respectively. Although some authorities advocate PTA as the first line of therapy in all patients with symptomatic TPOD, the authors advocate its use for patients who do not have a continuous single segment of GSV, those with significant comorbid conditions that increase the risk of problems with general anesthesia and a long operation, and those with a limited life expectancy. According to the TASC I classification for infrapopliteal lesions (TASC II did not include an anatomic classification of tibial disease), PTA is recommended for TASC classes A, B, and single-level C lesions in the tibial or peroneal arteries. In general, lesions that are more amenable to successful endovascular interventions are stenoses narrower than 4 cm or segments of occlusion narrower than 2 cm. Extensive disease that involves the trifurcation, numerous stenoses, a diffusely diseased tibioperoneal artery, or long occlusions are best treated with surgical bypass. In these situations, endovascular therapies may be employed as an adjunct to open surgical bypass to improve inflow or outflow during bypass procedures or for patients who are poor candidates for open surgical bypass because of either a lack of conduit or significant medical comorbid conditions.

Vascular Access and Imaging

Preprocedure imaging with CTA is most helpful in planning the point of arterial access and locations of critical stenoses and occlusions. For tibioperoneal interventions, the contralateral CFA is the preferred access site. If this is not a suitable option, either because of extensive atherosclerosis or because of the presence of an aortobifemoral graft, then the left brachial artery or ipsilateral CFA can be accessed with an antegrade approach. These alternatives are less ideal because of the increased level of difficulty and complication rate. The contralateral CFA is accessed with a 21-gauge needle. The Seldinger technique is used, and under continuous fluoroscopic guidance, a short 5F or 6F sheath is placed in the artery. The patient then receives systemic heparin, with an initial dose of 80 to 100 U/kg, followed by periodic boluses to maintain an activated clotting time of 250 to 300 seconds.

A diagnostic catheter is advanced into the abdominal aorta and exchanged for a pigtail catheter in order to cross the aortic bifurcation and guide a wire into the ipsilateral iliac artery. As with open surgical bypass, inflow and outflow must be considered in maintaining perfusion throughout the infrapopliteal system. The advantage of contralateral retrograde access is that it allows for access to the aortoiliac and femoropopliteal regions; stenoses in this area can be addressed at the same time as the infrapopliteal intervention in many cases. Once the aortic bifurcation is crossed, the short sheath is then exchanged for a longer and stiffer sheath that is parked at the

ipsilateral femoral or distal external iliac artery. This allows for stable access to support the various devices and catheters used in infrapopliteal interventions. Additional support sheaths (e.g., tibial shuttle sheath, Cook Medical, Bloomington, Ind) in association with a crossing catheter is used to provide adequate support to cross the tibial arterial occlusions. The authors also use 0.014-inch or 0.018-inch wires with added weight at the tip, which provide enough "pushability" to cross the infrapopliteal lesions. If this route is unsuccessful, the pedal arteries can be cannulated under ultrasound guidance, and a wire can be advanced in a retrograde direction. A snare device can then be employed to grasp the proximal wire and navigate it through the tibioperoneal arteries (Figure 7, *A* to *D*). Although these techniques are intuitive, they require significant operator experience as well as adequate imaging tools.

Precise mapping of infrapopliteal anatomy is crucial for proper intervention. In more proximal arterial imaging, diluted contrast material or carbon dioxide can be used to reduce the contrast load. However, for imaging below the knee, full-strength contrast material allows for the best resolution. Imaging of the trifurcation is usually performed with a zero-degree anterior-posterior view. A 30-degree ipsilateral oblique or 90-degree true lateral view may be utilized to properly detail the anterior and posterior tibial arteries. While the tibial vessels are imaged, the catheter should be positioned at the distal popliteal artery.

Balloon Angioplasty and Stent Placement

The mainstay of endovascular treatment of the tibioperoneal vessels has been PTA. Balloons suitable for these interventions range from 1.5 to 4 mm in diameter and are up to 20 cm in length. Currently available tibial arterial balloons are delivered into shaft lengths of up to 170 cm. It is better to use a balloon length that will cross the entire lesion in a single pass. These balloons are noncompliant and low profile, and a long inflation time of 1 to 3 minutes reduces the risk of dissection of the artery. If disease is still present, then the balloon can be inflated for 3 to 4 minutes, or a cutting balloon can be utilized.

The use of stents has previously been as a "bailout" technique after PTA if there was residual stenosis of more than 30% or a flow-limiting dissection after balloon inflation. The stents used in these situations were classically bare metal, and the restenosis rate was approximately 50% at 6 months. There has been a growing trend toward placement of drug-eluting stents (DES) in hopes of improving patency rates similar to those observed with the use of DES in coronary revascularization. Because of the comparable caliber of coronary and tibioperoneal arteries, researchers in several case series have employed coronary DES in the infrapopliteal arteries and have shown that restenosis rates decreased to nearly 10% at 6 months. Randomized trials are currently under way to see whether there is a benefit to routine use of DES comparison with PTA alone. At the completion of the procedure, various commercial closure devices can be used to seal the arteriotomy at the access site. This reduces the amount of time spent on manual compression. Protamine can be administered at the physician's discretion to reverse the anticoagulation.

OTHER TECHNOLOGIES

Mechanical atherectomy devices, both rotational and directional, can be used to remove a portion of the atheromatous plaque from the luminal surface. The advantage of this method is an actual decrease in the plaque burden in comparison with PTA and stent placement; however, the concern is for distal embolization of plaque. Other interventions include laser atherectomy devices, cryo-balloon angiop lasty, and drug-covered balloon angioplasty. Industry-sponsored trials are currently underway to determine the role of these devices in endovascular interventions.

POSTINTERVENTION MANAGEMENT AND SURVEILLANCE

After intervention, all patients are placed in a monitored setting in which pulses are routinely checked every 1 to 2 hours. Patients who received an endovascular intervention with percutaneous access to the groin are kept on strict bed rest with the hip in a neutral position for 6 hours. Patients in whom access to the groin was open are kept on bed rest for at least 24 hours in order to decrease the incidence of lymph leak. After a period of observation of 6 hours and if no hematoma is present at the access site, discharge may be considered for patient who underwent percutaneous endovascular intervention. Those who underwent open surgical bypass are kept in a monitored setting for approximately 72 hours to assess for hemodynamic stability and fluid shifts. After this period of time, the focus can then shift to physical therapy and mobility. All patients should be maintained on aspirin regimens after their intervention. Dual antiplatelet therapy of aspirin and clopidogrel is prescribed to all endovascular therapy recipients; strong consideration is given to patients who underwent open surgical bypass as well. Patients who underwent open surgical bypass are started on routine thromboembolism prophylaxis after 24 hours. Patients with a synthetic conduit are started on a therapeutic heparin regimen, with eventual conversion to warfarin (Coumadin). Medical therapy should include beta-blockade to maintain a heart rate of 80 to 100 beats per minute and tight glucose control. Statin therapy has been shown to improve the patency rate in bypass recipients, and this is routinely started if a patient is not already receiving it.

Patients who have undergone bypass grafting are monitored by duplex ultrasonography of the bypass along with measurement of the ankle-brachial index (ABI) before discharge and then again at 1 month, 3 months, 6 months, and 1 year. Increasing focal velocities within the bypass or at the anastomoses or a decrease in the ABI of more than 0.15 should prompt further investigation with angiography (CTA, magnetic resonance angiography, or catheter-based angiography) in order to prevent graft failure. Patients with endovascular interventions are monitored at similar intervals, although reintervention is based on symptoms of CLI rather than on numeric values.

COMPLICATIONS

Immediate complications include hemorrhage or graft thrombosis and necessitate reoperation. Hemorrhage manifests as an expanding hematoma in the groin or leg and possibly hemodynamic instability. Affected patients should be taken back to the operating room for exploration and evacuation of the hematoma in order to prevent shock, infection, or formation of a pseudoaneurysm. Early graft thrombosis is almost always the result of a technical complication but can arise from compression of the graft or an undiagnosed hypercoagulable state. Affected patients should undergo thrombectomy and arteriography to examine for issues related to anastomosis, twisting of the graft, an intimal flap, or inadequate outflow.

Late complications include infection, pseudoaneurysm formation, and graft thrombosis. Graft thrombosis during the period of 1 to 24 months after the initial operation probably results from neointimal hyperplasia, whereas those that occur after this period are typically caused by recurrent atherosclerotic disease.

FUTURE TREATMENT: CELL-BASED THERAPIES

Although revascularization with either surgical bypass or endovascular techniques can result in exceptional improvements in AFS with

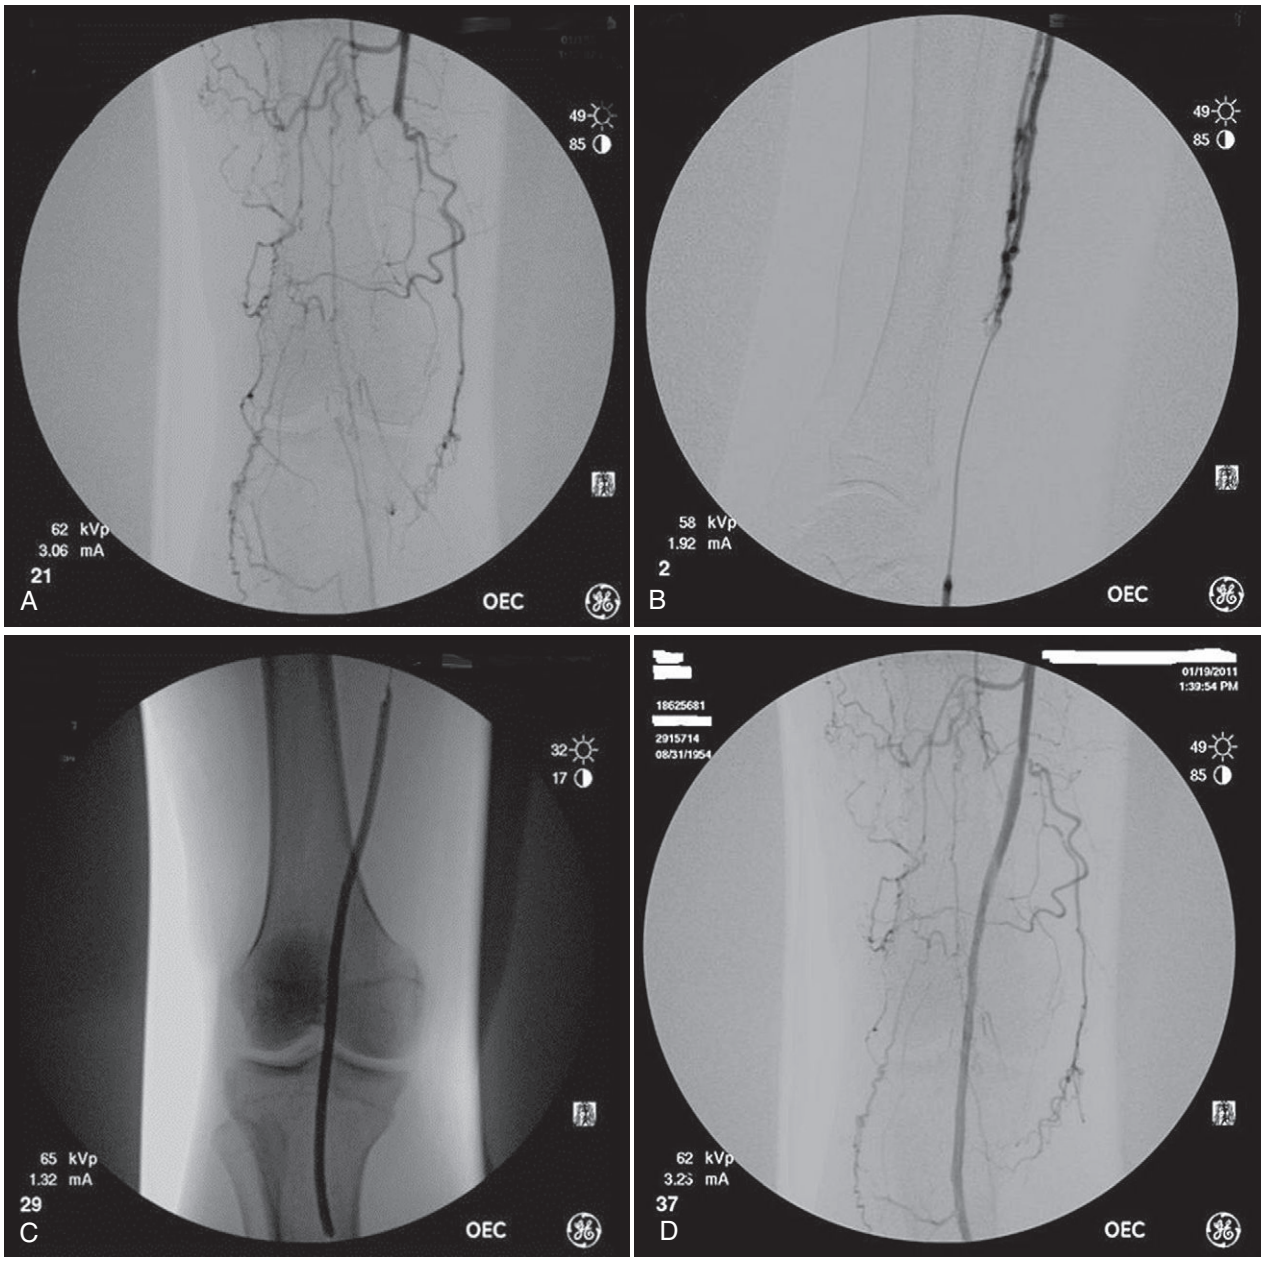

FIGURE 7 Retrograde access of the posterior tibial artery in a patient with critical limb ischemia and previously harvested great saphenous vein. **A,** Chronic total occlusion that could not be traversed with subintimal dissection with a guide wire. **B,** Retrograde access of the posterior tibial artery with a 0.014-inch guidewire and Quick-Cross catheter that is snared from the ipsilateral common femoral artery (CFA) acccess. **C,** Inflation of 3 mm × 20 cm balloon placed in an antegrade manner after wire exchange. **D,** Completion arteriogram, demonstrating unrestricted flow to the ankle. *(Courtesy George A. Akingba, MD, PhD.)*

acceptably low rates of morbidity and mortality, approximately 20% to 40% of patients with CLI are not candidates for these interventions because of lack of conduits or because of extensive disease within the outflow tibioperoneal vessels. For these patients with historically unsalvageable disease, stem cell therapies are emerging as a potential option.

The authors completed the first Food and Drug Administration–approved cell-based trial for PAD within the United States. In this phase I/II trial, the researchers utilized intramuscularly injected autologous bone marrow mononuclear cells (ABMNCs) in patients who were not candidates for revascularization. The AFS was 86.3% at 1 year; 33% to 50% of patients had clinically significant improvements in arterial perfusion (TBI or ABI > 0.15); and 33% of ulcers healed completely.

These results are encouraging but must be tempered by the fact that the study's patient population excluded those with renal failure or a hemoglobin A_{1C} level higher than 8.5%. Any conclusions regarding cell-based therapies for CLI await the results of a much broader, randomized study. The authors are currently conducting a phase III randomized, double-blind study to test the concept that ABMNCs can affect AFS in patients with CLI with no other options.

CONCLUSION

The management of TPOD should be focused on promoting amputation-free survival. Claudication should be dealt with through medication management and lifestyle modification, and intervention should be reserved for patients who present with CLI. Open surgical bypass and endovascular therapies are available treatment options. There is significant enthusiasm for endovascular therapy because of its decreased morbidity and mortality rates and shortened hospital stay. However, in cases of severe disease, the open surgical bypass is the preferred procedure if the patient is an appropriate surgical candidate and has adequate conduit. Endovascular therapies are increasingly used in the management of CLI, and the role of drug-eluting stents and balloons is now recognized in the management of these complex lesions. Cell-based therapies are an intriguing option for patients who do not qualify for surgical or endovascular intervention, but this therapy is only in the preliminary stages of research.

Profunda Femoris Reconstruction

Tod M. Hanover, MD, Mark P. Androes, MD, and Spence M. Taylor, MD

PROFUNDA FEMORIS ARTERY

The profunda femoris artery (PFA), or deep femoral artery, is critical to the viability of the lower extremity because it is the primary source of blood flow to the muscles of the thigh. In addition, it provides rich collateral flow to the tibial arteries in the event of significant superficial femoral or popliteal artery disease. The PFA also provides collateral flow to the pelvis in the event of common iliac or internal iliac artery occlusion.

BASIC ANATOMY

The common femoral artery (CFA) bifurcates into the profunda femoral artery and the superficial femoral artery (SFA) 3 to 5 cm distal to the inguinal ligament. The profunda femoral artery arises from the posterolateral surface of the common femoral artery and travels in a posterior direction deep to the superficial femoral artery. The medial and lateral circumflex femoral arteries that provide collateral supply to the tibial and pelvic vessels usually arise directly from the profunda femoral artery. They do, however, originate directly from the common femoral artery 14% to 20% of the time. The PFA continues distally to give off three perforating branches to supply the muscles of the thigh before terminating in the distal thigh. The lateral circumflex femoral vein crosses anterior to the profunda femoral artery near the latter's origin. Anatomically, the profunda femoris artery may be divided into three zones. The proximal zone (zone 1) begins at the origin of the artery and extends to the lateral circumflex femoral artery (LCFA). The middle zone (zone 2) begins at the LCFA and extends to the second perforating branch. The distal zone (zone 3) continues beyond the second perforating branch and lies deep to the adductor longus muscle. An oblique line from the anterior superior iliac crest to the medial knee corresponds to the course of the sartorius muscle and serves as a useful landmark (Figures 1 to 3).

OPERATIVE ROLE

The profunda femoris artery offers a variety of uses to the operating surgeon. It can provide inflow as an origin vessel, for infrainguinal procedures such as femoropopliteal bypass or femorotibial artery bypass. It can also serve as an outflow, or target vessel, for suprainguinal procedures such as aortofemoral bypass, axillofemoral bypass, femoral-femoral bypass, and iliofemoral obturator bypass. Finally, in certain situations, localized surgery on the PFA may be indicated (i.e., profundaplasty).

Profunda Femoris as an Inflow Vessel

Indications for use of the profunda femoris as a graft origin include inadequate available vein length, the need for concomitant extended profundaplasty, occlusion or stenosis of the superficial femoral or popliteal arteries (thereby precluding their use as an inflow vessel), and avoidance of groin scar from previous surgical reconstruction or wound infection. The profunda femoris artery tends to be spared of significant atherosclerotic occlusive disease, and when present, the disease tends to be confined to the origin or proximal portion of the PFA, especially in the patient without diabetes (Figure 4).

The route for access to the PFA as an inflow source is dictated by the specific indication for operation and is tailored to the individual patient. Recognized surgical approaches include the standard anterior incision, an anterolateral and anteromedial incision, a posteromedial incision (previously called the posterior incision), and the true posterior incision. If exposure of the CFA is performed to treat occlusive disease within the CFA or proximal PFA as an addition to an infrainguinal bypass, the standard anterior approach through an extended anterior groin incision should be used. For these, the PFA is traced from its origin far enough distally to obtain suitable length for a proximal anastomosis. If the patient needs both prosthetic inflow graft revision and outflow bypass, sufficient PFA should be dissected distally to permit anastomosis of the infrainguinal vein graft to native PFA. This should be done in preference to anastomosis of the proximal vein graft to a prosthetic inflow graft.

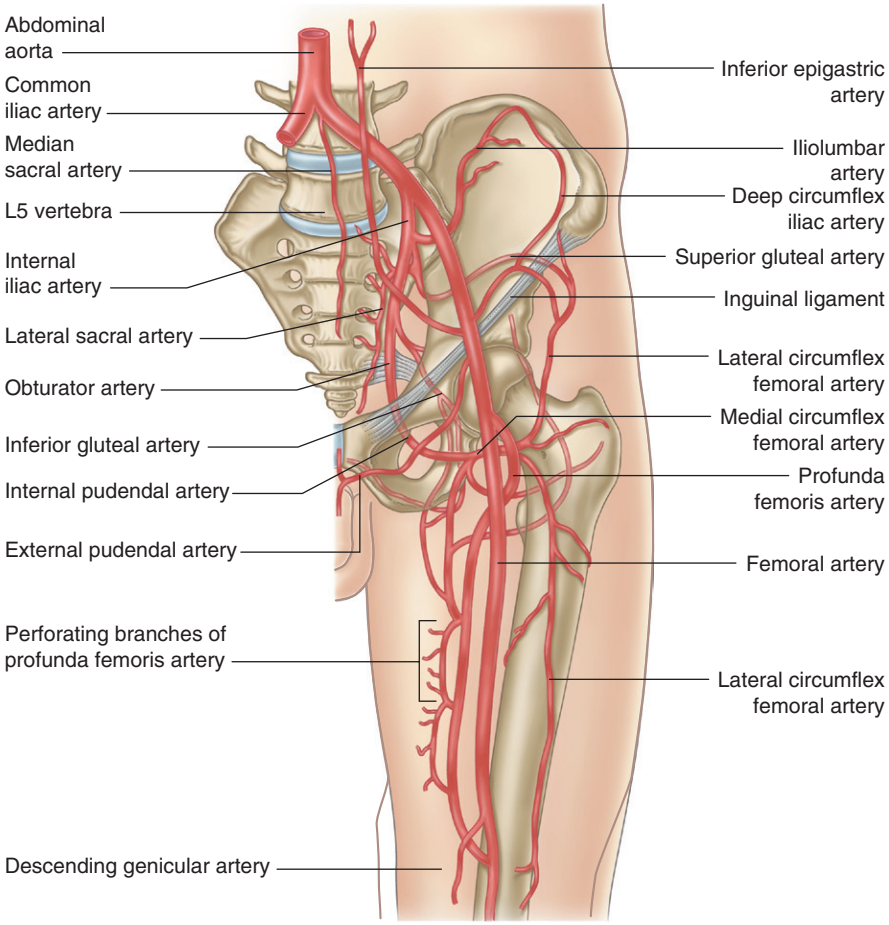

FIGURE 1 Vascular anatomy of the thigh depicting the rich collateral network between the internal iliac artery, profunda femoris artery, and popliteal artery.

Outflow

The profunda femoral artery is well suited as a critical outflow source for suprainguinal bypasses such as aortofemoral, axillofemoral, and femorofemoral bypasses. Often the profunda femoral artery outflow is crucial for maintenance of inflow graft patency. If progressive stenosis or occlusion of the superficial femoral artery occurs, the profunda femoral flow is usually adequate to support aortofemoral bypass graft outflow and maintain limb viability. Although not validated with prospective studies, intraoperative evaluation of a PFA that accepts a 4-mm probe and then allows passage of a soft catheter for 20 to 25 cm implies significant runoff in the presence of SFA occlusion and proves to be adequate for patency of an aortofemoral, axillofemoral, or femorofemoral bypass (Brewster and colleagues, 1987). If the PFA does not reliably serve as the only outflow, then a synchronous distal bypass (such as PFA to popliteal artery or profunda femoral to tibial artery bypass) may be necessary. In patients with tissue loss, synchronous infrainguinal bypass with vein is preferred for in-line pulsatile flow to the foot.

In some situations, a proximal groin incision is to be avoided in a femoral outflow procedure. If the groin is infected or scarred from previous operations or arteriography reveals the profunda target to be more distal, an alternative incision should be chosen.

ISOLATED PROFUNDAPLASTY

Although the role of isolated profundaplasty is limited it can be an effective alternative to more extensive surgery and is an important adjunct when performing concomitant infrainguinal bypass. Profundaplasty may prove useful in removal of an infected prosthetic graft from the groin, in salvage of a nonhealing above-knee or below-knee amputation, and in improvement of the clinical status of constant rest pain to intermittent claudication with limited bypass or endovascular options. It is not recommended for the treatment of tissue loss unless concomitant distal bypass is performed to provide pulsatile in-line flow to the foot.

The success of an isolated profundaplasty at improvement of distal flow can be estimated with the profunda popliteal collateral index (PPCI):

$$\text{PPCI} = \text{AKSP} - \text{BKSP}/\text{AKSP}$$

with AKSP for above-knee segmental pressure and BKSP for below-knee segmental pressure.

A PPCI of more than 0.5 indicates poor collateral development and likely failure of a stand-alone profundaplasty. A PPCI of less than 0.19 represents significant collateral development and an expected good response to isolated profundaplasty (Boran and associates, 1980).

OPERATIVE APPROACHES

Standard Anterior Approach

The standard anterior approach is useful for access to the common femoral artery and the proximal profunda and superficial femoral arteries. It is by far the most common incision used for the

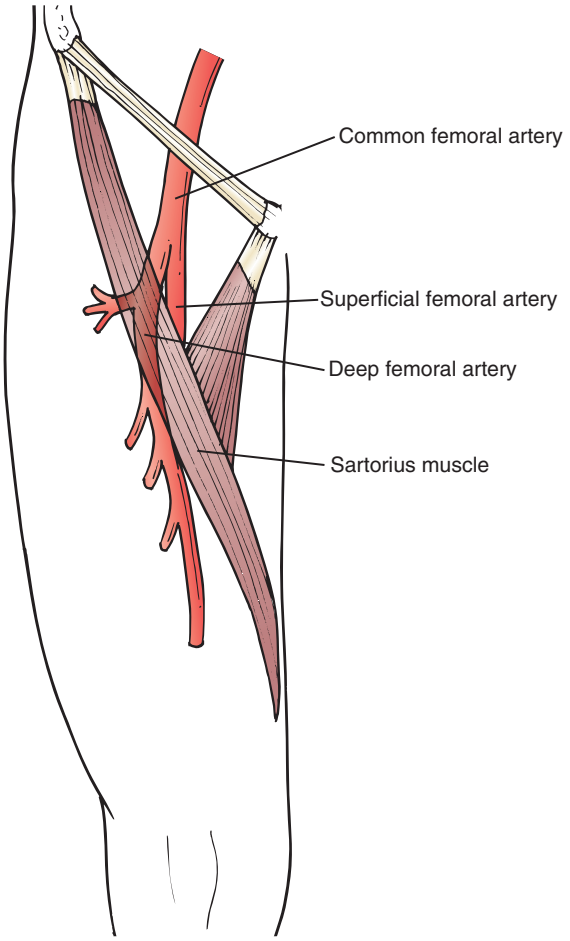

FIGURE 2 The course of the sartorius muscle is represented in relation to the profunda femoris artery.

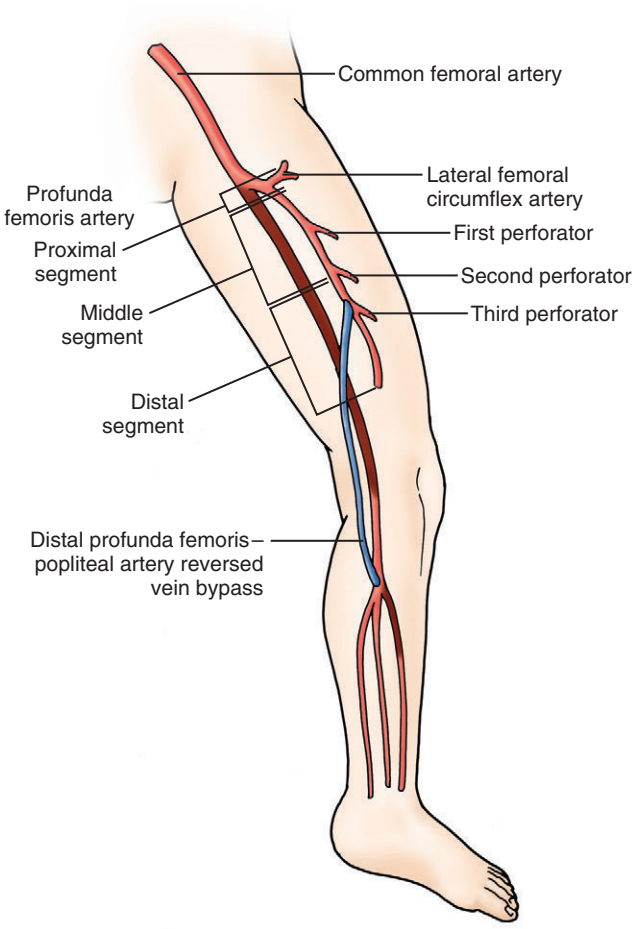

FIGURE 4 Schematic of the profunda femoris artery used as an inflow source for an infrainguinal bypass.

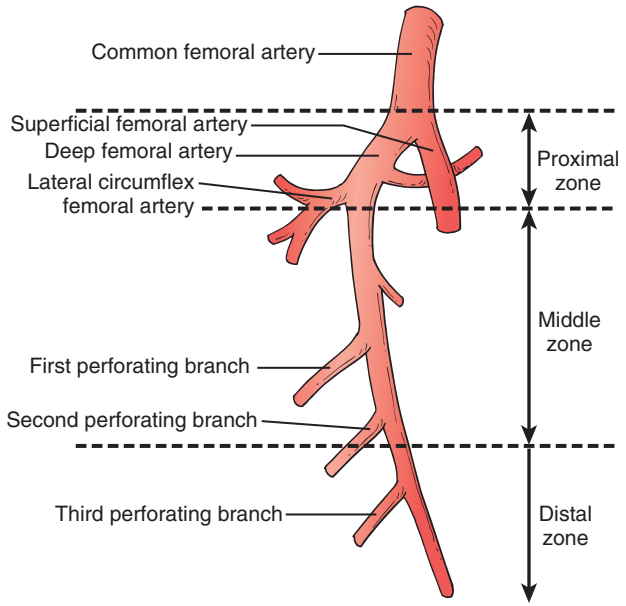

FIGURE 3 The branches and zones of the profunda femoris artery.

aortobifemoral bypass and for infrainguinal bypasses arising from the common femoral artery.

This incision is begun over the femoral pulse or, if the pulse is absent, two fingers breadth lateral to the pubic tubercle and extended distally for 5 cm. The subcutaneous tissue is divided, with ligation of any visible nodal tissue or small veins and the superficial circumflex iliac vein if needed. Dissection is continued to the femoral sheath, which is then opened to gain access to the CFA and proximal profunda femoral and superficial femoral arteries. If the common femoral artery is pulseless, it often can be identified with palpation of its calcifications. Dissection should continue close to the vessel in a relatively avascular loose areolar plain. Occasionally dissection is more difficult because of the inflammatory nature of atherosclerotic disease.

Vessel loops around the CFA assist with more distal dissection. Progressing distally, a visible decrease is seen in the diameter of the CFA. At this point, the PFA branches off in a posterolateral direction. Dissection continues along the lateral aspect of the CFA at the diameter change to expose the PFA. If needed, PFA dissection can be aided with either medial or lateral traction on vessel loops placed on the CFA and SFA.

The PFA is a soft, thin-walled artery, and care should be taken not to avulse any of its branches. The medial and lateral circumflex femoral arteries usually arise from the PFA but as noted previously may come directly from the CFA. Their control needs to be obtained (Figure 5).

Standard Anterior Approach for Extended Profundaplasty

The required length of dissection of the PFA depends on extent of disease and indication for the operation. Extent of disease is judged with palpation of the artery combined with review of previously obtained imaging studies. A single view arteriogram without pull-back pressures can be misleading and may underestimate significant disease layering on the posterior wall.

The profunda femoris is identified at its origin as in the standard anterior approach. Further dissection distally on the PFA requires division of the lateral circumflex femoral vein where it crosses anterior to the proximal PFA. Care must be taken to remain close to the profunda femoris artery to avoid injuring femoral nerve fibers. Dissection is continued distally until past any significant disease. In the mid thigh, the adductor longus muscle must be partially divided for distal profunda exposure.

The patient undergoes systemic anticoagulation with heparin. Vessels loops are pulled taunt to occlude any inflow or outflow.

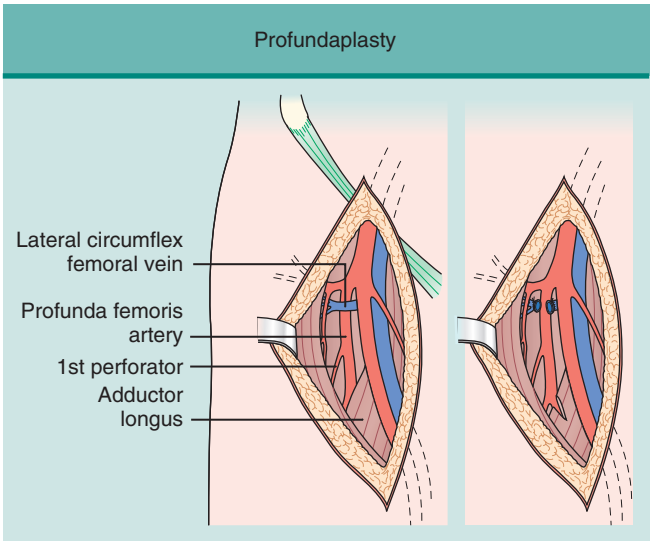

FIGURE 5 Standard anterior approach to the profunda femoris artery.

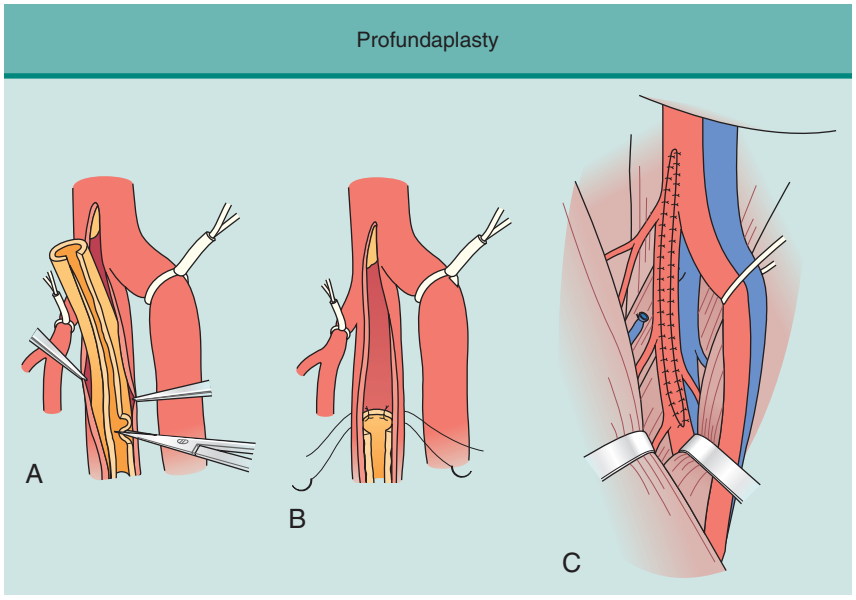
Profunda clamps are shaped to provide distal PFA occlusion without being cumbersome or intrusive. Because clamps do not put longitudinal tension on the vessel, the arterial back wall is not pulled close to the front wall and thus visualization of the lumen is enhanced. Arteriotomy is begun in the common femoral artery with a #11 blade and extended onto the profunda with Potts scissors until past gross disease.



With significant atherosclerosis, an endarterectomy is then indicated. Proximally, in the CFA, a deep media plane is entered with an elevator, the plaque is divided, and the elevator is used to continue the endarterectomy into the PFA. Ideally, the endarterectomy is continued to the distal extent of disease where a thin, feathered endpoint is often reached. If this feathered endpoint is not seen, then the plaque is sharply divided and its endpoint tacked down with interrupted 7-0 polypropylene sutures. In the authors' experience, tacking sutures are usually needed to prevent distal arterial flap formation and should be used liberally. Remaining medial fibers are removed with fine forceps in a radial fashion.

The extended arteriotomy is closed with a vein patch. If vein is not available, a piece of occluded superficial femoral artery can be used as an autogenous patch. The needed length of this occluded artery is removed and opened longitudinally. A complete endarterectomy of the scavenged artery makes it a durable patch (Figure 6).

Anteromedial and Anterolateral Approach

The anteromedial and anterolateral approaches are quite similar. The anteromedial allows access to the proximal and mid zones. The anterolateral gives access to the mid and distal zones. These incisions are commonly used when groin infection or intense scarring precludes the standard anterior approach. Both incisions are parallel to the sartorius muscle and are begun along the medial or lateral border, respectively, of the sartorius muscle, dependent on the approach chosen. The sartorius is retracted medially for the lateral route and correspondingly laterally for the medial approach. Dissection is continued deep to the SFA neurovascular bundle. The PFA is found lying between the vastus medialis and adductor longus muscle. A dense connective tissue membrane, or raphe, overlying the PFA must be incised to expose the artery. If used as an inflow vessel, a pulse may be palpable through the raphe. If used for outflow, a pulse may not be palpable and continuous wave Doppler scan then aids in identifying its location (Figures 7 and 8).

Posteromedial Approach

The posteromedial approach has previously been referred to as the posterior approach. However, posteromedial characterization is more accurate and less confusing because there is a true posterior approach. The posteromedial approach is best used for situations in which standard groin incision is contraindicated (infection or scar), SFA occlusion is present, or an extraanatomic bypass target is required, such as in the case of an iliofemoral obturator bypass. The distal zone can be reached with this approach and allows access to the profunda femoris artery without encroachment into the subsartorial plane. With the knee flexed and the hip externally rotated, a longitudinal incision is placed on the medial thigh. The deep fascia is opened, and dissection is continued posterior to the adductor longus muscle. The profunda femoris artery is located between the deep portion of adductor longus and the adductor brevis (see Figure 7; Figure 9).

Posterior Approach

The true posterior approach is rarely needed, although it may be the best choice if other approaches are unsuitable because of trauma, infection, scarring, or radiation. Computed tomographic angiography may be helpful for anatomic definition in this approach. The patient is placed in the prone position. A vertical incision is placed to extend one third proximally and two thirds distally to the gluteal crease. The sciatic nerve must be identified. A plane can be developed between the biceps femoris muscle retracted medially and the vastus lateralis muscle laterally. The adductor magnus and adductor brevis are separated from the linea aspera of the femur and then retracted medially. The profunda femoris is thereby exposed.

ENDOVASCULAR THERAPY

Although endovascular treatment of PFA stenosis historically has been infrequently used, it is used more frequently as surgeons have become increasingly familiar with percutaneous interventional techniques. In general, PFA angioplasty is reserved for cases where severe systemic patient morbidity or intense local scarring of the groin precludes open reconstruction. Most disease in the PFA is near the artery origin and thus lends itself to endovascular treatment techniques. When the native common and external iliac and common femoral arteries are patent, a contralateral retrograde endovascular approach to the CFA is used. After heparinization, a sheath is passed over the aortic bifurcation for access to the target lesion. Angioplasty can then be performed in the standard fashion. The use of stents as a bailout procedure in the case of dissection, recoil, rupture, or significant residual stenosis remains controversial at this time.

With a history of aortobifemoral bypass, passing of a sheath from the contralateral CFA across the prosthetic bifurcation seldom is feasible because of the acute angle of the prosthetic bifurcation. In the case of outflow stenosis in the PFA, a left brachial artery endovascular access is preferred. The left brachial approach allows access to either lower extremity without crossing the aortic arch and accordingly should decrease associated complications. With newer, low-profile balloons, access through the brachial artery can be performed with a long 4F sheath (Figure 10).

CONCLUSION

The PFA plays an important role in maintaining viability of the lower extremity in the presence of superficial femoral or popliteal artery occlusive disease. It is a versatile vessel that serves as an outflow target for suprainguinal bypass or as an inflow source for infrainguinal bypass. Isolated profundaplasty may be useful in selected cases that do not involve tissue loss. Although controversial, the use of endovascular therapy is increasing and may become more applicable in the future as technology advances.

Femoral and Popliteal Artery Aneurysms

James L. Guzzo, MD, and Ying Wei Lum, MD

OVERVIEW

Peripheral arterial aneurysms in the lower extremity are the second most common type of arterial aneurysm after abdominal aortic aneurysms (AAAs). However, unlike AAAs, the natural history of (true degenerative) extremity arterial aneurysms is not one of expansion and rupture but of thromboembolism. This is particularly true of popliteal aneurysms, which are encountered more frequently than true femoral aneurysms.

True femoral and popliteal aneurysms are typically degenerative aneurysms that occur as a result of atherosclerosis, whereas false aneurysms, or pseudoaneurysms, are frequently the result of access site complications after vascular sheath removal for endovascular procedures. In clinical practice, femoral pseudoaneurysms are more frequently encountered than any other lower extremity aneurysm.

Both femoral and popliteal aneurysms are strongly associated with contralateral extremity arterial aneurysms, and as much as 50% of patients with a femoropopliteal aneurysm also have a coexistent infrarenal abdominal aortic aneurysm. Hence, the diagnosis of a femoral or popliteal aneurysm mandates routine imaging evaluation to rule out concomitant disease of the contralateral extremity and the abdominal aorta before any operative intervention is planned. If indeed multiple aneurysms are identified, sequential treatment of the lesions is preferable, with the more symptomatic or threatening lesion addressed first.

DEGENERATIVE FEMORAL ANEURYSMS

Introduction

True degenerative aneurysms (involving all three layers of the arterial wall) must be distinguished from false aneurysms (pseudoaneurysms) because of differing treatment principles. Although most popliteal aneurysms are true degenerative aneurysms, most femoral "aneurysms" encountered in current clinical practice are usually pseudoaneurysms (see discussion in the next section). In fact, true degenerative femoral aneurysms of the common femoral artery are rather rare. Aneurysms limited to just the deep femoral artery and superficial femoral artery are even less common.

Clinical Presentation and Diagnosis

Femoral artery aneurysms are frequently asymptomatic and can often be discovered incidentally as a pulsatile mass. However, some present with local pain or with distal ischemia as a result of thromboembolic events. Rupture and bleeding is rarely encountered. Once the aneurysms are discovered, patients should be evaluated with duplex ultrasound scan or contrast-enhanced computed tomographic (CT) scan with the objective of identification of other concurrent aneurysms and the extent of the femoral aneurysm. Contrast angiography and magnetic resonance angiography (MRA) are also useful adjuncts that can provide further precise information regarding patency of the distal outflow if concern exists for thromboembolic events.

Treatment

All symptomatic femoral aneurysms, regardless of etiology, should be repaired. Asymptomatic (true) aneurysms larger than 2.5 cm at presentation should also warrant consideration for surgical intervention. Aneurysms less than 2.5 cm typically have a more benign natural history and can be followed serially with duplex ultrasound scan on an annual basis.

Open surgical repair for aneurysms limited to the common femoral artery remains the gold standard management with excellent early and long-term outcomes. Endovascular options are generally not recommended in this location because of the flexion crease in the groin, which subjects the endovascular prostheses to potential kinking, migration, and metal fatigue. Surgical reconstruction for common femoral artery aneurysms is dependent on the extent of the aneurysm, the patency of the femoropopliteal segment, and the patency of the aneurysm itself. Aneurysms that are limited to the proximal common femoral artery (type I) can be repaired with an interposition graft (Figure 1), whereas aneurysms that involve the origin of the deep femoral artery (type II) typically require more complex reconstructions that involve revascularization of both the superficial femoral artery and the deep femoral artery (Figure 2).

Prosthetic grafts (8-mm to 10-mm polyester or expanded polytetrafluoroethylene [ePTFE]) can be used for most cases, although reversed saphenous vein graft should be used if concern exists for an infected or mycotic aneurysm.

The principles for repair of deep femoral artery aneurysms are similar, with the primary goal of aneurysm exclusion and maintenance of distal arterial perfusion. A vertical groin incision is preferred with adequate exposure of the common femoral artery for proximal control and medial retraction of the superficial femoral artery. Overlying venous branches off the deep femoral vein need to be carefully ligated to obtain adequate exposure of the deep femoral artery. Balloon occlusion catheters can be useful adjuncts in obtaining distal control. Although surgical reconstruction to maintain distal arterial perfusion is generally preferred, simple ligation may

also be used, particularly in patients who present with rupture or when the aneurysm is located in the deeper branches of the deep femoral artery. Alternatively, aneurysms that are located in the deeper branches of the deep femoral artery have also been treated endovascularly with transcatheter coil embolization. This technique can be used safely in selected patients when no disease is found in the common femoral artery and the origin of the profunda femoral artery.

Surgical treatment options for aneurysms in the superficial femoral artery depend on location. Open surgical techniques include direct repair with interposition graft (prosthetic or saphenous vein, depending on size match with the proximal and distal ends of normal caliber artery). Alternatively, arterial bypass in conjunction with proximal and distal ligation is also another option. Although open repair remains the gold standard, a few case reports have used endovascular stent grafts for aneurysm exclusion. This is in contrast to aneurysms located in the common femoral artery, which are less suitable for endovascular repair. Self-expanding nitinol stent grafts covered with expanded polytetrafluoroethylene are typically used and can be deployed either via the ipsilateral common femoral artery or across the aortic bifurcation from the contralateral common femoral artery. Device profiles for such endovascular prostheses have improved in the last decade, and these procedures can be done entirely percutaneously with a closure device or via a common femoral artery cut down, depending on individual surgeon experience.

Results

Published results from individual institutions have reported 5-year patency rates of up to 85% for open surgical common femoral artery aneurysm repairs. Choice of conduit does not seem to affect results. Deep femoral artery and superficial femoral artery aneurysms are rarer; not many case series with long-term results have been reported. Endovascular repairs (particularly for superficial femoral artery aneurysms) have only recently been reported with satisfactory short-term patency rates. Long-term outcomes remain to be determined. Of early failures recognized after endovascular repair, the lack of adequate distal outflow appears to be a negative prognostic factor.

IATROGENIC FEMORAL PSEUDOANEURYSMS

Introduction

Iatrogenic femoral pseudoaneurysms are well-recognized complications of arterial catheterization that occur in 0.2% to 6% of interventional procedures. They are formed as a result of a direct defect in the arterial wall after arterial cannulation and subsequent sheath removal. The pseudoaneurysm is formed as a result of this persistent communication between the arterial lumen and the hematoma. The risk of pseudoaneurysm formation has been correlated with the use of anticoagulant, antiplatelet, and thrombolytic therapy. Other technical factors associated include inadequate manual compression for hemostasis after sheath removal, larger diameter sheath sizes, and duration of procedure.

Clinical Presentation and Diagnosis

The spectrum of clinical presentation for iatrogenic femoral pseudoaneurysms can range widely. Quite commonly, they are identified incidentally during physical examination with the presence of a femoral bruit, on the day after the endovascular procedure. Another classic presentation is a painful pulsatile mass in the groin associated with hematoma and overlying ecchymosis. Fortunately, presentation with rupture and hemorrhagic exsanguination is less common. Such cases are usually associated with "high sticks" in which the puncture site is along the external iliac artery where manual compression against the femoral head is less effective.

Treatment

The treatment algorithm for iatrogenic femoral pseudoaneurysm is dependent on several factors and is summarized in Figure 3.

In patients not receiving any form of anticoagulation therapy with an iatrogenic femoral pseudoaneurysm less than 2 cm in diameter, several studies have shown that a vast majority (90%) of these lesions thrombose and resolve on their own within 2 months. On the contrary, prompt treatment is usually warranted for pseudoaneurysms greater than 2 cm or pseudoaneurysms that develop in patients undergoing anticoagulation, antiplatelet, or thrombolytic therapy.

The treatment principles differ greatly for pseudoaneurysms versus true aneurysms. Surgical repair was previously the mainstay of treatment, but other methods such as ultrasound scan–guided compression therapy and direct thrombin injection into the pseudoaneurysm cavity have now emerged to be safe and effective first-line therapy. Ultrasound scan–guided compression allows visual confirmation that flow within the pseudoaneurysm is being compressed while flow is maintained in the common femoral artery. Compression should be performed for 10 to 20 minutes and may be repeated again if flow persists after the first try.

Alternatively, direct thrombin injection can be performed with ultrasound scan guidance. Duplex ultrasound scan should be performed first to evaluate the anatomy of the pseudoaneurysm in relation to the femoral artery (Figure 4). The characteristics of the neck, including its visualization, length, and width, should be taken into consideration because short wide necks have the highest risk for distal thromboembolism as a complication from thrombin injection. After infiltration with local anesthetic, the authors prefer to puncture the pseudoaneurysm cavity with a 22-gauge spinal needle. The tip of the needle may be scored with a sterile scalpel to increase echogenicity and assist with visualization with ultrasound scan. Once the needle is visualized with ultrasound scan and centered in the middle of the pseudoaneurysm cavity, topical recombinant thrombin (1000 IU/mL) is infused percutaneously through the spinal needle with color Doppler visualization. Typically less than 1 mL is required to cause complete thrombosis of the pseudoaneurysm almost instantaneously (Figure 5). Repeat duplex scan examination is then performed to evaluate flow in the femoral artery and vein.

In both ultrasound scan–guided compression and direct thrombin injection, patients are required to remain on bed rest for 6 hours after the procedure, and a repeat duplex examination is performed 24 hours later to confirm thrombosis of the pseudoaneurysm.

Open surgical repair is indicated in patients in whom previously mentioned therapies have failed and in patients whom present with hemorrhage, expanding hematoma, unsuitable pseudoaneurysm neck anatomy, ischemic necrosis of the overlying skin, and compression neuropathy of the femoral nerve. The surgical dissection can

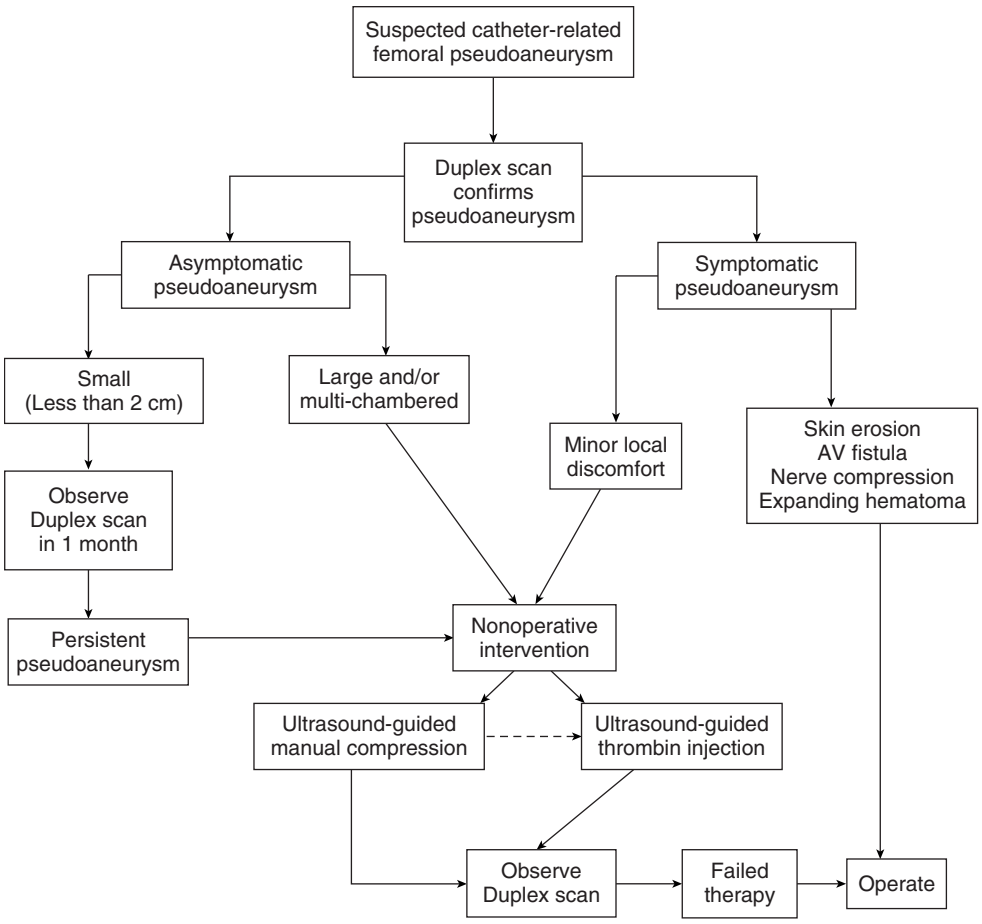

FIGURE 3 Algorithm for treatment of iatrogenic femoral artery pseudoaneurysms. *(Hirsch AT, Haskal ZJ, Hertzer NR, et al: Peripheral arterial disease: ACC/AHA 2005 guidelines for the management of patients with peripheral arterial disease [lower extremity, renal, mesenteric, and abdominal aortic].* J Am Coll Cardiol *47:1239-1312, 2006.)*

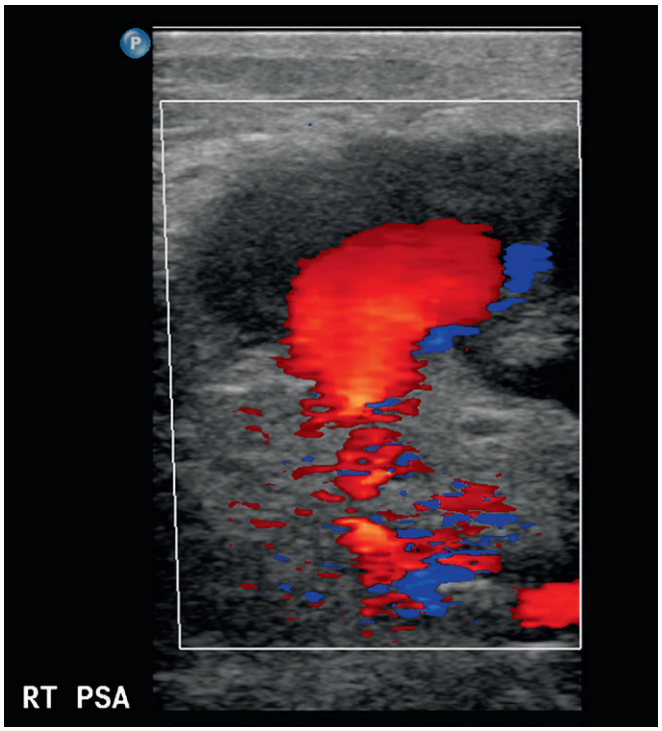

FIGURE 4 Color duplex ultrasound scan shows a pseudoaneurysm coming off the common femoral artery with some surrounding hematoma.

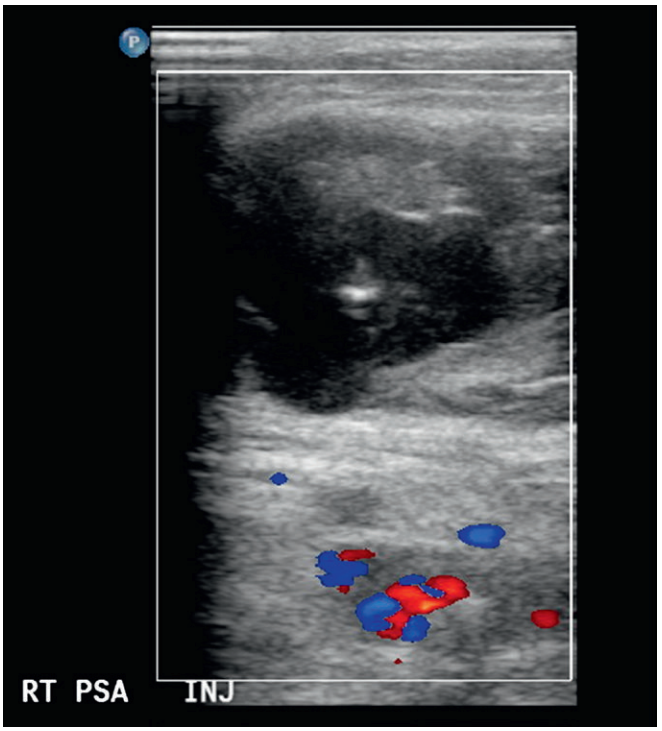

FIGURE 5 Color duplex ultrasound scan shows thrombosed femoral artery pseudoaneurysm with needle in the middle of the cavity *(horizontal axis)*.

occasionally be troublesome given the presence of the overlying pseudoaneurysm above the femoral vessels that bleed profusely once it is encountered. A peanut sponge is often useful and can be placed over the underlying arterial puncture site to assist in controlling hemorrhage while proximal and distal control is obtained. A distal retroperitoneal dissection may sometimes be necessary to obtain more proximal control of the distal external iliac artery in difficult circumstances. Simple surgical repair with horizontal stitches is usually sufficient once the arterial puncture site is clearly visualized and dissected free from the surrounding femoral sheath. The femoral sheath should be closed together in the event of a wound breakdown that can occur, particularly in cases with extensive undermining of the skin from the hematoma cavity. A closed-suction drain should be left in place in these circumstances. In some instances in which extensive skin necrosis is present, wide débridement followed by placement of a wound vacuum device has been used with success.

Results

Although ultrasound scan–guided compression is relatively safe and effective, it has several limitations. From a practical standpoint, this method imposes considerable constraint on the resources and availability of the vascular laboratory. It can be particularly uncomfortable for the patient as well. Furthermore, the results in patients who are undergoing concurrent anticoagulation therapy have considerably lower success rates (<40%). Consequently, direct thrombin injection with ultrasound scan guidance is frequently more favorable. Several studies have reported success rates of 92% to 100% with a periprocedural complication of distal arterial thromboembolism in less than 2% of cases. The recurrence rate after injection is approximately 5% after an initial injection, but repeat attempts of thrombin injection may be attempted safely. The major morbidity of open surgical repair of iatrogenic femoral pseudoaneurysms is related to wound healing issues, particularly in patients who are obese.

POPLITEAL ANEURYSMS

Introduction

Popliteal aneurysms account for nearly 70% of all lower extremity arterial aneurysms and are most commonly true degenerative aneurysms. Similar to degenerative aneurysms of the femoral artery, other coexistent aneurysms are frequently discovered. Popliteal aneurysms are bilateral in up to 50% of patients, and 30% to 60% harbor aneurysms in the aortoiliac location as well. As such, a thorough physical examination is indeed important to ensure all potential aneurysm sites are investigated.

Clinical Presentation and Diagnosis

Popliteal aneurysms are frequently asymptomatic at presentation. However, when they are symptomatic, they can present with a constellation of symptoms that range from compressive phenomena, thromboembolism and acute limb threat, intermittent claudication, ischemic rest pain, and rarely, rupture. When aneurysm size approaches or eclipses 3 cm, compressive symptoms may occur. Symptoms include posterior knee fullness or decreased range of motion, painless pulsatile mass, nerve related pain (paresthesias, foot drop), and congestive venous symptoms of distal swelling and deep vein thrombosis. The absence of foot pulses can be a harbinger of poor outcome because this finding is seen in patients with the highest rate of progression to ischemic complications.

Depending on the manner of presentation (incidental examination finding, acute or chronic ischemic symptoms), a number of modalities can be helpful with an accurate diagnosis that supports physical examination findings and assists operative reconstruction planning. Given that outcomes are best if popliteal aneurysms are

treated in the elective setting with reconstruction before acute limb ischemia, imaging the lesions becomes a critical step. The vascular laboratory can be helpful in diagnosis of popliteal aneurysms with duplex ultrasound scan; in evaluation of size, presence of mural thrombus, and velocity through the vessel; and in objective documentation of overall leg perfusion with ankle-brachial indices. CT angiogram can be particularly useful in the elective setting not only for identification of the lesion of interest but also for evaluation of the entire aortic tree to ensure all potentially occult aneurysms are identified. MRA yields information similar to CT angiogram, and both offer three-dimensional reconstructions that greatly aid operative planning. Contrast angiography alone generally is limited by showing only luminal flow through the aneurysm, but it is useful in assessing distal outflow, particularly in cases in which distal thromboembolism is suspected or in which endovascular intervention is being considered.

Treatment

Patients who present with symptomatic popliteal aneurysms should undergo prompt operative repair. Those that present with acute thrombosis or distal embolization have a significantly lower rate of limb salvage. Hence, identification of patients at risk of such complications before occurrence is important. Elective repair is often recommended in asymptomatic patients once an aneurysm diameter greater than 2 cm is discovered. Patient-specific variables, such as medical comorbidities, ambulation and functional status, and life expectancy, should be taken into account in consideration of elective repair.

After delineation of lower extremity arterial anatomy and anastomotic targets with contrast angiography or MRA, elective repair can be accomplished with two open reconstruction options via two different exposures. The medial approach affords the vascular surgeon with two arterial exposures that are very familiar: the above-knee and below-knee popliteal artery segments. Nontunneled reversed or nonreversed saphenous vein grafts with ligation of the artery between the anastomoses bypass the aneurysmal segment and interrupt flow via ligation. Surgeons who champion this approach note the familiarity with the exposures and the ease of harvesting the greater saphenous vein. However, genicular branches may still feed the aneurysm sac between ligation points, and endotension similar to endovascular aneurysm repair has been reported during follow-up, prompting secondary procedures. The posterior approach with the patient in a prone position via a lazy S-curve incision in the popliteal fossa allows the surgeon to perform aneurysmorrhaphy and also allows ligation of geniculate vessels and other tributaries in a manner similar to treatment of lumbar vessels in abdominal aortic aneurysm repair. Proponents of this approach report complete aneurysm excision, ligation of all branches, and relief of any compression symptoms by larger aneurysms. This approach, however, places the tibial nerve at risk, and the surgeon must be sure the aneurysm can be safely controlled proximally and distally from within this space. In addition, vein harvest, if necessary, is more challenging in the prone patient position.

Endovascular repair has become an attractive option for patients with suitable anatomy and outflow vessels (Figure 6). It may have an important role in the treatment of patients with extensive major medical comorbidity as well. The standard considerations for any endograft apply, requiring healthy proximal and distal landing zones and freedom from excessive calcification, thrombus, or tortuosity. CT angiogram is pivotal before any endovascular procedure to appropriately measure for the diameter, length, and number of stent grafts needed to exclude the aneurysm. Percutaneous access is an option for patients with normal-sized proximal and distal superficial femoral or popliteal artery landing zones and can usually be accommodated with a 6F or 7F sheath. For patients with arteriomegaly and larger landing zones that necessitate larger diameter devices, a larger introducer sheath may be necessary and an open femoral cut down may be preferred.

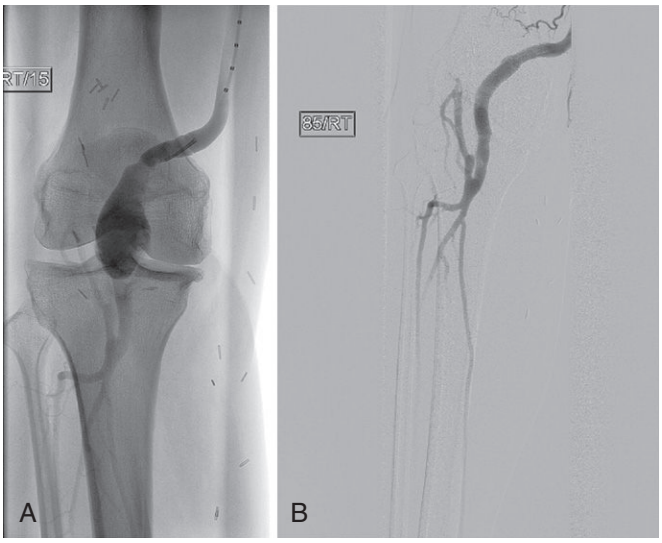

FIGURE 6 **A,** Arteriogram shows popliteal artery aneurysm with three vessel run-off. **B,** Arteriogram shows endovascular exclusion of popliteal artery aneurysm with two covered stent grafts, with preservation of three vessel runoff.

With regards to deployment of the stent graft, remember that although traversing the knee joint with any endovascular device may not seem appealing, studies have suggested that graft slippage and kinking can be minimized if areas of flexion are appropriately overlapped. In particular, the most proximal position of the stent-graft deployment should be generous and allowed to span widely. This is because the distal superficial femoral artery/proximal popliteal artery is most flexible and where graft migration is most likely to occur if insufficient stent graft is deployed proximally. After endovascular repair, patients should be continued on dual antiplatelet therapy (aspirin and clopidogrel) lifelong. Close follow-up with ultrasound scan or CT angiogram is recommended.

In patients who present with acute ischemia from popliteal aneurysm thrombosis or distal embolism, catheter-directed thrombolysis or mechanical thrombectomy is recommended to restore distal runoff and resolve emboli. Catheter-directed therapy is more likely to be successful if the thrombotic event is recent. If severe limb ischemia is present at the time of diagnosis, then endovascular therapy should not be considered given the longer duration of time necessary to establish reperfusion. Surgical mechanical thrombectomy should be recommended instead in such instances.

If catheter-directed thrombolytic therapy is indicated and initiated, repeat angiogram should be performed at 12 to 24 hours to assess progress and potentially identify a suitable distal reconstruction target. In addition, thrombolysis can treat the microvascular circulation and reperfuse the infragenicular vessels in a less traumatic manner compared with open mechanical thrombectomy. When targets are identified after lysis, arterial reconstruction should be planned expeditiously as described previously. This paradigm has seen improvement in limb salvage rates. However, if no suitable outflow vessel target appears, thrombolysis beyond 24 hours is unhelpful, bypass is not indicated, and full anticoagulation therapy should be continued. Unfortunately, these patients ultimately need amputation.

Results

At the present time, open operative therapy remains the gold standard for elective repair of popliteal artery aneurysms. Several

long-term case series have reported limb salvage rates of up to 90% at 10 years for repair of asymptomatic popliteal aneurysms. The success rates are significantly less when surgery is performed for symptomatic aneurysms, particularly acute limb ischemia. There is a trend to suggest that long-term patency is affected by the choice of conduit, with autogenous saphenous vein conduit associated with the best results.

Endovascular repair with covered stent grafts has become an attractive option for repair in select patient populations. The main determinate of successful surgical outcome remains the number of patent outflow vessels. Current data have shown favorable short-term results in patients with at least two vessel outflow who are able to tolerate dual antiplatelet therapy. Most studies that compare open with endovascular approaches reveal that endovascular therapy yields similar early and midterm patency as open repair but frequently requires secondary interventions to maintain patency. Nevertheless, several studies have suggested that endovascular repairs perform at least as well as prosthetic graft reconstructions for popliteal aneurysms. As always, surgeon familiarity with the chosen procedure and patient selection remain critical for successful and durable outcomes.

The Treatment of Claudication

Neal R. Barshes, MD, MPH, and C. Keith Ozaki, MD, FACS

With the aging population and the rising prevalence of diabetes and the metabolic syndrome, peripheral arterial disease is increasingly common. Among patients with peripheral arterial disease, up to half, including 6% to 8% of the general U.S. population over the age of 65 years, may have exertional leg pains consistent with vasculogenic claudication. Although claudication is not a limb-threatening problem, the symptoms associated with it can be disabling. Furthermore, atherosclerotic disease in the lower extremities stands as a marker for generalized atherosclerosis and an increased risk of cerebrovascular and coronary events.

This chapter focuses on the standard management of lower extremity arterial claudication from atherosclerosis. Recommendations for management are based on consensus guidelines and high-quality clinical data where available. The lifestyle, symptoms, medical comorbidities, and anatomic heterogeneity present with claudication necessitate that decision making be tailored to each patient, but fundamental principles do exist. Attentive management of patients with claudication not only diminishes or relieves the discomfort associated with walking but also lessens the chance of stroke, myocardial infarct, progression to critical limb ischemia, and premature death.

THE INITIAL EVALUATION OF THE PATIENT WITH SUSPECTED CLAUDICATION

The initial evaluation of a patient with exertional lower extremity pain must be thorough. The first objective is to elicit the quality of the pain, location, inciting and relieving factors, consistency and progression of symptoms, and other related characteristics. Typical claudication symptoms occur in a muscular area of the limb (calf, thigh, or buttock) with onset at a relatively fixed distance, are relieved with rest, and have developed gradually over the course of several years. Electric-like "shooting" pains, especially those that began suddenly or after exertion, should raise suspicion for radiculopathy, and pain that is relieved only with sitting or leaning over may be the result of spinal stenosis (neurogenic claudication). Pains that are located at a joint, are worse in the mornings or after inactivity, and are variable in intensity ("good days" and "bad days," especially when dependent on the weather) may be more suspicious for osteoarthritis or rheumatoid arthritis.

In addition to the quality of the symptoms, the impact of these symptoms on a patient's daily life should be assessed. Impact ranges from the mere presence of symptoms with no functional impairment to symptoms that limit some vigorous activities (e.g., unloading a truck at work) to symptoms that are truly disabling and impair even activities of daily living (e.g., walking from the bedroom to the kitchen or from the front door to the mailbox). The severity of typical claudication symptoms is often quantified by pain-free walking distance, but the correlation between this and impact on daily function is imperfect. Claudication at 300 ft may have no impact on an 80-year-old man who lives with his son but may prevent a 55-year-old man from fulfilling his responsibilities on the job.

Evaluation is important for rest pain or nonhealing wounds of the foot, both of which represent limb-threatening problems that may be present in patients with claudication. Rest pain of a vascular etiology may range from cramping pains that awaken the patient at night and are relieved with standing or putting the leg in a dependent position to severe pains present throughout the day and night. Any history of foot ulceration, digital gangrene, toe amputation, or other nonhealing wounds should also be elicited.

Other history of relevance includes risk factors for atherosclerotic disease (e.g., diabetes, hypertension, chronic kidney disease, dyslipidemia, and hyperhomocystinemia) and other comorbidities that may influence functional status, procedural risk, or long-term mortality (e.g., chronic obstructive pulmonary disease, congestive heart failure, cerebrovascular disease, and significant coronary artery disease). Finally, a thorough history related to tobacco use is important. This should include current smoking status, smoking history (measured in pack-years), previous attempts at smoking cessation, and current interest in smoking cessation.

The focused physical examination of the patient with claudication consists of palpation for pulses (specifically femoral, popliteal, and pedal). Pulses should be quantified as normal (2+), weak (1+), or absent (0). Conversely, the presence of a large-amplitude, wide popliteal pulse is suspicious for the presence of a popliteal aneurysm. The feet should be inspected for ulcers or evidence of thromboembolism.

The systemic blood pressure, as measured with an arm cuff, is relevant as well.

Ankle-brachial indices (ABIs), either done informally in the clinic or formally in the noninvasive vascular laboratory, are of utility for objective documentation of resting arterial hemodynamics. Patients with claudication typically have an ABI of less than 0.9 at rest, and most with moderate to severe symptoms have ABIs in the range of 0.6 to 0.8. Some active patients, however, may have normal ABIs at rest (i.e., >0.9). In such patients, ABIs done after treadmill testing can unmask subcritical stenosis, show an abnormal ABI with activity, and better quantify walking distance. Anatomic imaging is generally *not* needed for the diagnosis of claudication and should be reserved until the decision to treat invasively has been made (see subsequent discussion).

Laboratory testing is not necessary for the diagnosis of claudication but may help manage associated risk factors. Specifically, a complete blood count, serum creatinine, fasting blood glucose or hemoglobin A1C, fasting lipid profile, serum homocystine level, and urinalysis (for microalbuminuria) may help identify or manage diabetes, hyperlipidemia, hyperhomocysteinemia, and chronic kidney disease.

Finally, some consideration may be given to other testing to further rule out or rule in nonvascular etiologies that may be causing or contributing to exertional leg symptoms. Although rare, some consideration should be given to other nonatherosclerotic vascular causes of exertional leg pain, including popliteal artery entrapment, chronic compartment syndrome, thromboembolic complications from arterial aneurysmal disease, arterial dissections, arteritis, adventitial cysts, radiation, iliac artery compression syndrome (endofibrosis; e.g., in avid cyclists), or vascular injury from previous trauma.

INITIAL MANAGEMENT OF THE PATIENT WITH CLAUDICATION: MANAGEMENT OF LIMB SYMPTOMS

After the diagnosis of claudication is made, two important objectives exist for the initial management of all patients: (1) amelioration of the exertional limb symptoms and (2) modification of risk factors to minimize the mortality from coronary and cerebrovascular events and to reduce the risk of progression to critical (limb-threatening) ischemia. These objectives refer to the management of patients with claudication alone and do not apply to patients with rest pain or nonhealing foot wounds.

Exercise therapy has been the first-line treatment for patients with claudication for decades. It is a level 1, grade B recommendation in multiple multispecialty consensus guidelines for the management of claudication. Specifically, multiple randomized trials have shown that consistent participation in an exercise regimen doubles the pain-free walking distance of patients with claudication. This improvement is likely the result of biologic changes in the affected muscle groups. Exercise does not improve macrovascular arterial circulation and thus should not be expected to improve ABIs. The vast majority of patients with claudication can safely participate in exercise therapy. Patients with mild to moderate chronic obstructive pulmonary disease, congestive heart failure, and coronary artery disease (without angina) can participate, and data suggest that this may also help lung and cardiac symptoms.

Exercise therapy has most thoroughly been studied in the context of supervised regimens and should be used in practice environments in which a formal (i.e., supervised) exercise program or cardiac rehabilitation is available. In practice environments without access to supervised exercise programs, a home-based exercise regimen can serve as an alternative. Although the adherence to home-based regimens is lower than adherence to supervised programs, home-based programs can have comparable effectiveness and, because of the negligible costs, may represent a cost-effective alternative.

Asking a patient to initiate a home-based regimen is more than simple advice to "go out and walk," however. Specifically, the authors recommend that patients with claudication start by walking at least 3 times per week for 30 minutes initially, working up to 60 minutes per walking session and as many days per week the patient is willing to do. Patients are instructed to walk until symptoms appear, to stop walking and remain standing until symptoms resolve, and then to start walking again to repeat this cycle. A route near the patient's home is recommended because it is more accessible and because a consistent route can be used to track progress. In warm climates, indoor shopping malls serve as a comfortable venue. Several investigators have shown that pedometers improve patient adherence to walking regimens, and patients should be asked to log their efforts in a journal to document compliance and further track progress. Finally, walking is generally the best form of exercise because of the ease and accessibility to this modality, but other forms of cardiovascular activity such as bicycling, stationary bicycle riding, or swimming may suffice. Regardless of the exercise modality chosen, adherence to and improvement with the exercise program should be assessed with frequent follow-up, either through return clinic visits or telephone calls.

In addition, reducing obesity can help reduce claudication symptoms, as the increased metabolic demand of walking with an obese body habitus can be lessened by simple weight loss. Obviously, an exercise regimen may help in this regard, but obese patients with claudication should specifically be counseled on the benefits of weight loss for both amelioration of limb symptoms and risk factor modification (see subsequent discussion).

Two medications are approved by the U.S. Food and Drug Administration (FDA) for intermittent claudication treatment. Consensus guidelines recommend a trial of cilostazol for *all* patients with lifestyle-limiting claudication without congestive heart failure (level A evidence). Cilostazol is a reversible phosphodiesterase inhibitor and is thought to improve symptoms by acting as a vasodilator. In eight randomized clinical trials, patients with claudication given cilostazol had a 67% improvement in pain-free walking distance. Pentoxifylline, a xanthine derivative that enhances red blood cell deformability, has also been extensively studied in the context of claudication. Multiple randomized clinical trials suggest a statistically significant benefit, but the clinical improvement in absolute walking distance with pentoxifylline appears to be small if any.

Data from several small randomized clinical trials suggest that the over-the-counter supplements ginkgo biloba, propionyl-L-carnitine, and L-arginine may all improve walking distance among patients with claudication who participate in an exercise regimen. Although the results from many of these studies reached statistical significance, whether the benefits from these supplements translate to meaningful clinical benefits is not clear. Likewise, some small randomized clinical trials have suggested that simvastatin may improve pain-free walking distance among patients with claudication, but its role has yet to be defined.

INITIAL MANAGEMENT OF THE PATIENT WITH CLAUDICATION: MANAGEMENT OF GENERALIZED ATHEROSCLEROSIS

In addition to addressing the limb symptoms, the clinician must educate the patient on the generalized nature of atherosclerosis and address modifiable risk factors (this should also be done for patients without claudication symptoms who are found through ABIs or other testing to have asymptomatic peripheral arterial disease). The simplest way for surgeons to remember the critical elements of risk-factor modification is by recalling the ABC(D)s: *A*spirin, *B*eta-blockers/management of hypertension, *C*holesterol management, and *D*iabetes management. Antiplatelet therapy reduces overall cerebrovascular and coronary event rates by 25% and is recommended

in all patients with peripheral arterial disease. Beta-blockers or other antihypertensives (including angiotensin-converting enzyme [ACE] inhibitors or thiazide diuretics) should be considered for all patients with peripheral arterial disease and for systolic blood pressure above the goal of 130 mm Hg for patients with diabetes or 140 mm Hg for patients without diabetes. The identification and management of dyslipidemia is also important in reducing the risk of cerebrovascular and coronary events. Among patients with peripheral arterial disease, the goal low-density lipoprotein (LDL) is less than 100 mg/dL. This goal can be achieved through statin therapy if diet modification alone does not suffice. Patients with diabetes with peripheral arterial disease should be urged to work with their primary care providers to achieve tight control of glucose because this too has been shown to reduce the risk of cardiovascular mortality.

Smoking cessation is critical and should be urged to all patients with peripheral arterial disease who remain active smokers. Smoking cessation has clear benefit in reducing cerebrovascular and coronary events, and patients with claudication who smoke should be reminded that it is never too late in life to derive health benefits from smoking cessation. Interest in smoking cessation should be assessed, and smokers should be counseled in strategies to succeed at smoking cessation efforts and be offered pharmacologic adjuncts (including nicotine replacement therapies, bupropion, or varenicline). In addition to the clear decrease in risk of cerebrovascular and coronary events and the decreased risk of cancer, data suggest that smoking cessation among patients with claudication can decrease the likelihood of progression to rest pain.

Patients with peripheral arterial disease, especially those with diabetic sensory neuropathy, should be taught the importance of daily inspection of their feet and shoes. Patients and their families should also be educated on the signs and symptoms of critical limb ischemia (rest pain and nonhealing ulcers) and be instructed to return for reevaluation should these develop.

FOLLOW-UP AFTER INITIATION OF MEDICAL MANAGEMENT AND SELECTION OF PATIENTS FOR INTERVENTION

An exercise regimen has remained the first-line therapy for the exertional limb symptoms of claudication because it is safe, effective, durable, and low cost. Patients should not be expected to successfully implement an exercise regimen, however, after a single clinic visit. Multiple follow-up appointments should be planned to verify interest and readiness, identify obstacles, and assess adherence to exercise regimens. Once patients are compliant with risk-factor modification and exercise therapy and have had a good response, follow-up appointments can be decreased in frequency. Some form of follow-up, either with the physician, with associated providers, or with the patient's primary care provider, should continue to ensure long-term compliance.

Invasive intervention, in the form of surgical or endovascular procedures, is not warranted for most patients with claudication. Multiple randomized clinical trials that have compared percutaneous endovascular interventions (angioplasty and stenting) with exercise therapy have failed to show a consistent benefit to endovascular intervention. In addition, claudication is *not* a limb-threatening problem (associated with a 1% to 2% risk of limb loss per year). Intervention, when performed, is done purely to ameliorate limb symptoms and is therefore purely discretionary.

In spite of a lack of an evidence-based benefit, however, the utilization of percutaneous endovascular interventions has doubled over the past decade in the United States. In addition to an increase in the frequency of interventions, there has been a growth in the number of specialties involved in the management of claudication, both invasive and noninvasive, and this has likely added to the heterogeneity in management strategies.

This being said, there continues to be some role for invasive treatment in the care of the patient with claudication. Traditionally, these interventions have been reserved for patients with "disabling" claudication with failed medical management. To date, no unified attempts to clarify what constitutes "disabling" or "failure" of medical management have been seen. Regardless, the following characteristics are often considered reasons to consider invasive intervention:

- Short-distance (<300 ft) claudication
- Claudication that impairs or prevents employment or prevents performance of all necessary job duties
- Claudication that impairs the patient's ability to perform important activities of daily living.

Additional consideration can also be given to patients with severe claudication and unilateral disease because intervention may be more straightforward and improve the patient's condition to a highly functional baseline. Also, patients with claudication with an ABI of less than 0.4, toe pressures of less than 40 mm Hg, or dependent rubor do merit more frequent clinic visits and a lower threshold for triage to procedural revascularization because they have a higher incidence of limb-threatening problems.

When a patient does meet criteria for invasive intervention and the decision has been made to pursue this, the physician has two preparatory tasks: (1) evaluation and optimization of the patient's cardiopulmonary status and (2) completion of imaging to delineate vascular anatomy and make a detailed plan for revascularization options. First, patients should be evaluated with the American Heart Association/American College of Cardiology guidelines for preprocedural cardiac optimization. History of unstable angina, severe or decompensated heart failure, recent myocardial infarction, severe valvular disease, or ventricular dysrhythmias merits further evaluation. Evidence from several good-quality observational studies suggests that perioperative use of beta-blockers can lower the incidence of cardiac complications, but at least one randomized trial has shown that preemptive coronary revascularization for all but the patients at highest risk may not significantly lower the rate of cardiac events.

Multiple imaging approaches have been used in patients with claudication to define anatomy before interventions, and the combination of physical examination with multilevel segmental blood pressures and renal function assessment is best to identify the most proximal level of disease and select the proper imaging modality. In general, patients with claudication with weak or nonpalpable femoral pulses and patients with high thigh pressures that are equal to or lower than brachial pressures should be suspected of having aortoiliac or common femoral artery disease. In these patients, computed tomographic angiography (CTA) or magnetic resonance angiography (MRA) can serve as the initial imaging modality to delineate anatomy when baseline renal function is not impaired (i.e., estimated glomerular function [eGFR] >60 mL/min) (Figure 1). In patients with suspected aortoiliac or common femoral artery disease and impaired renal function (eGFR <60 mL/min), an aortogram with pelvic runoff from contralateral femoral access or brachial access is probably the best initial imaging modality to limit contrast exposure.

Patients with claudication with palpable femoral pulses but impaired ABIs and suspected infrainguinal (femoropopliteal or tibial level) disease should probably undergo digital subtraction angiography (DSA) to further delineate anatomy (see Figure 1) because this provides the opportunity to treat patients with claudication with good baseline renal function and lesions that are amenable to percutaneous endovascular intervention in a single setting (see subsequent discussion).

Duplex ultrasound scan can identify the location of arterial lesions, but the examination is often time consuming and technician dependent. This modality holds the most utility for determination of the anatomy of vein conduit available for surgical reconstructions. Like duplex ultrasound scan, MRA with gadolinium avoids ionizing radiation, but it requires post image acquisition processing for useful

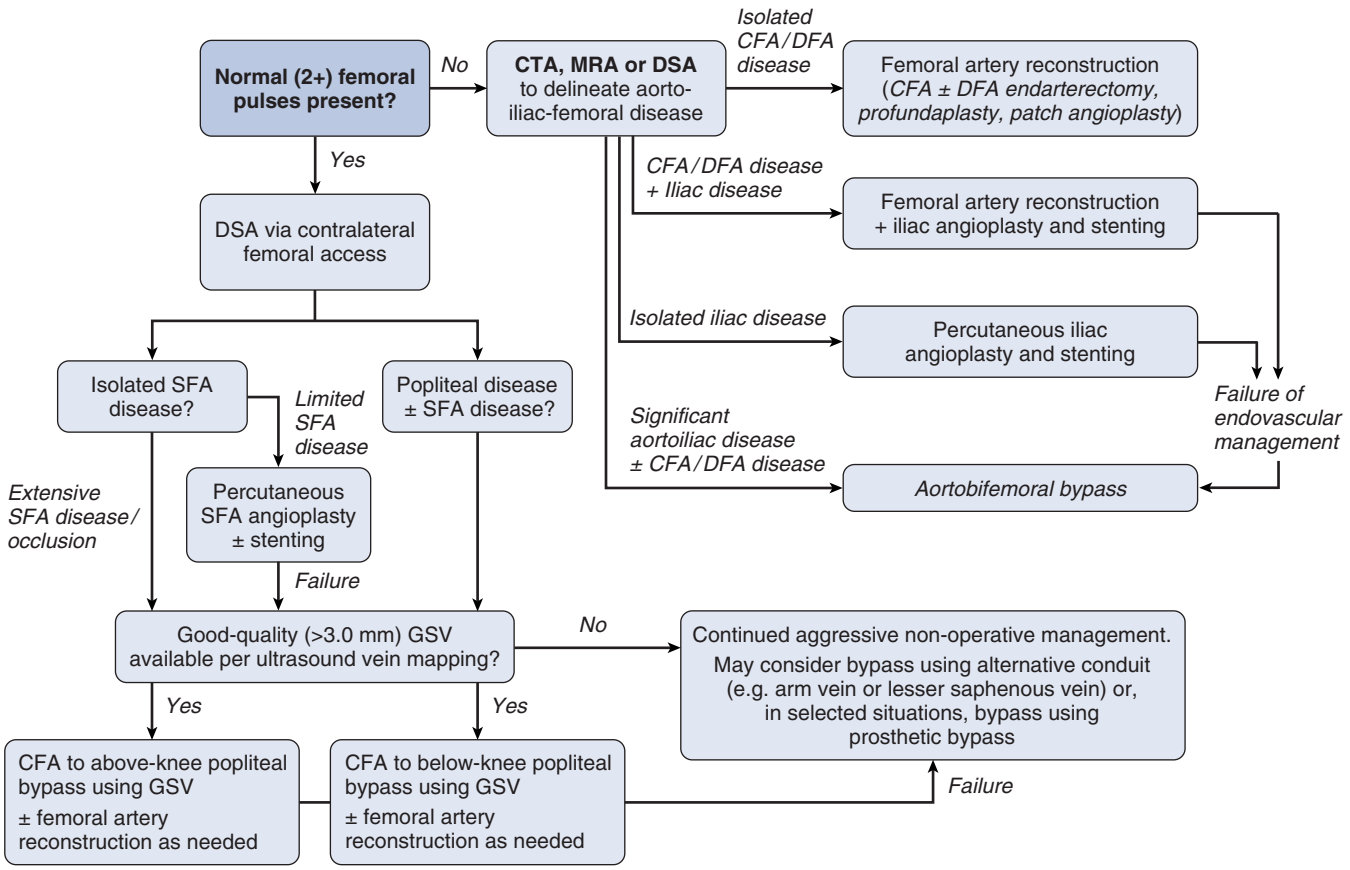

FIGURE 1 General decision-making algorithm for patients with lifestyle-limiting claudication and failed nonoperative therapy, assuming medical fitness for intervention. *CFA,* Common femoral artery; *CTA,* computed tomographic angiography; *DFA,* deep femoral artery; *DSA,* digital subtraction angiography; *GSV,* greater saphenous vein; *MRA,* magnetic resonance angiography; *SFA,* superficial femoral artery.

evaluation. Furthermore, the use of gadolinium in patients with severe renal insufficiency can cause the debilitating side effect of nephrogenic systemic fibrosis.

Regardless of the imaging modality that is selected, profunda femoris (deep femoral) artery disease should also aggressively be sought and treated. It usually occurs at the origin with at least some degree of common femoral disease or iliac disease, so it is uncommon that patients with significant profunda disease have normal high-thigh ABIs. However, CTA or DSA might be worth considering to evaluate for common femoral/profunda femoris disease in thigh claudication and normal high-thigh ABIs.

TREATMENT OF THE ARTERIAL OCCLUSIVE LESIONS THAT CAUSE CLAUDICATION

When formulating interventional strategies for patients with claudication, the objectives should be either optimizing inflow to the deep femoral (profunda femoris) artery in patients with aortoiliac disease or establishing durable perfusion to the popliteal artery in patients with isolated femoropopliteal artery disease. Vascular imaging may show multilevel atherosclerotic disease (i.e., aortoiliac and femoropopliteal disease) in many patients with claudication. However, in contrast to the management of multilevel disease in the context of nonhealing wounds or rest pain, *the symptoms of claudication generally resolve or are greatly improved with treatment of aortoiliac disease alone* if the profunda is of good quality or reconstructed.

Aortobifemoral bypass has been the mainstay of treatment for patients with aortoiliac occlusive disease. Although this operation does offer excellent long-term patency rates, it also has a nonnegligible rate of morbidity, including groin lymphocele formation (9%), surgical site or other infection (23%), and need for emergent reoperations (6%). As an alternative, the first-line therapy for most patients with aortoiliac occlusive disease is now angioplasty and stenting. The patency rates for iliac artery angioplasty and stenting approach those of aortobifemoral bypass and with lower morbidity rates. Once reserved for patients with stenotic but nonoccluded iliac vessels, clinicians with endovascular skills can now often recanalize completely occluded iliac arteries with long-term patency rates that are comparable with those of stenotic nonoccluded arteries (see Figure 1).

Disease isolated to the common and proximal deep femoral arteries can be effectively treated with common femoral endarterectomy, profundaplasty, and patch angioplasty (typically done with either autogenous or prosthetic patch material) or iliofemoral bypass (usually prosthetic conduit). When aortoiliac disease occurs in conjunction with common femoral disease, the combination of common femoral endarterectomy, profundaplasty, and patch angioplasty plus iliac stenting is a good treatment option (see Figure 1). Again, patients with multilevel disease should undergo treatment of aortoiliac disease first because this alone (i.e., without anything to address femoropopliteal disease) suffices to resolve or greatly diminish claudication symptoms in most patients with claudication.

Femoral-femoral bypass and axillofemoral bypass are alternative options to establish inflow in the context of aortoiliac occlusive disease, but because of the relatively low patency of these options in the context of occlusive disease, they should not be routinely considered for patients with claudication. Patients who are deemed too ill for either aortobifemoral or ileofemoral bypass or iliac artery angioplasty and stenting and have claudication only are generally best managed with medical management alone.

Patients with either isolated superficial femoral artery disease or those who have severe symptoms in spite of having had inflow addressed may merit treatment of this segment. As with iliac lesions, endovascular intervention is becoming first-line therapy for selected superficial femoral artery lesions, albeit with less good-quality data to support this practice. Furthermore, endovascular intervention of femoropopliteal disease should be limited to the treatment of disease in the superficial femoral artery only; popliteal angioplasty and especially popliteal stenting is generally not recommended, especially for claudication, because the durability is poor and it constrains further treatment options.

In patients whose anatomy is not amenable to angioplasty with or without stenting or in patients in whom this treatment fails, bypass may be considered. Perhaps the most important determination of whether this is a good option is the availability of good-caliber, single-segment saphenous vein because this leads to the best long-term outcome, regardless of level. Patients who do not have good-caliber, single-segment saphenous vein should probably be largely managed with medical therapy. Whereas occluded vein graft bypasses only infrequently cause limb-threatening ischemia, occluded prosthetic grafts frequently do. When this does occur, a patient with claudication, a disease whose natural history is benign and *not* limb-threatening, may find the viability of the limb in jeopardy. So although some patients may explicitly ask for an intervention for symptoms that they see as very bothersome, infrainguinal bypass for claudication with prosthetic grafts should only be done with a detailed, informed discussion between the physician and the patient about the long-term potential risks. In addition, patients who continue to smoke have a threefold to sixfold higher risk of graft occlusion, so putting prosthetic infrainguinal bypasses in a patient with claudication who continues to smoke should be especially discouraged. Finally, biologic conduits such as cryopreserved cadaveric vein and artery are expensive and have dismal long-term patency and therefore are not generally helpful in the setting of claudication.

Other treatment strategies are being investigated. Intermittent pneumatic compression, angiogenesis (TRAFFIC [The Rapeutic Angiogenesis with recombinant Fibroblast growth Factor-2 for Intermittent Claudication]), and cell-based therapies are emerging techniques to enhance lower limb perfusion, but none of these approaches currently have sufficient supporting evidence for recommendation as a first-line therapy.

SUMMARY

Claudication is an increasingly common problem that is not limb threatening but may impair quality-of-life or daily functioning. The systemic nature of atherosclerotic disease does put patients with claudication at high risk for mortality from coronary and cerebrovascular events.

Initial management for all patients with claudication includes efforts to ameliorate limb symptoms and modification of atherosclerotic risk factors. Exercise therapy is the mainstay of medical management for claudication; cilostazol and loss of excess body weight may also help ameliorate exertional limb pains. Risk factor modification with antiplatelet agents; control of obesity, hypertension, and hyperlipidemia; and diabetes management are important to decrease the risk of death from cerebrovascular and coronary events.

Interventions (percutaneous endovascular procedures, open surgical reconstructions, or combination "hybrid" procedures) are considered for severe, lifestyle-limiting symptoms that have not improved with the patient compliant to medical therapy. Interventions done for patients with claudication should focus on establishing inflow to the deep femoral artery. Highly selected patients with isolated femoropopliteal artery disease may benefit from intervention for this segment.

Finally, although general algorithms for patient care are offered, the field of lower extremity arterial peripheral vascular disease is ripe for further investigation to better define best practice approaches for individual patients.

Pseudoaneurysms and Arteriovenous Fistulas

Phong T. Dargon, MD, and Erica L. Mitchell, MD

PSEUDOANEURYSMS

Definitions

Pseudoaneurysms (PSAs), or false aneurysms, are the result of a contained arterial wall rupture. PSAs usually result from injury to the arterial wall but can result from other etiologies (Table 1). Injury to the arterial wall results in pulsatile flow into the perivascular space, dissection into surrounding tissues, and hematoma formation. Luminal recanalization of the injury site results in a flow channel, or neck, that leads into a false lumen, or sac. PSAs, unlike true aneurysms, lack all three normal elements of the arterial wall and are therefore at risk of rupture. Rupture of the PSA can lead to catastrophic bleeding. Postcatheterization femoral artery PSAs are the focus of this section.

Risk Factors

PSAs most commonly result from complications related to arterial access. The common femoral artery (CFA) is the most common access site for catheter-based interventions. The incidence of femoral artery PSA is increased when the puncture site is not in the CFA but rather in the external iliac artery (EIA) or superficial femoral artery (SFA) or profunda femoral artery (PFA). Risk factors for the development of iatrogenic PSA associated with arterial access procedures are listed in Table 2 and can be divided into procedural contributing factors and patient contributing factors. Complexity of intraarterial interventions has been shown to increase the risk of vascular complications, and therapeutic interventions, such as arterial angioplasty and stenting, atherectomy, and intraprocedural thrombolytic therapy, have a higher rate of PSA formation (2% to 8%) than diagnostic procedures (0.05% to 2%). The diameter of the catheter used to access the artery also correlates with PSA development, and larger catheters and sheaths result in higher rates of PSA formation. Other procedure-related factors include simultaneous arterial and venous puncture, the use of arterial puncture closure devices, and insufficient duration of compression of the puncture site after the sheath is removed. PSA formation is less common when ultrasound scan guidance or fluoroscopic localization of the femoral head is used for femoral artery (FA) puncture. Patient-related risk factors that contribute to PSA formation include those listed in Table 2.

Diagnosis

The presence of pain or swelling in the groin after catheterization is the most common presentation of a PSA. Mass effect of a hematoma or large PSA may result in skin necrosis (Figure 1) or compression of nerves and vessels in the groin. Any patient who experiences pain disproportionate to that expected after a percutaneous procedure should undergo evaluation to exclude PSA. Examination should include a thorough peripheral pulse examination, documentation of ankle-brachial index (ABI) and limited ultrasound scan of the vasculature in the affected groin.

The diagnostic examination of choice is duplex ultrasound scan (DUS; 5-MHz to 7-MHz linear transducer). Because B-mode imaging alone is unable to differentiate PSA from hematoma, color Doppler scan should be used to enhance the diagnostic accuracy of ultrasound scan (sensitivity, 94%; specificity, 97%) as it allows for identification of pulsatile flow within the sac. The typical appearance of a PSA on DUS is shown in Figures 2 and 3. The PSA size and the length and width of the PSA neck should be measured with DUS because they are important for determination of treatment options. If an arterial duplex examination cannot be performed or the results are equivocal, computed tomographic (CT) imaging (with intravenous contrast) can be used to make the diagnosis of PSA (Figure 4).

Treatment

A number of treatment options for iatrogenic femoral PSA exist, depending on the PSA size, neck characteristics, and patient symptoms. Treatment options include observation, ultrasound scan (US)–guided compression, percutaneous US-guided thrombin injection, and open surgical repair.

Observation

Studies have shown that most small PSAs (<2 cm) thrombose spontaneously within 4 weeks. Conservative management, or a watch-and-wait policy, has been advocated for small asymptomatic PSAs. Spontaneous resolution, however, can be unpredictable; therefore, patients with small PSAs need surveillance with DUS. The disadvantage of this watch-and-wait policy is that patients undergoing surveillance may have activity restrictions, discomfort with serial DUS, and prolonged hospital stays.

Ultrasound Scan–Guided Compression

Ultrasound scan–guided compression (USGC) therapy has been shown to be a safe and noninvasive method for treatment of PSA, with success rates ranging between 73% and 93%. US is used to identify the PSA sac and neck of the PSA. The ultrasound transducer is positioned over the PSA neck, and pressure is applied. Compression of the PSA neck and obstruction of flow into the sac is maintained while flow in the native artery is preserved. Direct US visualization confirms cessation of flow into the PSA sac. Compression is usually held for increments of 10 to 15 minutes. This process is repeated until successful PSA sac thrombosis or until a discretionary failure time is met. Compression times average 33 minutes for acute PSAs and 51 minutes for more chronic PSAs (>14 days).

Successful USGC can be limited by patient and operator factors. The procedure is generally restricted to lower extremity peripheral arterial PSAs. Suprainguinal PSA compression is generally not recommended because it may result in PSA rupture and inability to quickly control bleeding. Brachial artery PSAs usually require operative decompression because of concomitant nerve compression symptoms. Unfortunately, PSA neck compression can be time consuming and is often not tolerated by patients, despite conscious sedation. Compression can also be technically challenging and tiring in the morbidly obese patient. Predictors of poor outcome include concomitant anticoagulation therapy, large PSA size (>4 cm), and patient obesity. Patients with these negative predictors generally have lower technical success rates (25% to 35%), higher recurrence rates (20%), and greater complication rates (3.6%) than patients without these

factors. Complications and contraindications to USGC are listed in Table 3.

Ultrasound Scan–Guided Thrombin Injection

Ultrasound scan–guided thrombin injection (UGTI) has become the treatment of choice for postcatheterization PSA. Thrombin is injected into the PSA sac for immediate thrombosis of the PSA (Figure 5 and Box 1). This is off-label use of thrombin; thrombin is approved by the U.S. Food and Drug Administration (FDA) "for topical use only." UGTI is contraindicated in the setting of lower extremity ischemia, infection, arteriovenous fistula, and pregnancy.

UGTI has many advantages over USGC therapy for the treatment of PSA. Procedural times are shorter, and the procedure is better tolerated by patients. It achieves greater technical success (>96%) and can be used effectively in the setting of concomitant anticoagulation

FIGURE 1 Pseudoaneurysms can cause mass effect with resultant tissue and skin necrosis as depicted in this photograph. Patients with tissue and skin necrosis need operative débridement and surgical pseudoaneurysm repair with or without hematoma evacuation.

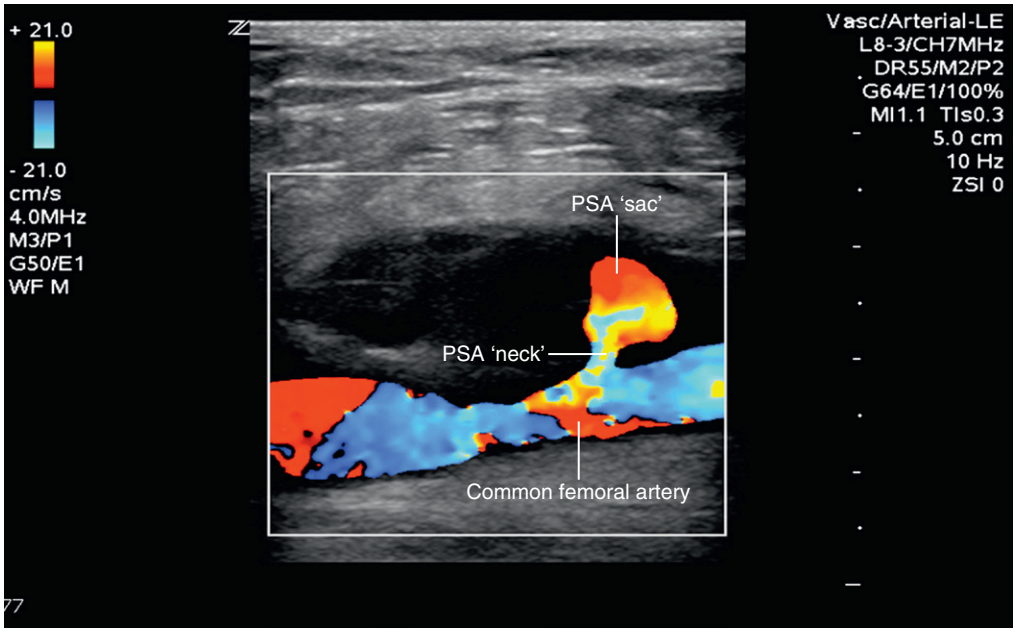

FIGURE 2 Duplex ultrasound scan (DUS) revealing a pseudoaneurysm *(PSA)*. DUS findings of a PSA include a fluid collection adjacent to the femoral artery (FA), high velocity jet through the FA wall, and a neck or communication with the FA.

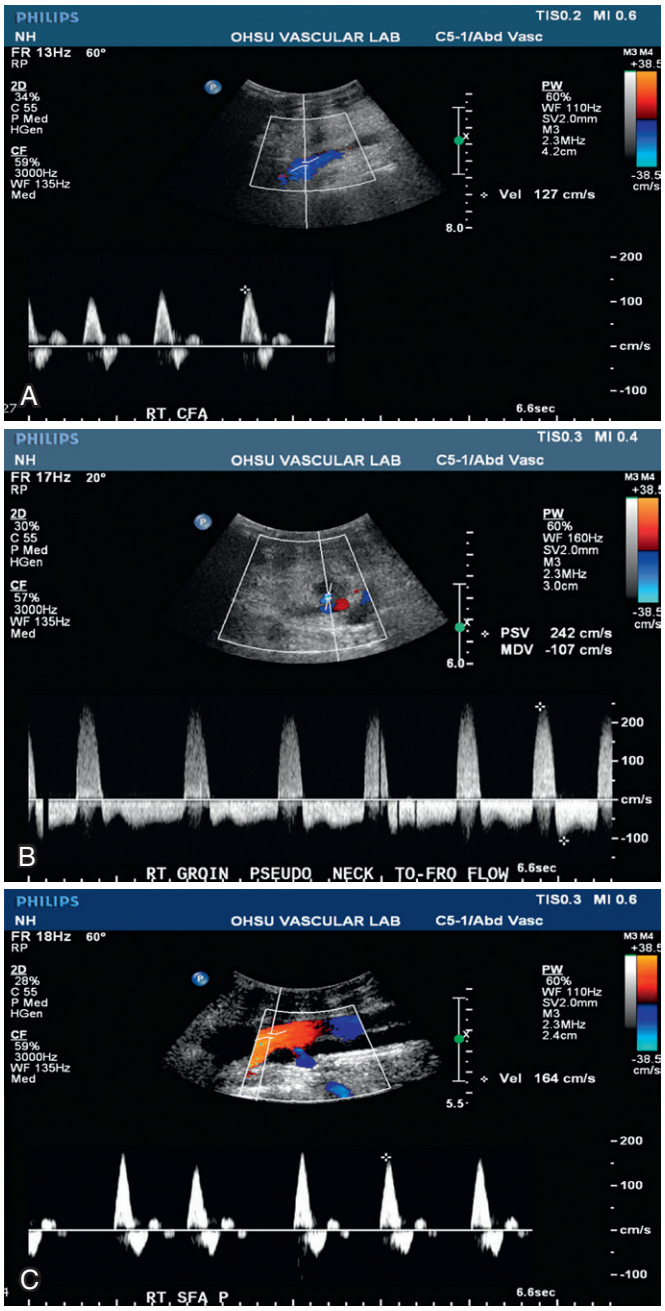

FIGURE 3 Duplex ultrasound scan of right common femoral artery (CFA) pseudoaneurysm (PSA). Images show: **A,** normal flow and peak systolic velocities (PSVs) in the proximal CFA; **B,** PSA arising off of the distal CFA with abnormal "to and fro" flow in the PSA neck; and **C,** normal flow and PSVs in the superficial femoral artery (SFA).

therapy or for suprainguinal PSAs. The ability to perform this procedure in the outpatient setting or at the bedside also reduces the relative cost. Complications for UGTI include intraarterial thrombosis (<2%), PSA rupture, and allergic response to bovine thrombin. Arterial thrombosis has been associated with the treatment of small PSAs (<2.5 cm) but appears not to be related to short neck length (<5 mm). Exposure to bovine factor V may cause some patients to form antibodies that cross react with human factor V and induce coagulopathy.

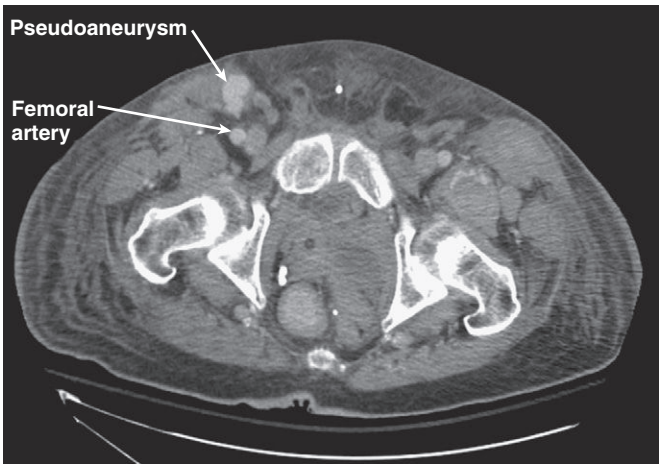

FIGURE 4 Computed tomographic scan image of femoral pseudoaneurysm. The scan was performed to exclude the diagnosis of a retroperitoneal hematoma; however, this femoral pseudoaneurysm was identified.

TABLE 3: Complications and contraindications of pseudoaneurysm ultrasound scan–guided compression therapy

Complications	Contraindications

PSA, Pseudoaneurysm.

Endovascular Repair

Covered stents have been widely used in the treatment of aneurysms, but their use in femoral PSA is limited. Current barriers include high cost, lower patency rates, the need for larger delivery systems, and the lack of long-term data. Endovascular repair is not recommended if treatment of the PSA requires placement of a stent across the groin crease or across the origin of the PFA. Complications unique to covered stents include infection, migration, and thrombosis. Duplex surveillance is required after the procedure to monitor for in-stent restenosis and stent patency.

Open Surgical Repair

Noninfected Pseudoaneurysms

Open surgical repair is indicated for patients with contraindications to nonoperative management (i.e., peripheral or cutaneous ischemia, infection, surgical graft, large suprainguinal PSA) and those who present with complications (i.e., rapid enlargement, skin necrosis, distal embolization, rupture). Suprainguinal PSAs require access to the retroperitoneum to achieve proximal control of the iliac vessels. Repair of the arterial defect with simple, interrupted polypropylene suture is usually sufficient to repair the vessel. The back wall of the

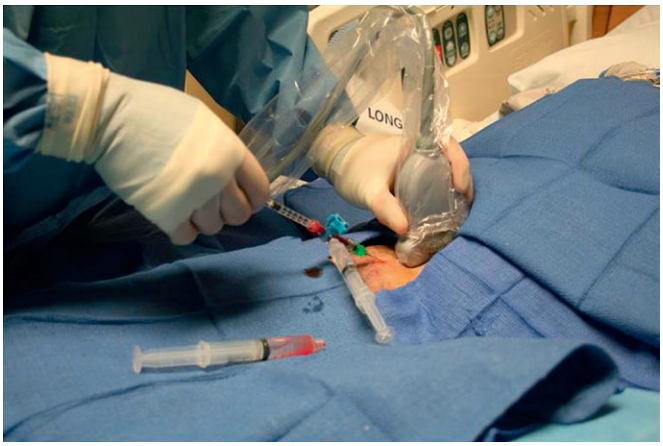

FIGURE 5 Technique of ultrasound scan (US)–guided thrombin injection. A 1-mL syringe containing bovine thrombin (1000 units/mL) and a 5-mL syringe with sterile normal saline solution flush are connected to a 3-way stopcock fitted with a 22-gauge needle (40-mm or 70-mm). If the pseudoaneurysm (PSA) is deeper than 3.75 cm, then a 21-gauge × 9-cm Echotip needle (Cook Medical, Bloomington, Ind) can be used. The PSA sac is visualized in transverse and longitudinal views on US. The thrombin port is placed in the "off" position, and the saline port is placed in the "on" position. US imaging is used to guide the needle into the PSA sac superficially and far from the PSA tract. Needle placement is confirmed with aspiration of blood, and a small injection of saline solution produces a flash of color on US. The thrombin port is placed in the "on" position, and the saline port is placed in the "off" position. Thrombin is then injected into the PSA sac in 0.2-mL aliquots until there is cessation of blood flow in the PSA sac and tract. This is usually achieved in seconds. The tract should never be directly injected because of associated risk of thrombosis of the native artery. An average of 300 units (0.3 mL) of thrombin (range, 50 to 1000 units) is necessary to thrombose the PSA sac. Arterial duplex scan should be repeated 24 hours after the procedure to check for recurrence (0 to 9%) and to rule out postprocedure complications.

BOX 1: Three-way stopcock technique of ultrasound scan–guided thrombin injection

1. The patient's groin is prepped and draped in the usual sterile fashion.
2. The distance from the skin to the most superficial portion of the pseudoaneurysm (PSA) sac and the distance to the PSA tract are measured.
3. The skin and subcutaneous tissue are infiltrated with 1% to 2% lidocaine.
4. A three-way stopcock is prepared as described in Figure 6.
5. The needle is advanced with ultrasound scan (US) guidance to the depth measured in step 2, and the PSA sac is entered superficially. Entry into the PSA sac is confirmed with aspiration of blood, and proper placement of the needle tip is confirmed with saline solution injection on US. The needle must be in the PSA sac and *not* in the tract, artery, or vein.
6. The thrombin port is turned "on," and the saline port is turned "off." Thrombin is injected gently in 0.2-mL aliquots until the PSA sac and tract are thrombosed or until 1.0 mL of thrombin is used.
7. If there are two or more PSA sacs, then the most superficial sac is injected first.
8. If the tract persists, do *not* inject directly into the tract. Follow the patient as the tract normally thromboses within 24 hours.
9. An arterial duplex scan is repeated 24 hours after the procedure to check for recurrence (0 to 9%), to confirm continued PSA thrombosis, and to rule out postprocedure complications such as arterial or venous thrombosis.
10. This procedure may be performed on an outpatient basis with the patient discharged immediately after injection.
11. A PSA that recanalizes after thrombin injection may be reinjected on follow-up visit.

artery should also be inspected to ensure no other arterial injury exists. Patch angioplasty or interposition bypass may be necessary if the arterial wall is significantly damaged or if there is luminal narrowing of the artery with primary repair. Hematoma evacuation and drainage may also be necessary. Complications associated with open surgical repair include wound infection, bleeding, lymphocele, radiculopathy, perioperative myocardial infarction, and death.

Infected Pseudoaneurysms

Infected PSAs should be managed aggressively with appropriate antibiotic coverage, débridement of infected tissue, and arterial repair or replacement with autogenous vein graft. Arterial ligation without revascularization is reserved for aggressive bacterial infection and may be associated with intermittent claudication or limb loss.

Anastomotic Pseudoaneurysms

Anastomotic PSAs are an infrequent but important late complication of prosthetic arterial reconstruction (Figure 6). The FA anastomosis is the most common site for an anastomotic PSA (13.6%). The presence of an anastomotic PSA should raise suspicion of a graft infection, and treatment should be performed with this in mind. Typically, an anastomotic PSA is composed of a fibrous pseudocapsule that surrounds the area of occult graft infection or arterial degeneration in a previously endarterectomized artery. Because anastomotic PSAs

FIGURE 6 Bilateral femoral anastomotic pseudoaneurysms. This patient underwent bilateral common femoral endarterectomies and an aortobifemoral bypass for aortoiliac occlusive disease 15 years before presentation. There are no fluid collections or edematous streaks within the tissue surrounding the pseudoaneurysms, which suggests no evidence of infection. On physical examination and laboratory testing, no clinical evidence of infection was found.

are unpredictable and are associated with a high incidence of rupture, they should be treated early and aggressively.

Observation is recommended only for patients with very small PSAs, prohibitive operative risk, or short life expectancy; operative repair is generally recommended for all groin anastomotic PSAs greater than 3 to 4 cm in diameter. Arterial replacement is usually necessary, with an interposition graft replacing the degenerative aneurysmal portion of the existing graft, providing there is no sign of ongoing infection. If the graft is infected, then removal and replacement of all infected graft and tissue is necessary. Revascularization may require extraanatomic bypass grafting in a noninfected field or replacement of the infected conduit with autogenous femoral vein. Grossly infected arterial beds may require coverage with sartorius or rectus femoris muscle flaps. Endovascular repair of FA anastomotic PSA has been reported; however, it is generally not recommended in the setting of infection or when stenting would result in occlusion of the PFA origin.

ARTERIOVENOUS FISTULA

An arteriovenous fistula (AVF) is described as an abnormal communication between an artery and a vein. The communication can be congenital but is frequently of an iatrogenic or traumatic etiology. Femoral AVFs almost always develop from penetrating injuries and percutaneous vascular interventions. The incidence rate of postcatheterization femoral AVF is 0.2% to 2%. Patient-related risk factors include female gender, hypertension, and ongoing anticoagulation therapy. Age and morbid obesity have not been identified as risk factors. Procedure-related risk factors include left-sided groin punctures and intense levels of anticoagulation therapy (>12,500 units of heparin). Postcatheterization femoral AVFs are the focus of this section.

Diagnosis

The diagnosis of an AVF in the extremities can be made with history and physical examination. Physical examination may reveal a loud bruit on auscultation and thrill on palpation. A to-and-fro holosystolic/diastolic bruit at the puncture site is diagnostic and pathognomonic for an AVF. The intensity of the sounds on auscultation typically correlates with the size of the fistula. Traumatic AVFs may also present as unilateral limb swelling, mild to severe limb ischemia (claudication or tissue loss), or heart failure. When the characteristic physical examination findings are not present but an AVF is suspected, DUS can be a useful tool in diagnosis of AVF (Figure 7). AVFs are characterized by high arterial peak systolic velocities (PSVs) proximal to the fistula because of low resistance at the fistula site (see Figure 7, *A*). Reduced arterial flow is seen distal to the fistula as a result of shunting (see Figure 7, *B*), and bidirectional or turbulent flow is seen at the fistula site (see Figure 7, *C*). Flow in the venous side of the AVF is characterized by elevated and pulsatile venous outflow PSVs that result from mixing of arterial and venous flows (see Figure 7, *D*).

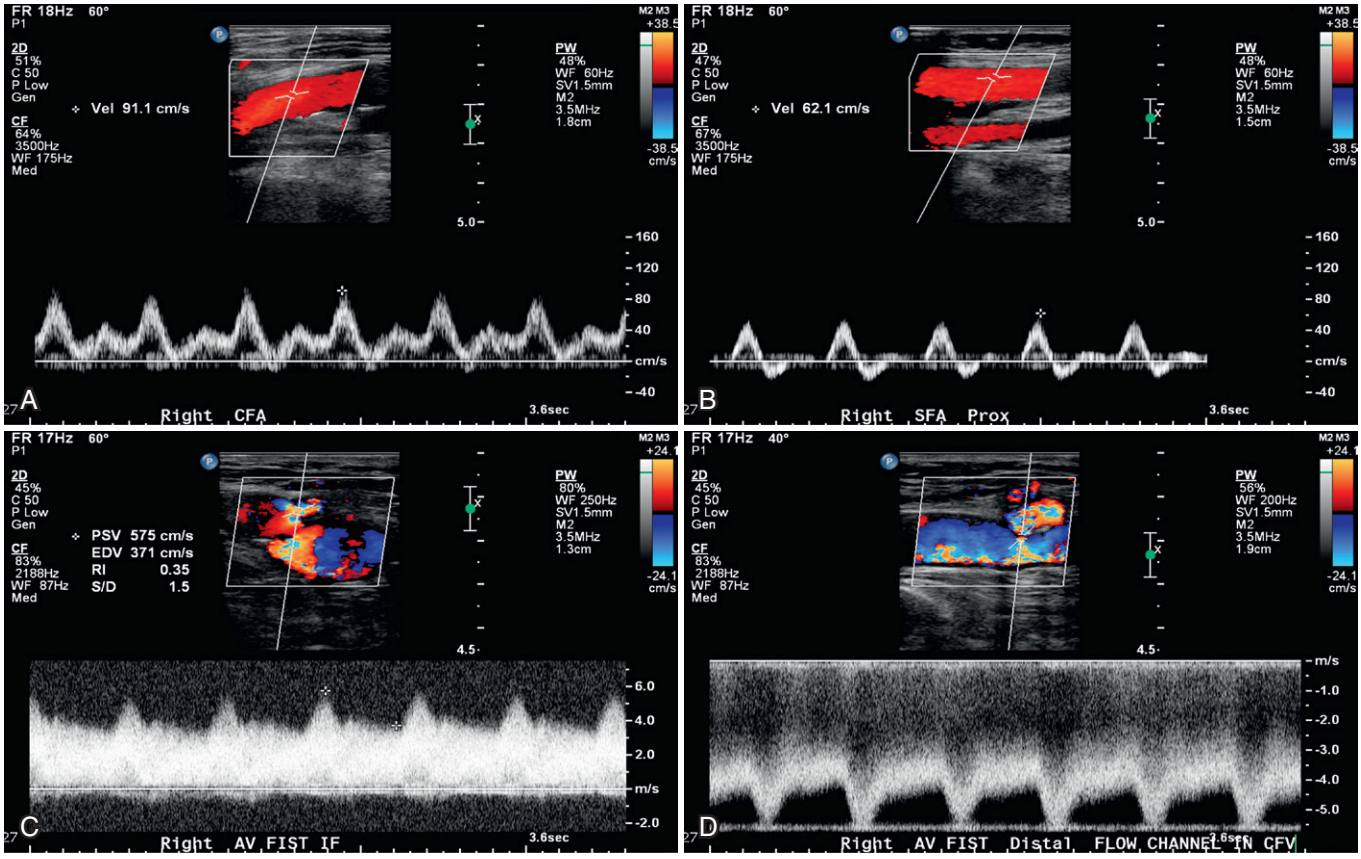

FIGURE 7 Duplex ultrasound scan examination of a traumatic arteriovenous fistula between the common femoral artery and common femoral vein (CFV). **A,** The arterial inflow is characterized by high peak systolic velocities. **B,** Reduced flow in the distal artery is caused by shunting at the fistula. **C,** Turbulent flow is seen at the fistula site. **D,** Mixing of arterial and venous flows causes elevated and pulsatile venous flow in the CFV.

Treatment

Iatrogenic AVFs, unlike traumatic AVFs, may close spontaneously. Studies have shown that 50% to 66% of iatrogenic postcatheterization femoral AVFs resolve spontaneously. Iatrogenic AVFs, however, are more likely to persist in patients with chronic renal insufficiency or concomitant steroid use. AVF repair is indicated for all symptomatic patients.

Open Surgical Repair

Surgical repair is the established method for treatment of femoral AVF and is associated with morbidity and mortality rates of 25% and 8%, respectively. Because AVF can result in significant enlargement of venous structures, operative repair can be associated with significant blood loss. Preoperative placement of arterial or venous balloons for intraoperative occlusion may help decrease blood loss during the repair, and cell-saver and rapid-infusion devices can be used when large volumes of blood loss are anticipated. Surgical repair requires obliterating the fistula and restoring normal arterial and venous blood flow. Therefore, repair of the fistula tract usually requires proximal and distal control of both the artery and the vein. Repair can be achieved with primary closure of the fistula tract. Vein patch angioplasty or interposition bypass grafts may be necessary for large AVF repair.

Endovascular Repair

Endovascular treatment of iatrogenic or traumatic femoral AVFs is becoming more commonplace. Catheter-based interventions are indicated for patients at high surgical risk or for those who present with "hostile" anatomy such as morbid obesity, previous femoral interventions, or groin surgery, and with obvious massive enlargement of venous collaterals. Patients who are not candidates for endovascular repair are those in whom endovascular stenting will obliterate the PFA or cross the groin crease. Intraarterial covered stents are required to obliterate the fistula connection with the vein. Venous stents are usually reserved for iliac vein or vena caval AVF occlusion after unsuccessful intraarterial stent placement. SFA stent grafts for iatrogenic femoral AVFs have reported 1-year and 4-year primary patency rates of 76% and 55%, respectively, and a 4-year secondary patency rate of 80%.

Axillofemoral Bypass

Jennifer A. Stableford, MD, and Evan C. Lipsitz, MD

INTRODUCTION

Although atherosclerosis is a diffuse process, distinct patterns of arterial occlusive disease can be identified. One such pattern is disease within the aortoiliac segment. Classic symptoms of aortoiliac occlusive disease include thigh and/or buttock claudication as well as impotence in male patients. This constellation of symptoms is known as Leriche syndrome. Aortoiliac occlusive disease can be seen in isolation, or in combination with infrainguinal occlusive disease. In patients with multilevel disease, the clinical presentation is more severe. The diagnosis of aortoiliac occlusive disease can be made on the basis of history and physical exam. Patients often have an extensive smoking history. Physical exam will reveal diminished or absent femoral pulses.

The diagnosis can be confirmed with a number of diagnostic tests. Pulse-volume recordings, a plethysmographic evaluation of lower-extremity arterial circulation, will show decreased waveforms in all segments. This is in distinct contrast to infrainguinal occlusive disease, which will have normal thigh tracings and diminished waveforms in the calf and ankle segments. Arterial duplex mapping can be used to estimate the degree of stenosis or occlusion within the aortoiliac segment, as well as identify any infrainguinal disease. Traditional angiography provides detailed anatomic information of the abdomen, pelvis, and lower-extremity arterial tree. In addition, it can identify patterns of collateral flow around obstructions. If warranted, intervention can be performed at the time of the diagnostic procedure. In the setting of aortoiliac occlusive disease, femoral artery access may be difficult or impossible, and the use of alternative access sites, such as the brachial artery, may be required. Computed tomographic (CT) angiography is another useful imaging modality for defining aortoiliac anatomy and planning intervention. CT angiography has the added advantage of delineating the extent of calcification within the aortoiliac segment, which assists in operative planning. A potential limitation of CT angiography is its ability to evaluate the extent of disease in the tibial vessels in the case of concomitant infrainguinal disease. Magnetic resonance angiography can also be useful in the evaluation of aortoiliac and lower-extremity disease; however, it, too, may be limited in the evaluation of distal circulation and does not provide information on the extent of calcification.

Axillofemoral bypass was first introduced in the early 1960s as an alternative to direct aortoiliac reconstruction with an aortoiliac or aortofemoral bypass. Axillofemoral bypass is considered an extra-anatomic bypass as it does not course along the normal anatomic path of the vessels being bypassed (Figure 1). The grafts are tunneled subcutaneously, avoiding a midline laparotomy and aortic cross-clamping, which significantly reduces the operative stresses, making this a favorable choice for reconstruction in patients at high risk (Figure 2).

INDICATIONS

Axillofemoral bypass is typically performed in patients with chronic arterial insufficiency and symptoms of critical limb ischemia, such as disabling claudication, rest pain, ischemic ulceration, or gangrene.

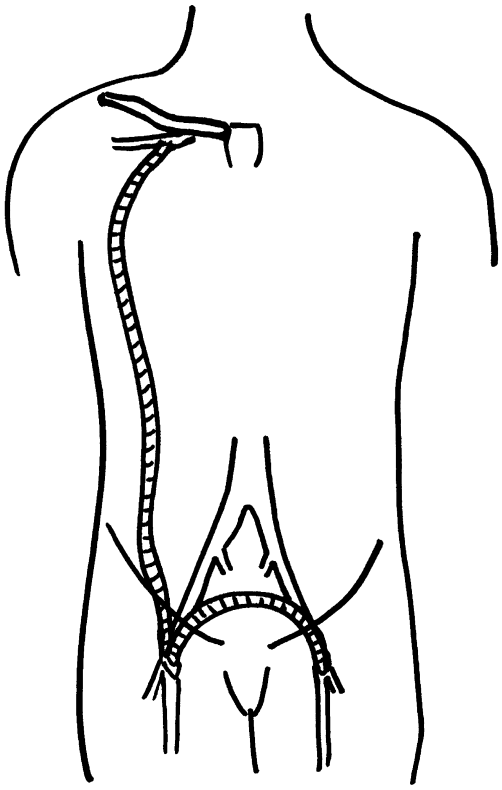

FIGURE 1 Typical configuration of a right axillobifemoral bypass.

FIGURE 2 A three-dimensional reconstruction of a computed tomographic angiogram in a patient with a left axillobifemoral bypass.

Occasionally it may be performed in the setting of acute occlusion or aortic dissection resulting in acute lower limb ischemia. The timing of intervention depends on the indication for the operation as well as the overall health status of the patient. The primary indication for axillofemoral bypass is a patient with severe aortoiliac disease, who is unable to undergo aortofemoral bypass. Aortofemoral bypass may be deemed unfavorable on the basis of anatomic considerations such as a heavily calcified aorta; a hostile abdomen or the need for peritoneal dialysis; medical comorbidities such as severe cardiopulmonary, renal, or hepatic disease; or the presence of intraabdominal infection (Box 1). Another indication is the temporary placement of axillofemoral bypass in order to maintain visceral and renal artery perfusion during complex thoracoabdominal aortic reconstruction.

BOX 1: Indications for axillofemoral bypass

Anatomic
Heavy aortic calcification
Hostile abdomen
- Previous surgery
- Extensive scarring
- Pelvic irradiation

Peritoneal dialysis

Comorbid Conditions
Severe cardiopulmonary disease
Severe renal or hepatic disease
Otherwise unfit for major surgery

Infectious
Infected intraabdominal graft
Other intraabdominal infection
Mycotic aneurysm
Aortoenteric fistula

Temporary
Need for temporary visceral and renal perfusion during major aortic reconstruction

The development and advancement of endovascular therapies has altered, and will continue to alter, the treatment of aortoiliac disease. In the early 1990s, reports demonstrating the efficacy and relative durability of angioplasty and stenting of focal stenoses (TransAtlantic Inter-Society Consensus [TASC] A and B lesions) led many patients to undergo endovascular treatment as their primary mode of therapy, reducing the number of aortofemoral reconstructions performed. Since the mid-1990s, advancements for crossing total occlusions (TASC C and D lesions), including the development of subintimal angioplasty, have made the treatment of an even greater number of patients with endovascular methods possible. As a result, many of the patients who ultimately require surgical repair are older, have more significant comorbidities, and are thus not candidates for direct aortic reconstruction, therefore requiring axillofemoral bypass.

A small subset of patients presenting with aortoiliac occlusive disease will also have associated abdominal aortic aneurysms, and axillofemoral bypass is not the preferred treatment for this group. These patients require aortofemoral bypass to address the aneurysmal component of the disease process, unless the aneurysms are particularly small or the patient is believed to be a prohibitive surgical risk.

For those patients in whom the abdominal aorta is unsuitable for inflow, an alternative is to use the supraceliac or distal thoracic aorta for inflow, gaining access through a transperitoneal incision with medial visceral rotation, a retroperitoneal incision, or a thoracotomy. When the common femoral artery is occluded, an alternative outflow artery must be selected, such as the profunda femoral artery, superficial femoral artery, or popliteal artery.

In patients with combined aortoiliac and infrainguinal occlusive disease requiring intervention, decisions regarding the extent of reconstruction are based on the patient's clinical status. In patients with claudication, rest pain, or minor tissue lesions, it is preferable to first address the proximal aortoiliac segment. Restoration of inflow

to the femoral level alone should be sufficient to relieve symptoms and the infrainguinal component treated subsequently only if needed. In cases of severe limb-threatening ischemia, concomitant axillofemoral and infrainguinal reconstruction may be required.

PREOPERATIVE EVALUATION

Patients should undergo a thorough preoperative evaluation. Many patients are selected for axillofemoral bypass on the basis of their comorbid conditions and therefore should be medically optimized to the greatest degree possible prior to surgery.

The choice of donor axillary artery depends on a number of factors. The axillary arteries may be evaluated by a number of invasive and noninvasive methods. Most simply, blood pressure measurements are taken in both arms and compared. If there is a significant gradient between the two sides (>20–30 mm Hg), the arm with the higher pressure is chosen as the inflow artery. The presence of such a gradient in the upper extremities may itself prompt further evaluation. Upper-extremity pulse-volume recordings and Doppler waveforms are useful in guiding therapy. Direct duplex of the subclavian arteries can be used to identify proximal stenoses. In addition, the inflow arteries may be evaluated with CT angiography or magnetic resonance angiography. Finally, digital subtraction angiography provides detailed anatomic information on the upper-extremity circulation. Full evaluation should include views of the aortic arch and great vessels. Although an invasive procedure, digital subtraction angiography provides the opportunity to address any lesion with angioplasty and stenting prior to the bypass procedure.

In cases with no notable disease on either side, the right axillary artery is typically selected for inflow because of the somewhat higher propensity for the left subclavian artery to develop a stenosis. This choice is made despite the fact that most patients are right-handed. Some authors advocate choosing the axillary artery ipsilateral to the lower extremity with the more severe symptoms. Grafts should not be based off an upper extremity with significant distal ischemia or where dialysis access is present. Additional anatomic considerations include the presence of thoracic outlet syndrome, breast cancer, or the presence of an ostomy, abdominal hernia, or previous surgery, which may complicate graft positioning. Finally, in patients undergoing axillofemoral bypass for reasons such as intraabdominal sepsis, who in the future may be candidates for aortic reconstruction via left retroperitoneal approach, the right axillary artery should be used to avoid interference with the retroperitoneal approach by a left-sided graft.

TECHNIQUES

Although this procedure can be performed under local anesthesia with sedation, general anesthesia is preferred because of the large volume of local anesthetic required to cover the extensive area, including all incisions and the subcutaneous tunnels. The room should be kept warm to prevent hypothermia, given the large body surface area that is exposed. The patient is positioned supine on a fluoroscopy-compatible table with the donor arm abducted to 90 degrees. A rolled towel is placed between the scapulae to facilitate exposure of the medial-most portion of the axillary artery. This also facilitates exposure of the lateral body wall for creation of the subcutaneous tunnel. The chest, abdomen, pelvis, and upper thighs are prepared and covered with impervious, sterile, plastic dressing. This permits wide exposure in the event that a thoracotomy or celiotomy is required. The donor arm is prepared, and an impervious stocking is placed to the level of the mid upper arm. This allows the operator to move the arm during the procedure to ensure that undue tension has not been placed on the axillary anastomosis.

A transverse, infraclavicular incision is made approximately one fingerbreadth below the lateral third of the clavicle, and the dissection is carried down through the clavipectoral fascia. The pectoralis major muscle fibers are split in the horizontal plane, exposing the deep fascia with the investing fat of the axillary artery, vein, and brachial plexus below. The pectoralis minor may be retracted laterally to enhance exposure of the first portion of the axillary artery; however, in most cases, it is preferable to divide the pectoralis minor. This both improves exposure and reduces the risk of graft kinking. The axillary vein is first identified, then isolated and retracted caudally. Frequently this requires ligation of venous tributaries. The axillary artery is then exposed and encircled with silicon vessel loops. Branches of the axillary artery are either controlled with silicone vessel loops under gentle tension or with removable microclips. Division of these arteries is rarely required. Because of the proximity to the brachial plexus, it is best to avoid excessive use of electrocautery in the vicinity of the vessels (Figure 3).

The femoral arteries are exposed through longitudinal groin incisions. This approach allows flexibility in the placement of the femoral anastomoses and facilitates the performance of any adjunctive procedures, which may be required, such as femoral endarterectomy. Oblique incisions may be used but can limit the ability to perform adjunctive procedures in the femoral vessels. If such incisions are used, the location of the femoral bifurcation should be identified preoperatively. The anastomoses are generally placed in the distal common femoral artery over the takeoff of the profunda femoris artery. In cases with a concomitant superficial femoral artery occlusion, the anastomosis can still be placed onto the common femoral artery, provided there is no stenosis of the profunda femoris artery. If there is an orificial stenosis, the distal anastomosis can be used to perform a profundaplasty, with the heel of the anastomosis over the common femoral artery and the toe onto the profunda femoral artery. Direct anastomosis to the profunda femoris may also be performed. If the common, superficial, and deep femoral arteries are all occluded, direct reconstruction to the popliteal artery may be required.

Once the vessels are exposed, a long, standard tunneling device is used to create a tunnel between the axilla and the groin. The graft must initially take a lateral course under the pectoralis major and

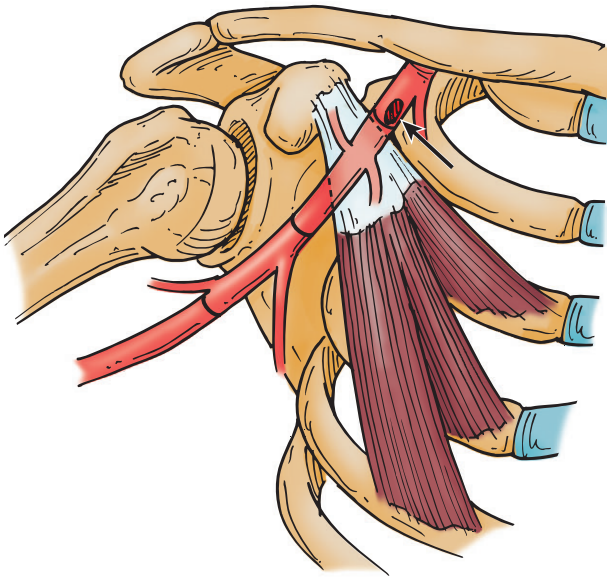

FIGURE 3 Following division of the pectoralis major, the approximate position of the axillary anastomosis at the distal portion of the first segment of the axillary artery is shown *(arrow)*. The divided pectoralis minor is indicated by the *dashed lines* and overlies the second portion of the axillary artery.

away from the axillary anastomosis before heading caudally in the subcutaneous tissue along the midaxillary line. It then courses anteromedially over the iliac crest and inguinal ligament to the groin. The use of a counter incision below the inferior aspect of the pectoralis major on the chest wall facilitates tunneling along the abdominal wall, thereby avoiding inadvertent injury to the abdominal contents. In the cases when a bifemoral bypass is being performed, a suprapubic tunnel for the crossover bypass is made in the subcutaneous space over the inguinal ligaments with either a tunneling device or large aortic clamp.

An externally supported polytetrafluoroethylene (PTFE) or Dacron graft is used for conduit. An 8-mm graft is preferred, but a 6-mm graft may be used in patients with small arteries without compromising patency. The graft is passed through the tunnels, and the patient is systemically heparinized. The graft is then cut to the appropriate length. It is essential that the graft not be made too short to avoid undue tension on the anastomoses, as well as not too long to prevent redundancy and possible kinking of the graft. We prefer to leave external ring supports to within 1 cm of the anastomosis as a further protection against kinking.

The axillary anastomosis is fashioned so that the graft takes an acute angle relative to the artery as it travels laterally to the abdominal sidewall (Figure 4). This is essential to reduce tension on the anastomosis and avoid graft dehiscence. It is sewn with a 5-0 or 6-0 polypropylene suture. The axillary artery is generally soft and delicate, so it should be handled with care when dissecting or suturing to avoid tearing of the vessel. The anastomosis can be constructed either in standard fashion from heel and toe toward the center of the arteriotomy, or the suture can be initiated at the midpoint of the posterior aspect of the anastomosis and run toward the heel and toe. In either case, it is essential to ensure that the posterior suture line is secure and without gaps because this area is difficult if not impossible to repair after the suture line is completed. The femoral anastomosis is sewn in standard fashion, beginning with the heel and proximal half of the anastomosis, then completing the distal anastomosis with the toe suture.

Confirmation of the patient's pulse status in both upper and lower extremities should be performed prior to reversal of heparin and closure. The incisions are closed in layers using absorbable polypropylene sutures. We prefer to use a subcuticular closure for all skin incisions, as staples and exposed sutures can catch clothing, requiring dressings until removed.

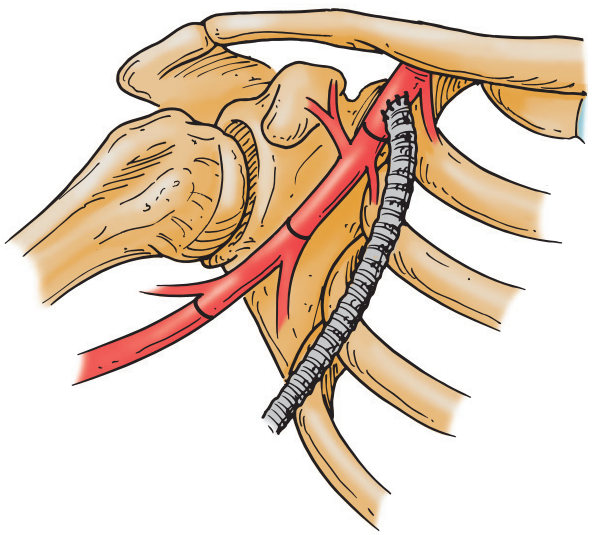

FIGURE 4 The course of the graft at the proximal anastomosis with the axillary artery.

GRAFT CONFIGURATIONS

Multiple possible graft configurations can be used when constructing the axillofemoral bypass, depending on the surgeon's preference and the patient's anatomy (Figure 5). There are now preformed grafts available with the femorofemoral graft fastened to the long axillary graft. Using such grafts reduces the total number of anastomoses from four to three, thereby reducing operative time. The order of anastomosis completion depends on the surgeon's preference as well as the number of operators. It is advantageous to have two teams so that anastomoses can be performed simultaneously, reducing operative and total anesthesia time.

RESULTS

The overall 5-year patency for axillobifemoral grafts, once as low as 30% to 40%, is now as high 60% to 80% since the introduction of externally supported grafts. These external rings prevent compression of the graft when the patients lie on their sides. Although this effect has not been proven by direct comparison, the use of externally supported grafts has been widely adopted on the basis of these theoretical advantages. There does not appear to be any difference in externally supported Dacron versus PTFE. The actual patency rates achieved vary widely according to the indication for surgery, patient selection, and extent of disease. Patients undergoing axillobifemoral bypass for infected abdominal grafts originally placed for aneurysmal disease, without concomitant occlusive disease, can be expected to have better patency than patients for whom the grafts were placed for severe occlusive disease. Axillobifemoral bypass grafts have better 5-year patency than the axillounifemoral grafts, presumably because of the increased flow rate in the axillary limb.

In the event of graft thrombosis, patency can frequently be reestablished with thrombectomy performed under local anesthesia. We prefer to perform these procedures under direct fluoroscopic guidance for several reasons. First, the chance of injury to the native vessel is reduced by preventing overdistention of the balloon-thrombectomy catheters. Second, it allows the surgeon to identify and possibly treat any underlying inflow or outflow lesions with an endovascular approach. Finally, should a revision be required, an angiogram defining the patient's anatomy can be obtained.

When comparing reports in the literature regarding axillofemoral bypass grafts, it is important to note that there is considerable variability in the techniques used and the outcome measures defined (e.g., primary versus secondary patency). In addition, it must be noted whether graft components are considered separately in patency calculations, as some authors may consider the axillofemoral and the femorofemoral components as distinct grafts.

COMPLICATIONS

Potential complications of this procedure include the standard risks of bleeding and wound infection common to all surgical procedures. The risk of graft infection is especially problematic because the majority of patients undergoing these procedures already have limited reconstructive options and significant medical comorbidities. Another potential complication is injury to intrathoracic or intraabdominal contents during tunneling of the graft. As noted earlier, care must be taken to avoid injury to other neurovascular structures, such as the axillary vein or brachial plexus.

POSTOPERATIVE MANAGEMENT

Patients are placed on an antiplatelet agent if not already on one preoperatively. Anticoagulation with warfarin is reserved for patients with a known hypercoagulable state, or in whom a secondary

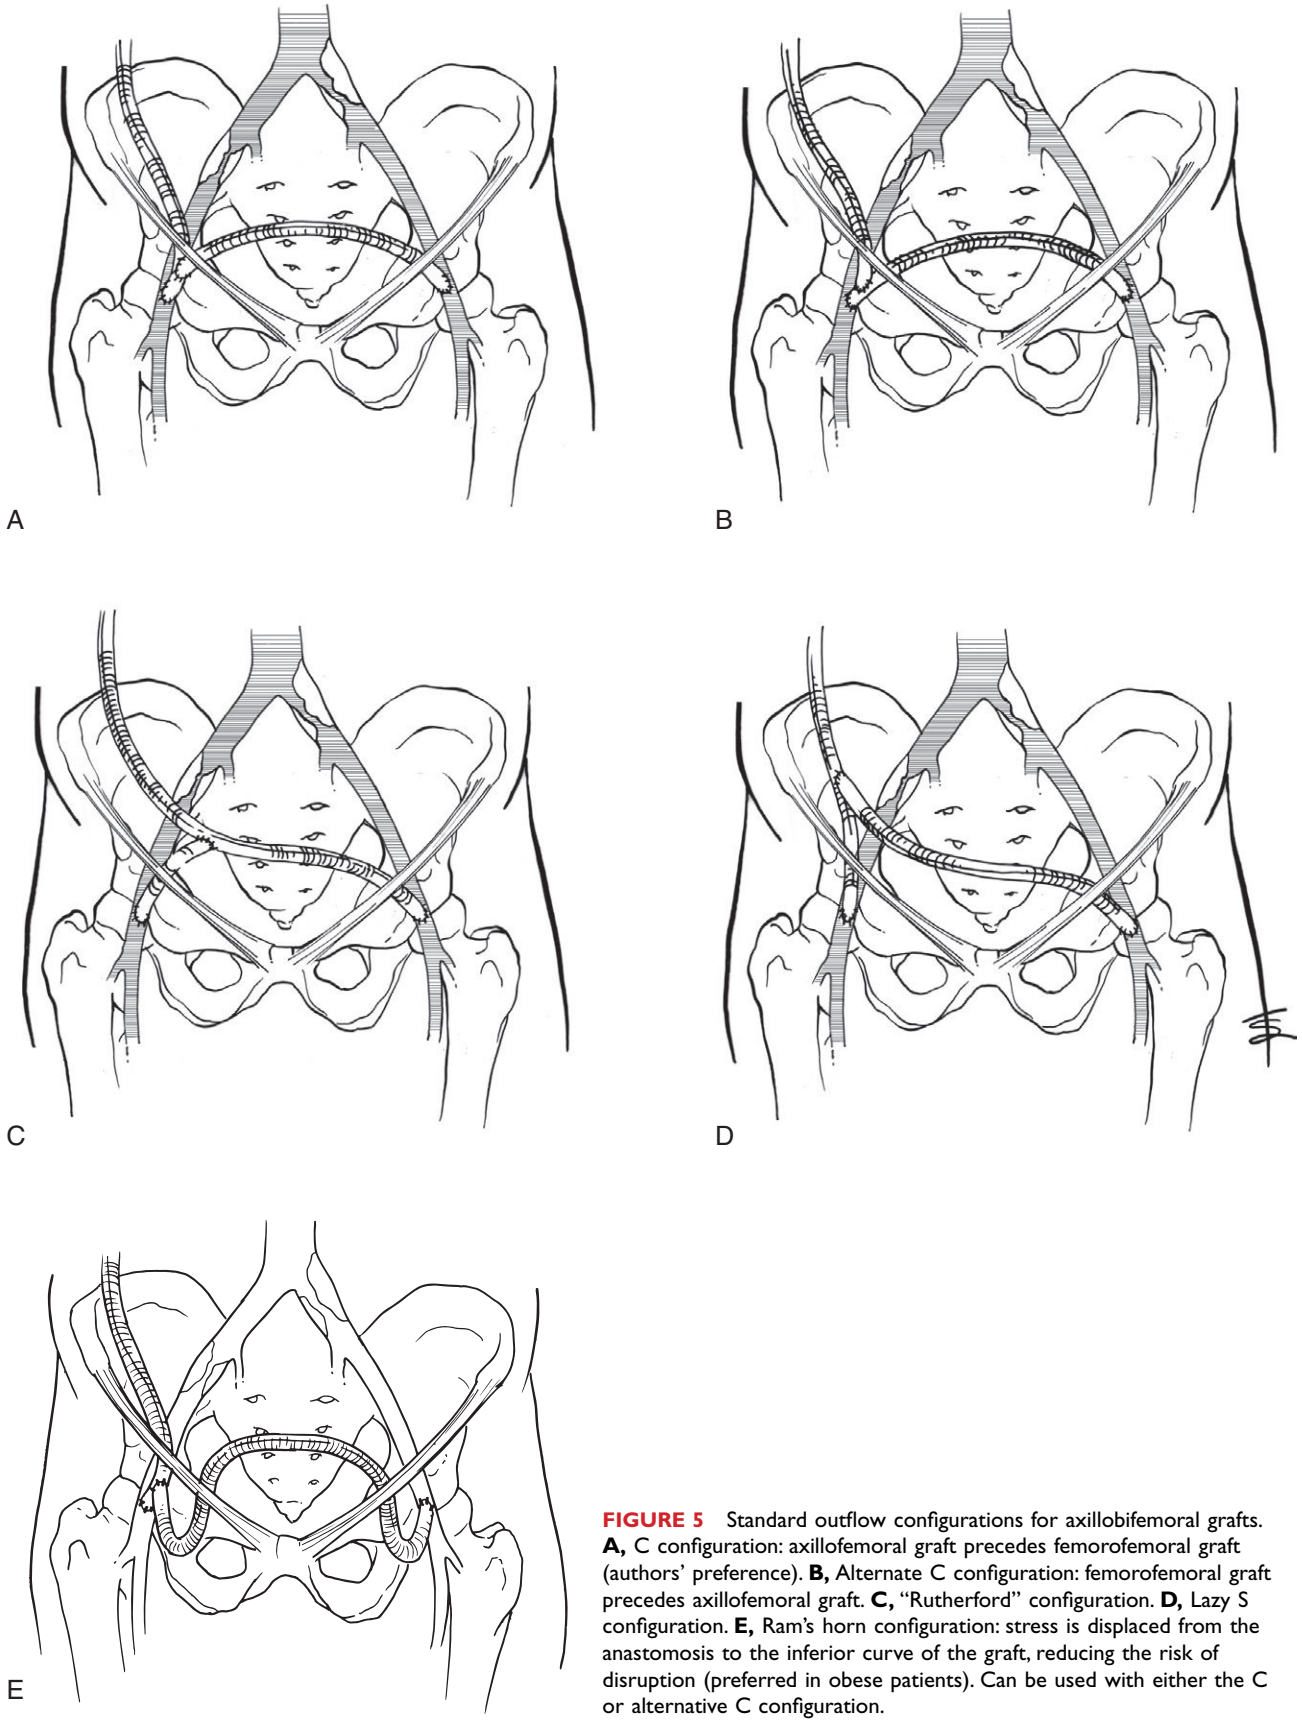

FIGURE 5 Standard outflow configurations for axillobifemoral grafts. **A,** C configuration: axillofemoral graft precedes femorofemoral graft (authors' preference). **B,** Alternate C configuration: femorofemoral graft precedes axillofemoral graft. **C,** "Rutherford" configuration. **D,** Lazy S configuration. **E,** Ram's horn configuration: stress is displaced from the anastomosis to the inferior curve of the graft, reducing the risk of disruption (preferred in obese patients). Can be used with either the C or alternative C configuration.

procedure was required to reestablish patency. As in all patients with peripheral artery disease, the use of a statin is recommended. Graft surveillance is performed every 3 months for the first year, every 6 months for the second year, and yearly thereafter. The need for a subsequent intervention or other abnormal findings on duplex may necessitate more frequent surveillance.

CONCLUSIONS

Axillofemoral bypass is an important and valuable option in the treatment of patients with aortoiliac occlusive disease. For many reasons, it is the preferred or only viable option for patients with significant anatomic or medical comorbidities, which preclude standard bypass options. Axillofemoral bypass can be performed with acceptable morbidity, mortality, and long-term results, even in patients at high risk. For these reasons, surgeons should be familiar with the indications and application of this technique.

The Management of Peripheral Arterial Emboli

Tze-Woei Tan, MD, and Alik Farber, MD, FACS

OVERVIEW

Embolus, derived from the Greek word *embolos* or plug, refers to intravascular material that originates in one location and travels to a remote site. When an embolus lodges in a distal artery or arteriole, it causes interruption of blood flow to downstream tissue. In the case of peripheral arteries, this often leads to acute limb ischemia (ALI). ALI presents a challenge for the surgeon because of both the consequences of potential tissue injury and the associated medical comorbidities inherent to this patient population. Diagnosis of ALI that results from embolism can often be successfully made with a comprehensive history and physical examination and selective use of diagnostic imaging studies. The goals of management of peripheral arterial embolism include immediate anticoagulation therapy to prevent thrombus propagation, expeditious restoration of arterial circulation with open or endovascular techniques, and identification and appropriate management of the source of embolism. Introduction of the Fogarty balloon embolectomy catheter in 1969 simplified surgical intervention by allowing an embolectomy to be performed from a remote surgical access site. Development and optimization of percutaneous endovascular techniques such as mechanical thrombectomy and pharmacologic thrombolysis have broadened minimally invasive approaches for treatment of peripheral arterial embolism.

CLASSIFICATION, SITE, AND SOURCE OF EMBOLISM

Peripheral arterial embolism can be classified according to the size of embolus (macro or micro), the site of embolism (extremity, visceral, or cerebral), and the source of embolism (cardiac or noncardiac; Table 1).

The heart is the most common source of macroembolism, whereas microembolism is typically associated with a noncardiac etiology. Embolism can affect the peripheral arterial (lower and upper extremity), visceral, or cerebral circulation. In the lower extremity, the most commonly affected site is the bifurcation of the common femoral artery, followed by the aortoiliac arterial segment and the popliteal artery. In the upper extremity, the most common location is the brachial artery at the bifurcation of the radial and ulnar arteries, followed by the axillary artery at the take-off of the deep brachial artery (see Table 1). Embolism is the most common cause of upper extremity ALI. Conversely, arterial embolization is second to in situ thrombosis as a cause of ALI in the lower extremity because of the higher predilection of arterial occlusive disease in the lower extremity.

The heart is the most frequent source of peripheral embolism; it accounts for approximately 80% of all cases. Although rheumatic heart disease used to be the most common cause of cardiogenic embolism, over the past several decades, atrial fibrillation has replaced it in frequency. Stagnant blood flow in a dilated left atrium of patients with atrial fibrillation predisposes to formation of thrombus that can lead to peripheral embolization. Similar conditions can occur in a dyskinetic left ventricle or ventricular aneurysm of a patient who has had a myocardial infarction. Less commonly, valvular abnormalities associated with rheumatic heart disease, infected vegetations associated with bacterial endocarditis, thrombus generated on prosthetic heart valves, and atrial myxoma can give rise to distal embolization (Figure 1).

Noncardiac sources account for 15% to 20% of peripheral arterial emboli. A discrete aortic ulcerative plaque can lead to microembolization of intraplaque debris or facilitate formation of associated aortic thrombus that may embolize to the periphery (Figure 2). Diffuse aortoiliac atheromatous plaque ("shaggy aorta") and ulcerative lower extremity plaque are less common causes for microembolization. Other sources of peripheral embolization include aneurysms, most commonly involving the aorta and popliteal artery. In some cases, embolization can be significant and can lead to complete obliteration of outflow vessels (Figure 3). Arterial thoracic outlet syndrome with associated subclavian artery aneurysm can also cause embolism and is the most common etiology of nontraumatic upper limb ischemia in young patients. Finally, paradoxic embolization, a less frequent cause of peripheral artery embolism, can occur

TABLE 1: Classification and frequency of extremity arterial embolism

Classification	Approximate frequency
Site of Emboli	
1. Lower Extremity	**84%**
Aortoiliac	25.7%
Common femoral	34%

Iatrogenic	
Foreign body	
3. Unknown	**5%**

in patients with a deep venous thrombosis and a right to left cardiac shunt usually caused by a patent foramen ovale.

PATHOPHYSIOLOGY

Macroemboli are usually composed of organized thrombus. They tend to lodge at arterial bifurcations where branching arteries decrease in caliber. Acute limb ischemia may ensue; its severity depends on the size and proximity of the vessel involved and the presence and extent of preexisting collateral circulation. Embolism to a normal artery leads to sudden onset of severe ischemia from absence of collateral circulation. In comparison, occlusion of a vessel with underlying atherosclerotic disease may provoke mild or even absent clinical symptoms as a result of preservation of distal perfusion through preexisting collateral pathways. Propagation of thrombus with subsequent occlusion of collateral vessels or fragmentation of an embolus with more distal embolization may aggravate limb ischemia.

The pathophysiologic basis of tissue injury from peripheral macroembolization is ischemia and reperfusion. Tissue hypoperfusion causes cellular hypoxia and local accumulation of toxic metabolites, including potassium and lactic acid, which lead to necrosis. Reperfusion, brought on by revascularization or embolus autolysis, provokes release of free oxygen radicals that further injure ischemic tissue. Locally, limb reperfusion and associated muscle edema can cause compartment syndrome. Systemic effects of reperfusion include hyperkalemia, metabolic acidosis, myoglobinuria, and acute renal failure. Limb ischemia and reperfusion in patients with ALI are associated with significant morbidity and mortality. Nerve is the most sensitive tissue to limb ischemia, and ischemic injury to peripheral nerves often leads to debilitating functional outcomes such as foot drop or Volkmann's contracture. Although irreversible nerve injury begins after 6 to 8 hours of ischemia, individual vascular limb anatomy and physiology may significantly increase this interval. Skeletal muscle, skin, and bone are less sensitive to ischemia and are able to tolerate longer delays in revascularization.

Microemboli are typically composed of platelet aggregates or cholesterol crystals that originate from atherosclerotic plaque. They can occur spontaneously as a result of plaque rupture or as a result of plaque disruption caused by arterial instrumentation during the course of a percutaneous endovascular procedure. Embolization of such debris into small arterioles induces an acute inflammatory response that is initially characterized by infiltration of polymorphonuclear cells and eosinophils. This process transitions into a chronic inflammatory state notable for endothelial and fibrous tissue proliferation that leads to luminal occlusion. Microembolization characteristically causes transient focal ischemia without major tissue loss; however, degree of injury correlates with the aggregate volume of embolus and can be extensive.

CLINICAL PRESENTATION

Patients with acute peripheral embolism usually present with ALI. The classic signs and symptoms of ALI, traditionally described as the six Ps, include *p*ain, *p*allor, *p*oikilothermia (coolness), *p*ulselessness, *p*aresthesias, and *p*aralysis. Pain is acute in onset, severe, and constant and is typically the main reason patients seek medical attention. It usually afflicts the distal limb; however, in the setting of proximal arterial occlusion, the entire limb may be affected. Skin pallor and coolness, or temperature level, usually occur at least one joint distal to the embolic occlusion and correlate with the extent of collateral flow. A careful pulse examination is important to the diagnosis of ALI and the relative location of arterial occlusion. Along with the patient's medical history, the pulse examination can help differentiate an embolic from a thrombotic arterial occlusion; normal palpable pulses in the contralateral limb, for example, may imply an embolic process. Conversely, a history of chronic ischemic symptoms and absence of palpable pulses in the contralateral extremity is highly suggestive of in situ thrombosis. An important note is that proximal to an embolic occlusion, a pulse may have a "water-hammer" quality and thereby can feel paradoxically augmented.

In some patients, sensory changes (numbness and paresthesias) in the distal extremity, rather than pain, can be the initial presenting symptom. Complete sensory loss, however, along with a motor deficit

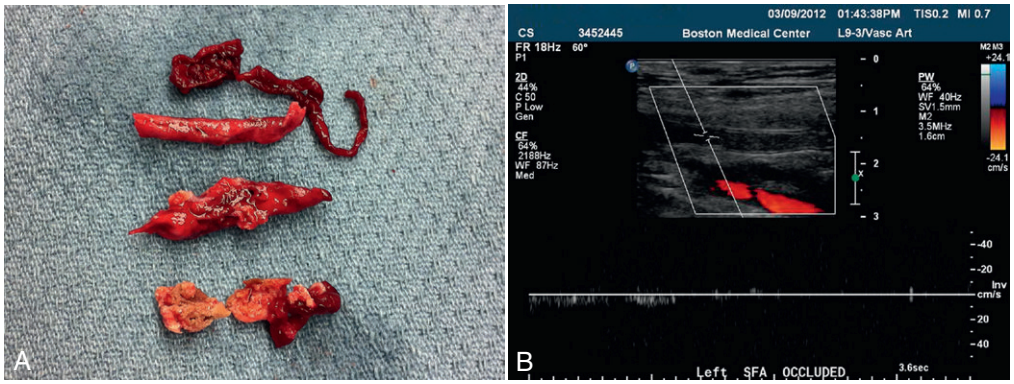

FIGURE 1 **A,** Intraoperative embolectomy specimens from a patient with acute limb ischemia from bacterial endocarditis. **B,** Preoperative duplex ultrasound scan of same patient reveals embolic occlusion of left superficial femoral artery.

represents advanced ischemia. Distal muscle weakness is strongly associated with ischemia severity and duration and, as such, is the most important factor in determination of both the urgency of revascularization and functional limb salvage. Continuous-wave Doppler scan is an important adjunct to the physical examination as the quality and presence of arterial Doppler flow correlates with degree of ischemia. Although a high clinical suspicion of ALI is important in patients who present with acute onset of limb pain, the differential diagnosis of this entity includes other clinical conditions, such as infection and deep venous thrombosis.

Acute limb ischemia is categorized based on the neurologic and vascular examination of the affected limb. The current Society for Vascular Surgery classification provides guidance with respect to the timing and the type of intervention and correlates with limb-related outcomes (Table 2). Class I, or viable, ALI defines patients with no continuing ischemic rest pain, no neurologic deficit, adequate skin capillary circulation, and clearly audible Doppler arterial signals in a pedal artery. Class II ALI refers to a limb with threatened viability and implies reversible ischemia in an extremity that is potentially salvageable with expeditious revascularization. This category further divides ischemic limbs into those that are marginally threatened (IIa) and immediately threatened (IIb). Patients with class IIa ALI may experience ischemic pain and have mild to moderate sensory loss. There is no muscle weakness, and venous Doppler signals are present. Patients with class IIb ALI have persistent ischemic rest pain and persistent lack of sensation in toes and have an associated loss of motor function. Lastly, patients with class III, or irreversible ischemia, have profound sensory and motor loss that extends above the foot, with evidence of advanced ischemia including muscle rigor or skin marbling. In these patients, thrombosis of the venous circulation from stagnant blood flow is often observed. For optimized limb salvage, patients with class I ALI need semiurgent (24 to 48 hours) intervention and patients with class IIa ALI need urgent (within 24 hours) intervention. Those with class IIb ischemia require emergent (within 2 to 4 hours) revascularization. Finally, patients with class III ischemia are best served with limb amputation rather than revascularization.

TABLE 2: Clinical categories of acute limb ischemia

Category	Description/prognosis	Findings		Doppler Signals	
		Sensory loss	Muscle weakness	Arterial	Venous
I. Viable	Not immediately threatening	None	None	Audible	Audible
II. Threatened					
a. Marginally	Salvageable if promptly treated	Minimal(toes)/none	None	Absent	Audible
b. Immediately	Salvageable with immediate revascularization	More than toes, associated rest pain	Mild, moderate	Absent	Audible
III. Irreversible	Major tissue loss or permanent neurologic damage	Profound, anesthetic	Profound, paralysis (rigors)	Absent	Absent

Modified from Rutherford RB, Baker JD, Ernst C, et al: Recommended standards for reports dealing with lower extremity ischemia: revised version, J Vasc Surg *26:517-538, 1997.*

TABLE 3: Differences in clinical presentation of acute peripheral artery embolism and in situ arterial thrombosis

	Arterial embolism	In situ thrombosis
History	Acute onset No history of PAD Arrhythmia, MI, valvular abnormalities may be present	Acute or gradual onset History of PAD usually present Arrhythmia, MI, valvular abnormalities usually absent
Physical examination	Pulses in contralateral leg usually normal Extremity signs suggestive of chronic ischemia (hair loss, shiny skin, hypertrophic nails, wounds) usually absent	Pulses in contralateral leg may be absent Extremity signs suggestive of chronic ischemia (hair loss, shiny skin, hypertrophic nails, wounds) may be present

MI, Myocardial infarct; *PAD,* peripheral artery disease.

When considering ALI, differentiation between peripheral arterial embolism and in situ vessel thrombosis is important (Table 3) because this can affect both choice of treatment approach and patient outcomes. Although such differentiation can be challenging, a careful history and physical examination is invaluable. Patients with peripheral embolism present with acute onset of leg pain without preexisting symptoms of peripheral arterial disease (PAD). They can usually pinpoint the exact onset of symptoms, and their degree of limb ischemia is usually more severe because of lack of collateral circulation. Cardiac history such as atrial fibrillation, myocardial infarction (MI), or valvular disease may be present. These patients may have a known history of aneurysm. On examination, pedal pulses on the unaffected leg are usually normal. As noted previously, patients with acute in situ thrombosis usually have preexisting symptoms of PAD, such as intermittent claudication, rest pain, or tissue loss. A history of previous percutaneous or open limb revascularization may be seen. Risk factors for PAD including hypertension, hyperlipidemia, diabetes, smoking, and a history of associated coronary or cerebrovascular atherosclerosis may be manifest. Because PAD is usually a diffuse and symmetric process, the contralateral leg may have nonpalpable pedal pulses.

Peripheral microembolism typically presents with localized toe or finger pain. It is more common in the lower rather than upper extremity. Patients with lower extremity embolization or "blue toe syndrome" have a painful and discolored toe. This process can involve multiple toes and, when extensive, is referred to as "trash foot." Depending on the degree of embolization, patients with diffuse toe ischemia may have palpable pedal pulses. Involvement of toes on *both* feet suggests that the culprit lesion is proximal to the aortic bifurcation. Livedo reticularis, or netlike mottling of the skin, can occur in the feet, thighs, and buttocks and reflects diffuse microembolization. Other potential skin manifestations include petechiae, purpura, and splinter hemorrhages. Palpation of the abdomen, popliteal fossa, and groin is important because it may reveal culprit aortic, popliteal, or femoral aneurysm.

DIAGNOSTIC EXAMINATION

Patients with peripheral arterial embolization may need diagnostic imaging for assessment of the degree of limb ischemia and identification of the embolic source. Although the diagnosis is usually made based on a careful history and physical examination, arterial noninvasive tests, such as an ankle-brachial index (ABI), pulse volume recording (PVR), or tibial Doppler waveform scan, may be confirmatory. Duplex ultrasound scan can be used to corroborate the site of embolic occlusion (see Figure 1, *B*). These studies can be performed at the bedside, and their use should be relegated to cases in which

the diagnosis is not clear or the ischemia is not severe. In the setting of class IIb ALI and an immediately threatened limb, care must be taken to avoid tests that add little to the diagnosis and potentially delay definitive treatment.

Cross-sectional imaging studies such as computed tomographic angiography (CTA) or magnetic resonance angiography (MRA) of the aorta and extremity arteries can be used to diagnose the location of an embolus but are more useful in the determination of an embolic source (see Figures 2, *B* and *C*). These studies can be used to visualize culprit ulcerative plaque or aneurysms and can evaluate for other causes of ALI such as aortic dissection and trauma.

Electrocardiogram can assess for cardiac dysrhythmias, ischemia, or prior infarct. Echocardiography is used to assess the heart when a cardiogenic embolism is suspected. Transthoracic echocardiography (TTE) is noninvasive and is performed first. An enlarged atrium, wall motion abnormality, intracardiac thrombus, and tumors may be identified. Transesophageal echocardiography (TEE) is more sensitive and should be ordered when TTE is negative yet suspicion for a cardiac source is high. A TEE with bubble study can identify a cardiac defect and lead to the diagnosis of paradoxic embolism.

Conventional angiography is performed when the diagnosis of peripheral embolism is unclear and significant preexisting atherosclerotic vascular disease is present or when an endovascular therapeutic approach is planned. Typical angiographic appearance of an embolus is that of an abrupt vessel occlusion associated with a meniscus sign. Minimal contrast filling is observed distal to the occlusion as a result of minimal collateral development (Figure 4). Intraoperative completion angiography may be necessary if concern regarding adequate revascularization persists or if distal extremity runoff needs to be visualized.

Laboratory evaluation should include complete blood count, electrolytes, creatinine, prothrombin time (PT), and activated partial thromboplastin time (PTT). In the setting of prolonged ischemia, lactate, creatinine phosphokinase (CPK), and urine myoglobin levels may be ordered to identify patients who need aggressive medical management to prevent nephrotoxicity. A hypercoagulable profile may be indicated in patients with a suspected hypercoagulable state.

FIGURE 4 Angiogram shows an abrupt cutoff of the left common femoral artery consistent with the appearance of an embolus *(arrow)*.

MANAGEMENT

Medical Management

On diagnosis of peripheral embolization and ALI, systemic anticoagulation therapy is administered as long as no contraindication exists. Unfractionated heparin is given as an initial bolus of 80 to 100 unit/kg, and an 18 to 20 unit/kg/h continuous infusion is started. Anticoagulation therapy prevents propagation of thrombus and thus mitigates against worsening of limb ischemia. For patients who need emergent intervention, anticoagulation therapy should be continued up to the time of the procedure. Degree of anticoagulation therapy should be carefully monitored with intermittent measurement of PTT with a goal of 60 to 80 seconds. In patients with history of heparin-induced thrombocytopenia, a direct thrombin inhibitor such as argatroban or lepirudin is used.

Patients with peripheral embolism usually have significant medical comorbidities that may require careful optimization before intervention. Tachyarrhythmias, dehydration, and electrolyte and metabolic abnormalities need to be appropriately corrected. In the setting of class IIb ALI, such interventions may need to be performed in the operating room. After reperfusion, care is taken to avoid or treat hyperkalemia and myoglobinuria. Myoglobinuria can cause acute renal failure; therefore, hydration and urine alkalinization with bicarbonate may be needed in patients with significant tissue damage and rising CPK values.

Surgical Management

Open embolectomy is the surgical approach of choice for management of embolic ALI during which thrombus is extracted from an artery though an arteriotomy. This procedure is performed with a Fogarty balloon embolectomy catheter that allows for extraction of thrombus distal and proximal to the arteriotomy site.

The choice of arteriotomy depends on several factors, including anticipated location of emboli, convenience of vascular exposure, and ease of arteriotomy closure. For iliac, femoral, and popliteal emboli, the common femoral artery (CFA) is the access artery of choice because of its ease of exposure and relatively large diameter. The below-knee popliteal artery can be used in the case of popliteal or tibial thrombus. Bilateral CFA access is necessary for embolectomy of a saddle embolus at the aortic bifurcation. The distal brachial artery, at its bifurcation, is usually accessed during upper extremity embolectomy. Smaller arteries, at the ankle or wrist, can also be accessed directly in selected cases where other approaches are not fruitful.

With exposure of the CFA, a horizontal or longitudinal skin incision is made at the groin below the inguinal ligament. This procedure can be performed with local anesthesia if general anesthesia is considered too high risk. The common, superficial, and deep femoral arteries are encircled with vessels loops for vascular control to prevent excessive blood loss during embolectomy. Before arteriotomy, systemic heparin is administered, with its dose dependent on the elapsed time since heparin cessation. The decision to perform a transverse or longitudinal arteriotomy depends on the quality of the CFA or the potential need to use the femoral arteriotomy as inflow to an infrainguinal bypass. The arteriotomy is made at the arterial bifurcation to allow intraluminal access to both the superficial and the deep femoral arteries. A transverse arteriotomy at the CFA bifurcation is used when the artery is normal and the need for a potential concomitant bypass is unlikely. In case of a diseased artery, a longitudinal arteriotomy is made to facilitate a potential endarterectomy or bypass if necessary. Such longitudinal arteriotomy allows for exposure of more proximal or distal artery if needed; however, it often requires closure with a patch. Although vein, polytetrafluoroethylene, polyester, and bovine pericardium can be used, the latter material has the advantage of

being "off the shelf" and having a lower risk of infection. The same principles with regard to arteriotomy choice apply to the popliteal, brachial, calf, and forearm arteries. The popliteal or brachial artery arteriotomy is made over the takeoff of the anterior tibial artery or the bifurcation of the brachial artery, respectively.

The Fogarty balloon embolectomy catheter is carefully inserted through the arteriotomy site with appropriate vessel loop vascular control. The catheter is advanced beyond the embolus, and the balloon is gently inflated while the catheter is slowly withdrawn. Inflation is only performed during slow withdrawal of the catheter to establish the appropriate amount of tension between the inflated balloon and the intimal surface of the artery. Overinflation is avoided because it can cause severe intimal injury. Although saline solution is used by some to fill the balloon, the authors believe that use of air allows for better sense of appropriate degree of balloon inflation. The catheter is retracted as thrombus is withdrawn from the artery. This maneuver is repeated multiple times proximal and distal to the arteriotomy until no further thrombus can be retrieved. Adequate proximal inflow and distal back bleeding suggest a successful result. The arteriotomy is then closed, and the affected limb is examined for evidence of restored perfusion. Completion angiogram is performed if the limb remains inadequately perfused and there is need to delineate arterial anatomy so as to locate residual thrombus. Adjuvant intraoperative recombinant tissue plasminogen activator (rTPA) can be injected intraarterially (5 to 10 mg) if adequate runoff cannot be established with embolectomy.

The Fogarty balloon embolectomy catheter is available in a variety of sizes: 2F catheters are reserved for the smallest pedal, tibial or forearm arteries; 3F-4F catheters are used in the femoral, popliteal, and brachial arteries; 4F-5F catheters are usually used in femoral and iliac arteries. When inserted through the CFA, the catheter usually takes a straight path into the peroneal artery. Insertion of the catheter into other tibial vessels can be facilitated by bending the catheter tip. If blind insertion is unsuccessful, other options include the use of the over-the-wire Fogarty balloon catheter with fluoroscopic guidance or open embolectomy through the distal below-knee popliteal artery.

Endovascular Approach

Minimally invasive approaches for treatment of peripheral artery embolism include percutaneous pharmacologic thrombolysis and mechanical thrombectomy. Multiple trials performed in the 1980s, including the Rochester study, STILE (Thrombolysis for Ischemia of the Lower Extremity) trial, and Thrombolysis or Peripheral Arterial Surgery (TOPAS) trial, showed that pharmacologic thrombolysis is a safe and effective treatment of ALI of less than 14 days duration. Thrombolysis with a lytic medication such as rTPA can be beneficial in the setting of class I or IIa ALI and in patients at medically high risk. Little role for this procedure is found in the setting of class IIb ALI. The theoretic benefits of thrombolysis are avoidance of general anesthesia that may be necessary for an open surgical procedure, gentle revascularization of an ischemic limb, and the ability to dissolve thrombus in smaller size vessels that would otherwise be difficult to treat with open embolectomy. In the case of thromboembolism associated with a popliteal artery aneurysm, if time permits, establishment of the distal peripheral circulation with thrombolysis is the first choice of therapy. The downsides of thrombolysis are the relatively longer time periods required to achieve tissue reperfusion and the risk of potential bleeding complications. Thrombolysis appears to work best on acute as opposed to subacute or chronic thrombus; therefore, thrombolytic agents have little effect on organized macroemboli. Embolic occlusion is, in general, less likely to respond to thrombolysis than in situ thrombosis.

The first step in percutaneous thrombolysis is to obtain vascular access and insert a vascular sheath. Angiography is performed to identify both the location of emboli and the remaining runoff vessels. A wire is inserted across the thrombus and exchanged for a multiple-hole infusion catheter. A thrombolytic agent is then delivered into the thrombus. Thrombolysis can be performed over 30 to 60 minutes (pulse-spray) or continued for 12 to 24 hours (infusion). In the setting of infusion thrombolysis, with use of rTPA, a rate of 1 mg/h is typically chosen. Heparin infusion (500 U/h) is administered concurrently to prevent sheath thrombosis. The patient is monitored closely in the intensive care unit for signs of bleeding or coagulation factor depletion. Rate of lysis is adjusted accordingly, and at a designated time, the patient is returned to the angiography suite to assess for successful recanalization. If persistent thrombus is present, the catheter may be advanced distally and the infusion continued for another period of time.

Percutaneous mechanical thrombectomy (PMT) is an evolving technique in the management of peripheral arterial embolism. Available devices include aspiration thrombectomy catheters and automated PMT devices such as Angiojet (Possis Medical, Minneapolis, Minn). After angiography is performed to identify the location of the embolus, the aspiration thrombectomy catheter is advanced to the area of embolus and syringe suction is used to aspirate the embolus. With Angiojet, the device is advanced across the embolus multiple times as thrombectomy is performed through the Venturi effect created by the negative pressure at the tip of the catheter. Pharmacologic thrombolysis with rTPA can be concurrently administered to treat residual thrombus. Although mechanical thrombectomy has the advantage of increasing the rate of thrombus breakdown, it is associated with a risk of distal embolization and hemolysis.

Compartment Syndrome

Compartment syndrome can develop during reperfusion as previously ischemic tissue swells within a confined fascial space of the calf or forearm. The incidence of compartment syndrome correlates with length and severity of ischemia. Severe pain is common, and neurologic changes portend a bad outcome. Distal pulses may be normal. Loss of sensation over the first web space is an early sign of a progressing compartment syndrome as the common peroneal nerve is compressed in the anterior compartment of the calf which is most sensitive to ischemia.

The diagnosis of compartment syndrome is made on clinical grounds, although compartment pressures may be helpful in guiding treatment. Fasciotomies are warranted if the difference between the diastolic pressure and the intercompartmental pressure is less than 10 mm Hg. During fasciotomy, care is taken to release every compartment and to open the skin over its entire length. The wound is kept open until muscle edema resolves. Incomplete skin release and attempts at early closure are to be avoided because they may lead to muscle necrosis. Delayed closure with split-thickness skin graft may be necessary. Delayed recognition and management of compartment syndrome has devastating consequences and can lead to both limb loss and mortality. An aggressive posture toward early, complete fasciotomy improves outcomes.

Postoperative Management

After successful embolectomy, patients with peripheral macroembolism should undergo anticoagulation therapy with heparin and conversion to warfarin as the risk of recurrent peripheral arterial embolism approaches 30%. Patients are maintained on lifelong anticoagulation therapy in the setting of cardiogenic embolism or when the source of embolism cannot be identified. Patients with microembolization caused by atherosclerotic plaque rupture benefit from antiplatelet agents that are purported to stabilize ulcerative plaque. In addition, evidence shows a benefit for use of antiinflammatory nonsteroidal agents to reduce local inflammation associated with microemboli.

After successful revascularization, workup to evaluate for the source of arterial embolism ensues. Transthoracic echocardiography, TEE, and CTA of the thoracic and abdominal aorta are performed. In cases of lower extremity embolization, and when no source is identified, a CTA or angiogram of the affected limb may identify a culprit atherosclerotic plaque. If a discrete noncardiogenic source is identified, it is addressed as long as the risk of the procedure is acceptable. Stent grafts have been used in the thoracic and abdominal aorta to treat both aneurysms and ulcerative plaque responsible for embolization. Aortobifemoral bypass and infrainguinal bypass have also been used. Atherosclerotic lesions in the arch of the aorta are difficult to address and therefore tend to be treated conservatively.

OUTCOMES/RESULTS

Patients with acute peripheral arterial emboli are usually elderly and have multiple associated medical comorbidities. Management of these patients is challenging, and operative mortality with open embolectomy is reported to be between 20% and 30%. The mortality rate has not changed significantly over the last decade, despite overall improvement in medical care. Limb salvage for survivors, however, is excellent, with rates approaching 80%. Limb salvage among patients with in situ thrombosis tends to be significantly lower. Depending on the source, recurrent emboli can occur in up 20% to 30% of patients despite appropriate anticoagulation therapy.

Acute Peripheral Arterial and Bypass Graft Occlusion: Thrombolytic Therapy

Gregory J. Landry, MD

OVERVIEW

Acute lower extremity arterial occlusion remains one of the most challenging clinical conditions encountered by vascular surgeons. Early recognition is critical in maximizing clinical outcomes. Options for treatment include both surgical and endovascular techniques. Despite significant technologic advances in this area, particularly in endovascular technology, morbidity—in particular, limb loss—and mortality remain high in this patient group. In this chapter, the current status of endovascular management of acute lower extremity arterial and graft occlusion is summarized.

PATIENT PRESENTATION AND WORKUP

History and Physical Exam

Prompt recognition of acute limb ischemia is critical for treatment success. In this regard, the six P's (*p*ain, *p*ulselessness, *p*allor, *p*oikilothermia, *p*aresthesias, and *p*aralysis) remain important clinical signs, either alone or in combination. It is important to note that patients with significant motor or sensory dysfunction have advanced ischemia with limited time for revascularization and high risk of limb loss. Given the time required for complete endovascular intervention, prompt surgical revascularization should be considered in this patient cohort. Patients with intact motor and sensory function are more appropriately considered for endovascular revascularization.

Acute native arterial occlusion is generally either embolic or thrombotic in nature. Embolic occlusion is most frequently (>80%) cardiac in origin, so history of arrhythmia, congestive heart failure, coronary artery disease, or valvular disease should be elicited. Noncardiac sources of emboli include atheroemboli from a proximal atherosclerotic lesion or mural thrombus from proximal aneurysmal disease.

Thrombotic occlusion tends to occur in the setting of underlying native atherosclerotic disease. While both may be of abrupt onset, embolic disease tends to be more severe symptomatically, as opposed to thrombosis of an underlying diseased artery in which some degree of native arterial collateralization may have already occurred. Acute thrombotic occlusion can also occur in association with hypercoagulable states.

Likewise, in cases of lower extremity bypass graft occlusion, the degree of presenting symptomatology may vary. Autogenous graft occlusion tends to occur in the face of antecedent vein graft stenosis, detectable with duplex surveillance, and tends to result only in occlusion of the graft itself. As such, patients tend to present with recurrence of their prebypass symptoms—that is, claudication or rest pain. In contrast, prosthetic graft occlusion often occurs without duplex-detected stenosis and frequently results not only in graft occlusion but also occlusion of native arterial outflow. As such, presenting symptoms may be worse than those present prior to the initial bypass.

In addition to examination of the affected extremity, examination of the contralateral extremity can give important clues as to the nature of the ipsilateral occlusion. Normal pulses throughout the contralateral extremity, in particular in a patient without other atherosclerotic risk factors, suggest an embolic process, whereas diminished pulses or reduced ankle:brachial index in the contralateral extremity suggest the presence of underlying atherosclerotic disease. However, the possibility of bilateral emboli must also be considered.

After the initial assessment, patients should be classified according to the Society for Vascular Surgery/International Society for Cardiovascular Surgery (SVS/ISCVS) system, with category I: viable, not immediately threatened; category IIa: marginally threatened, salvageable if promptly treated; category IIb: immediately threatened, salvageable with immediate revascularization; and category III: irreversible, major tissue loss or permanent nerve damage inevitable.

Patients for whom thrombolysis is most appropriate are those in category I and possibly IIa, with category IIb requiring a more immediate attempt at surgical revascularization.

Imaging

Duplex ultrasound is generally the most readily available diagnostic imaging modality. Abrupt arterial occlusion with "water hammer" pulse in the proximal patent artery is seen in embolic occlusion. In thrombotic occlusion, atherosclerotic arterial wall abnormalities are seen, often with extensive collateralization around the area of occlusion. Computed tomographic (CT) and magnetic resonance (MR) angiography can give accurate anatomic information regarding the nature and location of arterial occlusion, but in most cases, they are not necessary. If contrast arteriography is planned, CT angiography has the disadvantage of increasing exposure to both iodinated contrast and radiation. It does, however, provide a rapid assessment as opposed to magnetic resonance imaging (MRI), which requires a longer acquisition time and also carries the potential risk of nephrogenic systemic fibrosis in patients with renal dysfunction.

Arteriography remains the gold standard for diagnosis with the additional benefit of allowing simultaneous percutaneous access for thrombolysis. As such, arterial access for arteriography should be chosen with this possibility in mind.

Medical Management

Regardless of etiology or therapy chosen, initial medical management should consist of intravenous hydration, supplemental oxygen, antiplatelet therapy (aspirin 81-325 mg orally) if the patient is not already taking it, and initiation of a continuous intravenous heparin infusion, with an initial bolus of at least 100 U/kg followed by a continuous infusion of at least 10 U/kg/hr, with a goal of maintaining the partial thromboplastin time at least twice normal.

Catheter Directed Thrombolysis

The indications for performing catheter-directed thrombolysis are relative and subject to debate. The most frequently accepted indication for thrombolysis is acute thrombosis (<14 days) of a native artery or bypass graft in patients of Rutherford class I or IIa. In Rutherford class IIa and IIb patients, adjunctive mechanical thrombectomy should be considered to reduce treatment and, thus, ischemic times. The surgeon's judgment is necessary to determine which patients should undergo direct surgical revascularization. Additional indications for thrombolysis include acute arterial embolus not accessible with embolectomy, acute popliteal artery aneurysm occlusion without identifiable runoff (in which thrombolytic therapy may reestablish runoff for subsequent surgical therapy), or in patients who are felt to be too high risk for surgery. Both absolute and relative contraindications for catheter-directed thrombolysis exist and are listed in Box 1.

Results of Thrombolysis

Three large randomized controlled trials comparing surgical with thrombolytic therapy in acute limb ischemia were performed in the 1990s and remain the only such trials in the medical literature: the Rochester (1994), Surgery Versus Thrombolysis for Ischemia of the Lower Extremity (STILE) (1996), and Thrombolysis or Peripheral Arterial Surger (TOPAS) (1996, 1998) trials. Results of these trials are summarized in Table 1.

In the Rochester trial, 114 patients with ischemia duration of less than 1 week were equally randomized to surgery or thrombolysis

BOX 1: Contraindications to catheter-directed thrombolysis

Absolute
Active bleeding
Gastrointestinal bleeding within 10 days
Stroke/TIA within 2 months
Neurosurgical intervention or intracranial trauma within 3 months

Relative
Cardiopulmonary resuscitation within 10 days
Major surgery or trauma within 10 days
Hypertension (SBP >180 mm Hg, DBP >110 mm Hg)
Intracranial tumor or arteriovenous malformation
Recent eye surgery
Diabetic hemorrhagic retinopathy
Intracranial tumor
Hepatic failure
Bacterial endocarditis
Pregnancy

TABLE 1: Results of randomized trials of thrombolysis

Trial	Number of patients	Length of follow-up (months)	Limb salvage—thrombolysis (%)	Limb salvage—surgery (%)	Survival—thrombolysis (%)	Survival—surgery (%)
Rochester (1994)	114	12	82	82	84	58
STILE (1994) overall	393	6	88	87	93	91
STILE (1994) ≤14 days ischemia	112	6	89	70	94	90
STILE (1994) >14 days ischemia	275	6	88	97	93	92
STILE (1996) native artery	237	12	90	100	89	85
STILE (1996) bypass graft	124	12	82	70	94	100
TOPAS (1998)	544	12	65	70	80	83

STILE, Surgery Versus Thrombolysis for Ischemia of the Lower Extremity; *TOPAS,* Thrombolysis or Peripheral Arterial Surger.

with urokinase. A significant survival advantage at 12 months was noted in the thrombolysis group (84% vs 58%, $P = 0.01$), which was largely due to increased cardiovascular morbidity and mortality in the surgery group. No difference in limb salvage was noted. Interestingly, the increase in cardiovascular mortality was not substantiated in the subsequent larger TOPAS trial.

The STILE trial was stopped early by the Safety Monitoring Committee due to a higher number of adverse outcomes in the group randomized to thrombolytic therapy, likely due to enrollment of patients with ischemia out to 6 months. In post hoc subgroup analysis, patients with duration of ischemia greater than 14 days had significantly improved amputation rates with surgery compared to the thrombolytic group at 6 months (3% vs 12%), but lower amputation rates were noted in the thrombolytic group if the duration of ischemia was less than 14 days (11% vs 30%). In the thrombolysis group for those with native artery ischemia, there was also a significant reduction in the level of surgical procedure performed—that is, initial thrombolysis reduced the magnitude of the subsequent surgical procedure required for revascularization. Subgroup analysis for bypass grafts similarly showed improved amputation rates for those with bypass graft occlusion less than 14 days treated with thrombolysis. Among patients with bypass grafts, greater morbidity was encountered in those with prosthetic grafts compared with autogenous grafts. It should be noted, though, that over 80% of the patients in the trial had an ischemia duration of over 14 days, so the subgroup analysis of the less than 14 days group has relatively small numbers.

The TOPAS trial was the largest of the three randomized trials, with 544 patients enrolled with an ischemia time of less than 14 days. Patients with all forms of ischemia (native artery thrombosis, prosthetic and vein graft thrombosis) were included. One-year limb salvage and mortality were not significantly different between the surgical and thrombolysis groups. The need for open surgical procedures was significantly reduced in the thrombolytic group (54% vs 91%, $P > 0.001$), which is not surprising given the study design.

A subsequent meta-analysis of the randomized trials showed no significant differences in limb salvage or mortality at 30 days, 6 months, and 12 months between patients treated with thrombolysis or surgery. While patients undergoing thrombolysis have a less severe degree of surgical intervention (odds ratio [OR] 5.4, 95% confidence interval [CI] 4.0-7.2), they also experience a higher rate of stroke, hemorrhage, and distal embolization. These findings have been substantiated in a number of large nonrandomized registries and clinical trials. Given these findings, thrombolysis for acute limb ischemia is appropriate for selected patients but does not supplant the need for open surgical revascularization, particularly in those with a longer duration or more severe presentation of ischemia.

Techniques of Thrombolysis

Competency in basic catheter and guidewire skills is essential to successfully perform peripheral thrombolysis. Access for thrombolysis is typically "up and over" from the contralateral side. Antegrade ipsilateral access can also be used, but this is less optimal for long-term infusion, particularly in patients with an abdominal pannus in which the catheter may be prone to kinking. Upper extremity access is suboptimal because the catheter would cross the vertebral artery origin. To minimize the risk of multiple punctures, posterior wall puncture, side wall puncture, or high (external iliac) or low (superficial or profunda femoral) puncture, ultrasound-guided access using a micropuncture (21-gauge) needle is preferred. Up and over access can be achieved with any standard curved catheter depending on the operator's choice. Guidewire placement into the contralateral external iliac or common femoral artery facilitates catheter placement over the aortic bifurcation. The initial starter wire can then be exchanged for a stiff wire, over which a sheath can be placed. Most thrombolytic infusion catheters can be placed through a 5 French (F) sheath, whereas mechanical thrombectomy devices may require a 6 to 8 F sheath.

Arteriography performed through a diagnostic catheter or through the sheath will show the site of arterial occlusion and will also give additional information about the nature of the occlusive process, showing abrupt occlusion with little collateralization in embolic occlusions and evidence of atherosclerotic disease (luminal irregularity, collateralization) in thrombotic occlusion. In a vein graft occlusion, knowledge of the site of origin of the graft is critical in locating the proximal graft. Often a small stump of patent graft will be present, but flush occlusion is also possible. Multiple oblique projections may be necessary to determine the optimal site of access of the occluded graft.

The next step is traversal of the occluded segment. Fresh thrombus is generally easy to traverse with standard 5 F catheters and 0.035-inch wires. A good catheter/guidewire combination to use in this setting is a catheter with a straight or slightly curved tip in association with either a straight or curved hydrophilic wire. In the presence of more chronic atherosclerotic disease, microcatheters (3 F) and wires (0.014-inch or 0.018-inch) may be necessary. In the acute setting, reentry into the patent native artery is rarely difficult. Reentry devices such as the Outback or Pioneer catheters may occasionally be necessary, but they are more typically used in the chronic setting. Once crossed with a guidewire, a catheter should be placed distal to the site of occlusion and contrast injected to ensure intraluminal placement.

A multisidehole infusion catheter is used for the lytic infusion. The infusion length of most multisidehole catheters ranges from 5 to 20 cm. The infusion length should ideally equal the length of occlusion, with all of the sideholes embedded in the thrombus. Sideholes outside of the thrombus are less effective in facilitating lysis because the agent generally washes out through collaterals. For longer occlusions, an infusion wire can be placed through the catheter, with lytic infusion administered simultaneously through both the catheter and the wire.

Proper securing of the sheath and catheter is critical to prevent dislodgement or movement of the devices. The sheath should be sutured to the skin and a sterile occlusive dressing placed over the sheath/catheter/infusion wire system.

Lytic Agents

Currently used lytic agents include urokinase (UK) and recombinant tissue plasminogen activator (rt-PA). Both act indirectly by converting plasminogen to plasmin, which, in turn, cleaves fibrin, leading to clot resolution. The safety and efficacy of these agents appear equal in studies to date, although there is some evidence that clot resolution occurs more quickly with rt-PA. Alfimeprase is a direct thrombolytic agent that has also been shown to be efficacious, although not studied as extensively as UK and rt-PA. Streptokinase is mainly of historical interest because it is less efficacious and more antigenic than the other agents.

A number of techniques can be used for lytic infusion. The most frequently used is the "pulse-spray" technique, in which an initial forced infusion bolus is followed by a continuous infusion. Urokinase is typically given as a 240,000-U bolus, followed by an infusion of 60,000 U/hr. Tissue plasminogen activator bolus and infusion rates vary, with a typical initial bolus of 1 to 5 mg, followed by an infusion rate of 0.125 to 2 mg/h. Simultaneous infusion of heparin, 500 U/hr, through the sheath is recommended to prevent thrombus formation on the catheter. The lytic agent and heparin should not be infused through the same catheter because precipitation can occur.

After initiation of therapy, patients should be monitored in an intensive care unit for potential complications of thrombolysis. Minor bleeding occurs in 15% of patients, with major bleeding in roughly 5% and intracranial bleeding in 1% to 2.3%. Distal embolization is occasionally encountered as thrombus dissolution occurs,

occurring in 1% to 20% of cases, depending on the series. This typically manifests as an increase in pain distal to the site of infusion. This is typically transient and resolves with continuation of therapy or catheter repositioning. Reperfusion may also be associated with compartment syndrome or rhabdomyolysis. In general, the risk of complications correlates with duration of therapy, with an overall complication rate of 4% at 8 hours and 34% at 40 hours. Examples of successful thrombolysis are shown if Figure 1 (occluded bypass graft) and Figure 2 (native artery occlusion).

Mechanical Thrombolysis

A number of devices are available as adjuncts to chemical thrombolysis (Table 2). Mechanical thrombolysis has the theoretical advantage of reducing the overall length of time required for catheter-directed thrombolysis. Many devices are approved only for use in thrombosed dialysis access, but some are also appropriate for use in the periphery. A general classification of mechanical thrombectomy devices includes suction thrombectomy, hemodynamic (rheolytic) devices, rotational devices, and ultrasonic devices.

Suction Thrombectomy

Simple aspiration catheters can be used to manually extract thrombus. The catheters are connected to a stopcock and large syringe, which creates a vacuum for clot removal. This is a low-cost technique because ancillary capital equipment is not required, but it does carry the risk of vessel wall injury during clot extraction. An additional use for suction thrombectomy catheters is the removal of distal embolic debris during percutaneous catheter-based procedures. Examples of suction thrombectomy devices include Pronto, Xpress, and Export catheters.

Rheolytic Devices

Rheolytic thrombectomy devices work by creating negative pressure at the catheter tip (Venturi effect) through saline pumps. Because the method of extraction is not through direct mechanical forces but rather through negative pressure at the catheter tip, risk of vessel wall damage is less than with the aspiration devices. Examples of such devices include the AngioJet, Hydrolyzer, Oasis, and ThromCat systems, of which only the AngioJet is currently FDA approved for use in the periphery. The device is most frequently used as an adjunct to pharmacologic thrombolysis, allowing reduced overall procedure time, but it can potentially be used as a stand-alone device in cases where pharmacologic thrombolysis is contraindicated.

Of all the mechanical thrombectomy devices currently available, the largest clinical experience has been with the AngioJet device. Technical success rates range from 56% to 95%, with distal embolization rates up to 10%. Another potential complication is hemolysis with associated renal dysfunction, so a treatment time of less than 10 minutes is advised by the manufacturer.

Rotational/Infusion Devices

The Trellis catheter has gained popularity for use in acute limb ischemia. This device combines rotational dynamics with drug infusion. A multisidehole sinusoidal infusion catheter is positioned between two balloons. After catheter positioning, the balloons are inflated to isolate the site of occlusion and to minimize the risk of distal embolization. When the catheter is activated, lytic agent is infused as the catheter oscillates, causing both clot fragmentation and dissolution. After 10 minutes of treatment, the proximal balloon is deflated, and the thrombus is aspirated through an 8 F sheath prior to deflating the distal balloon. In small series, technical success rates of up to 90% have been reported, although distal embolization occurs in up to 11% of cases.

Ultrasonographic

The EKOS device uses ultrasonic waves to augment chemical thrombus dissolution. The device combines a multisidehole infusion catheter with a coaxial ultrasonic core. Saline coolant and the lytic agent can be infused simultaneously when the catheter is activated. Thrombus deformation by the ultrasonic wave increases the surface area

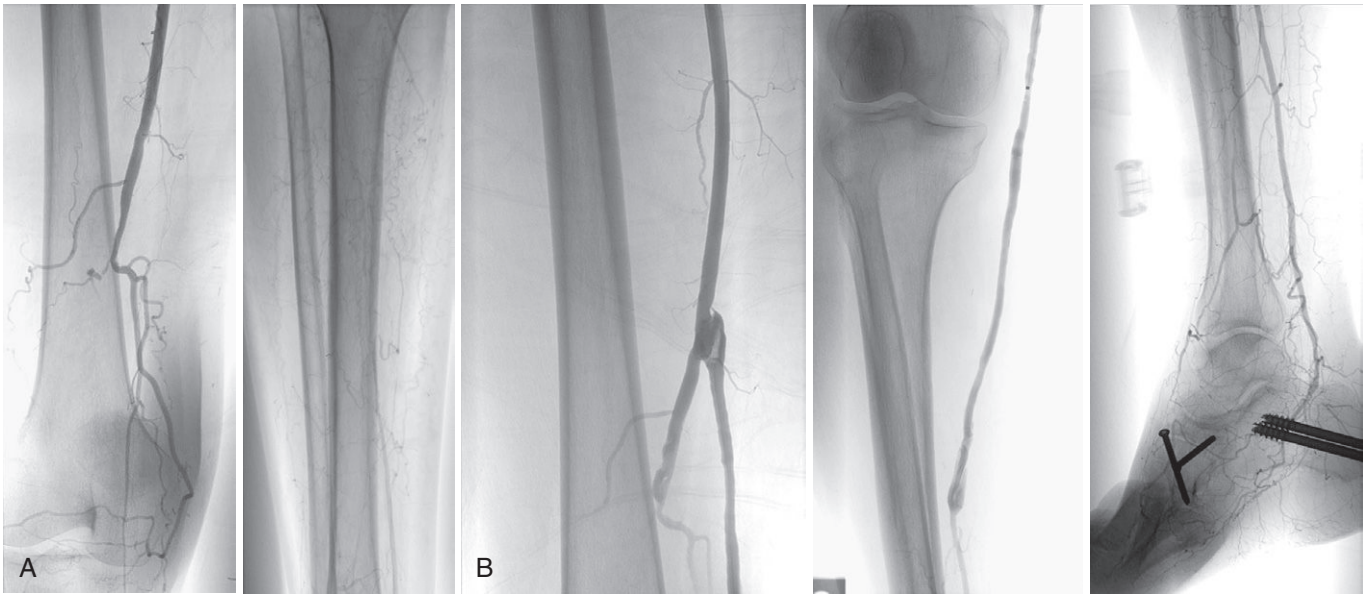

FIGURE 1 **A,** Angiogram demonstrating occlusion of superficial femoral to posterior tibial reversed saphenous vein graft. Minimal distal collateralization with weak reconstitution of distal posterior tibial artery. **B,** Postinfusion arteriogram at 24 hours demonstrating patency of graft with residual chronic thrombus present in proximal anastomosis. Markedly improved posterior tibial runoff. Patient subsequently underwent open revision of vein graft with removal of chronic thrombus from proximal hood of graft.

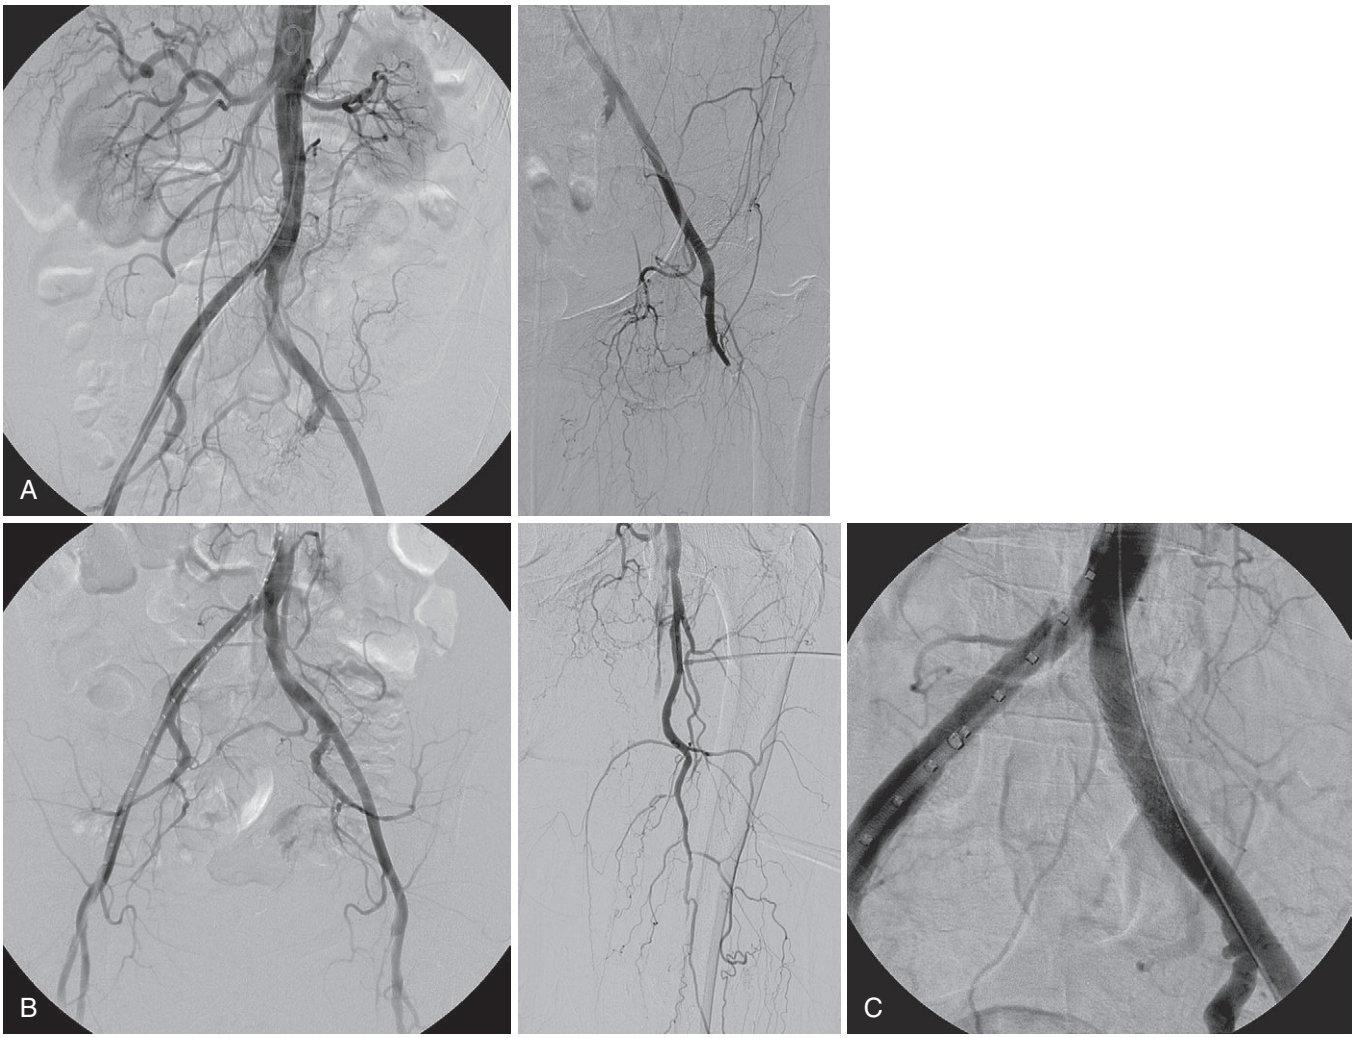

FIGURE 2 **A,** Arteriogram demonstrating acute thrombus in left common iliac artery, and occlusion of left internal iliac artery and left superficial and profunda femoral arteries. **B,** Postinfusion arteriogram at 24 hours showing resolution of thrombus in common and internal iliac and profunda femoral arteries. Superficial femoral artery found to be chronically occluded. Distal leg perfusion was present through internal iliac and profunda femoral collaterals, resulting in limb salvage. **C,** Left common iliac artery stenosis treated with balloon expandable stent with no residual stenosis.

TABLE 2: Mechanical thrombectomy devices

Mechanism	Name, manufacturer	Sheath size (French)	Guidewire (inches)	Working length (cm)
Suction thrombectomy	Pronto, Vascular Solutions	5.5-10	0.014-0.035	115-140
	Xpress, Atrium	6-7	0.014	140
	Export, Medtronic	6-7	0.014	140-145
Rheolytic devices	AngioJet, Possis/Medrad	4-6	0.014-0.035	50-145

	OmniWave, Cybersonics	7	0.018	100

exposure for the lytic agent. In small, uncontrolled series, treatment times have been shown to be significantly reduced with ultrasound augmentation.

CONCLUSION

Since its initial use over 30 years ago, catheter-directed thrombolysis for acute arterial and bypass graft occlusion has grown and now can be considered the procedure of choice in some patients, particularly those with minimal or no symptoms and with ischemia duration of less than 14 days. While previously in the purview of interventional radiology, the acquisition of advanced catheter and guidewire skills among vascular surgeons has led to this technique becoming an important component of the vascular surgical armamentarium. While still associated with significant morbidity and mortality, technical advances continue to reduce treatment times and associated risks.

ATHEROSCLEROTIC RENAL ARTERY DISEASE

Francis J. Caputo, MD, and Gregorio A. Sicard, MD

INTRODUCTION

Twenty to thirty percent of the population in the United States is hypertensive. Approximately 5% of patients with hypertension will have renovascular hypertension. While renal artery disease includes many different pathophysiologies, this chapter focuses on atherosclerotic renal artery stenosis (RAS), the most common cause of RAS. Atherosclerotic RAS has been implicated as a major contributor to systemic hypertension as well as impaired renal function. However, rarely is RAS the sole contributor to these two multifactorial clinical pathologies. Although the incidence of RAS may be as high as 45% in high-risk groups, no data are available to justify prophylactic treatment of patients with asymptomatic disease. In fact, the majority of patients with symptomatic RAS will be medically managed, and revascularization will be unwarranted.

INCIDENCE

Ninety percent of RAS is due to atherosclerosis. Autopsy reports found increased prevalence of significant RAS with increasing age: 6% in patients younger than 55 years, 18% in patients 65 to 74 years of age, and 40% in patients older than 75, with the proximal renal artery being the most common location. The prevalence of unsuspected renal artery stenosis in 5194 consecutive autopsies found RAS greater than 50% in 4.3% of the patient population, with 73% of these patients having had a history of hypertension. The prevalence of RAS increases as a population becomes more high risk (Table 1).

NATURAL HISTORY OF RENAL ARTERY STENOSIS

Anatomic Progression

While RAS is often implicated as a cause of hypertension and worsening renal function, frequently RAS is an incidental finding either through a screening test or while undergoing intraabdominal imaging, computed tomographic angiography (CTA), magnetic resonance angiography (MRA), or arteriography for other reasons. Although

TABLE 1: Prevalence of renal artery stenosis in high-risk populations

Population	Prevalence
All commers	0.1%
Hypertensive	4.0%
Hypertensive and coronary artery disease	30%
Malignant hypertension	20% to 30%
Renal insufficiency and malignant hypertension	30% to 40%

the severity of RAS is an independent predictor of mortality (Table 2), it is uncertain as to whether RAS is a direct cause or just a marker of decreased survival. Thus, the importance of treating "silent lesions" remains to be fully understood. In angiographic studies, the percentage of patients showing progression of renal artery atherosclerosis ranged from 11% to 44%, and approximately 10% to 16% progressed to complete occlusion in arteries that previously had severe stenosis. Interestingly, only 3% had loss of a previously reconstructible renal artery. Duplex ultrasound has also been used in surveillance of RAS. Zierler and colleagues performed serial duplex ultrasounds on 90 patients diagnosed with renovascular hypertension. The patients' arteries were classified as normal, less than 60% stenosis, or greater than 60% stenosis. At the 3-year follow-up, 8% of normal arteries and 43% of arteries with less than 60% stenosis had progressed to greater than 60% stenosis. Seven percent of arteries surveyed progressed to complete occlusion, but this only occurred in arteries with a preexisting lesion that was less than 60%.

Functional Progression

The implication of RAS on functional end points has been studied using ultrasound surveillance. Dean and colleagues found that 46% of patients ($n = 41$) being treated with medical therapy showed a significant rise in serum creatinine, and 37% of patients had lost more than 10% of renal length. At a 33-month follow-up, Caps and colleagues observed renal atrophy (loss of 1 cm length) of 5.5%, 11.7%, and 20.8% in renal arteries classified as normal, less than 60% stenotic, and greater than 60% stenotic, respectively. Other factors correlated with renal atrophy include elevated creatinine, systolic blood pressure of greater than 180 mm Hg, peak systolic velocity of greater than 400 cm/sec, and an end diastolic velocity of less than 5 cm/sec. Schrieber and colleagues showed that a large number of patients with greater than 60% RAS had increased creatinine.

TREATMENT

Patient Selection

Although RAS is a negative predictor for cardiovascular morbidity and mortality, no consensus statement has been made regarding treatment of RAS. Furthermore, no level 1 data show that revascularization of asymptomatic RAS leads to better outcomes and survival as compared to medical management. Therefore, we reserve revascularization of patients with RAS for those patients with renovascular hypertension nonresponsive to maximal medical therapy and for those patients with renovascular hypertension and concomitant worsening of excretory renal function. Flash pulmonary edema is an uncommon manifestation of RAS—in particular, bilateral RAS or high-grade RAS in a single kidney. These patients often benefit from revascularization.

TABLE 2: Renal artery stenosis–independent predictor of mortality

Severity of renal artery stenosis	4-year survival
50%	70%
75%	68%
>95%	48%

Medical Therapy

As mentioned before, patients with RAS, even if asymptomatic, are at increased risk of cardiac mortality and morbidity. Therefore, all patients with diagnosed RAS should be treated for hypertension and risk factors associated with progression of atherosclerosis. Goals of therapy include aggressive treatment of hypertension, smoking cessation, aggressive lipid-lowering strategies, and antiplatelet therapy.

Hypertension Control

Control of hypertension remains a key component in patients with RAS. While there are several classes of medication to control blood pressure, particular interest has been given to angiotensin converting enzyme inhibitors (ACEI) and angiotensin receptor blockers (ARBs). Since a leading mechanism of hypertension due to RAS is secondary to the effects of the increased renin-angiotensin pathway, it makes sense that inhibiting this pathway would prove to be a favorable therapeutic maneuver. Furthermore, several studies have suggested that in patients with preexisting cardiovascular disease, treatment with ACEI leads to reduction in total mortality and adverse cardiovascular events, as well as being renoprotective in patients with nephropathy. ACEI/ARBs have been associated with renal failure in patients with severe RAS, most often in patients with bilateral severe RAS or high-grade RAS in a single kidney. Although physicians are hesitant to use ACEI or ARBs in patients with bilateral RAS due to the potential of acute deterioration of renal function, this is uncommon. While ARBs/ACEI should be the initial treatment of hypertension in patients with renovascular hypertension, additional medications may be needed when blood pressure is difficult to control.

Lipid-Lowering Agents

Statins remain the cornerstone of treating hypercholesterolemia in patients with atherosclerosis and its associated morbidities. It has been shown that statins prevent coronary artery disease, decrease myocardial infarction rates, prevent progression of atherosclerosis, and decrease cardiovascular death. While few studies have correlated statin use with outcomes of patients with RAS, Cheung and colleagues showed a reduction of 72% in risk for angiographic progression of patients with RAS. Statins have been shown to decrease progression of disease in carotid artery stenosis as well as peripheral vascular disease.

Antiplatelet Therapy

While aspirin or clopidogrel has not been shown to directly affect RAS, antiplatelet therapy has been shown to be important in the decrease of adverse cardiovascular events and mortality in patients with significant atherosclerotic burden. Also, antiplatelet therapy is an important adjunct when endovascular revascularization is employed for RAS. Typically patients are loaded with clopidogrel either preoperatively or immediately postoperatively after percutaneous revascularization. Antiplatelet therapy presumably decreases immediate thrombotic events as well as helps prevent progression of restenosis.

Other Risk Modifications

It is recommended, as in other high-risk populations, that patients should be counseled in smoking cessation. Smoking has been implicated in endothelial cell damage, increased low-density lipoprotein (LDL) cholesterol, increased platelet aggregation, and a source of oxidative stress. Furthermore, smoking leads to increased vasoconstriction, increased heart rate, and increased blood pressure. Smoking cessation has shown to improve survival in patients with peripheral arterial disease (PAD) as well as coronary artery disease (CAD). In

fact, patients who quit smoking have a 13% decreased reduction in risk for all-cause mortality.

Additionally, patients with documented diabetes and concomitant atherosclerosis are at increased risk of progression of disease. While intensive glycemic control has not been shown to decrease cardiovascular events, good glycemic control (hemoglobin A1c <7.0%) does help prevent microvascular complications.

Surgical Therapy

We reserve surgical intervention, whether endovascular or open, to patients with refractory hypertension despite maximal medical therapy as well as patients with hypertension and concomitant progressive decreasing renal function. While endovascular revascularization is technically feasible and early-patency is excellent, increased restenosis rates as well as lack of long-term patency data lead us to prefer open surgical revascularization when the patient is a good candidate.

Unilateral Renal Artery Stenosis

In patients with unilateral RAS, we prefer a retroperitoneal approach to renal revascularization. While direct aortorenal bypass is possible through this exposure, we prefer ileorenal bypass if the common iliac is free of plaque and calcific disease. With the patient in the lateral decubitus position, a curvilinear incision is performed extending from just lateral to the rectus muscle and sheath to the 12th rib (Figure 1). This incision is carried down through the subcutaneous tissue and fascia. The anterior sheath is divided, and the 12th rib is excised. The internal oblique and transversalis muscles are divided, and the retroperitoneum is entered just lateral to the junction of the rectus sheath in the lateral abdominal wall muscles. The peritoneum is then mobilized medially and cephalad. Once the peritoneum is mobilized, the ureter is identified and gently dissected down to the level of the distal common iliac artery inferiorly and superiorly to the level of the renal pelvis. If the dissection is being performed on the left side, it is often necessary to identify and ligate the gonadal vein as well as the inferior lumbar branch of the left renal vein. Once the ureter is mobilized, Gerota's fascia is entered, and the kidney is circumferentially mobilized. The renal artery is identified and dissected to its junction with the aorta. At this point, the patient is systematically heparinized, the common iliac artery is clamped, and an end-to-side anastomosis is performed to our conduit. We prefer to use saphenous vein, but if deemed unsuitable (<3 mm, sclerotic), PTFE is used. Once the iliac anastomosis is performed, the renal artery is mobilized proximally and doubly ligated with silk suture. Iced slush is applied over the kidney to decrease its temperature, and an end-to-end anastomosis is performed between the conduit and the renal artery in a running or interrupted fashion, depending on the size of the renal artery. Doppler signals confirm flow in the renal artery and the renal parenchyma. In patients with right-sided RAS (Figure 2), it is important to circumferentially mobilize the right renal vein at the lateral border of the inferior vena cava in order to fully dissect the right renal artery. In instances where two small diseased renal arteries are identified (Figure 2, *A*), it may be necessary to surgically combine the two arteries into one larger orifice to facilitate revascularization (Figure 2,*B*).

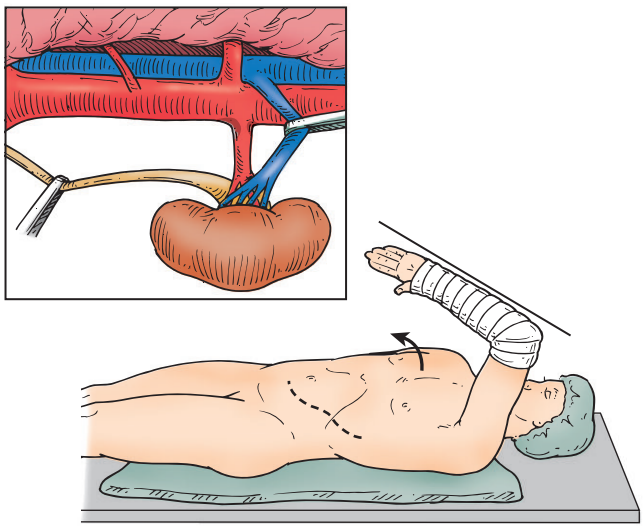

FIGURE 1 Proper positioning of patient for retroperitoneal dissection includes right lateral decubitus, with flexion of bed and elevated kidney rest. Dashed line shows planned incision from 12th rib to umbilicus. *(Inset)* Left renal vein is fully mobilized with ligated left gonadal vein. Ureter is dissected from surrounding tissue, and disease is shown at ostium of left renal artery.

Bilateral Renal Artery Stenosis

In patients with bilateral RAS, often the renal artery plaque is an extension of aortic wall atherosclerosis. In this situation, bilateral renal endarterectomy is the procedure of choice. While transaortic endarterectomy has been described, transrenal endarterectomy (Figure 3) allows direct visualization of distal end points and permits tacking sutures if necessary. A midline incision is made from the xiphoid process to the symphysis pubis. The linea alba is incised and the peritoneal cavity is entered. It is necessary to extend the incision superior along one side of the xiphoid process to allow full abdominal wall mobilization. The posterior peritoneum overlying the aorta is incised, the ligament of Treitz is sharply dissected, and the duodenum is mobilized. The small bowel is eviscerated and retracted to the right. The aorta is identified and dissected in a cephalad direction until the renal vein is identified. Circumferential dissection of the renal vein is necessary, as is dissection of the immediate inferior vena cava superiorly and inferiorly 2 cm. Usually, the gonadal and adrenal veins must be ligated, as well as the inferior lumbar branch of the left renal vein. This allows full visualization of both renal arteries. Once both renal arteries are fully mobilized, the patient is systemically heparinized, the aorta is clamped above and below the renal arteries, and a transverse incision is made across both renal arteries (Figure 3). An endarterectomy is performed using a dural elevator, and any concerning flaps at the distal end point are tacked with 6-0 Prolene suture. A Dacron patch closure (Figure 3,*B*) is then used to close the aortotomy and prevent narrowing.

Other Surgical Options

Other surgical techniques, including splanchnorenal bypass and renal artery transposition, have been described. This may be necessary in situations where the aorta or iliac is of inadequate quality to provide inflow for revascularizations. Situations may include ectatic vessels as well as severe calcification.

Open Surgical Results

Open renal artery carries an approximate mortality of 0.8% for isolated renal artery repair and 1.6% for bilateral renal artery revascularization. While perioperative morbidity can be as high as 20%, patients who ended up on permanent dialysis within 30 days of their revascularization were less than 1%. The majority of patients (85%) exhibit improved hypertension, and more than 50% of patients have improved renal function. Open repair of RAS has a patency of greater than 95% at 2 years as surveilled by duplex ultrasonography.

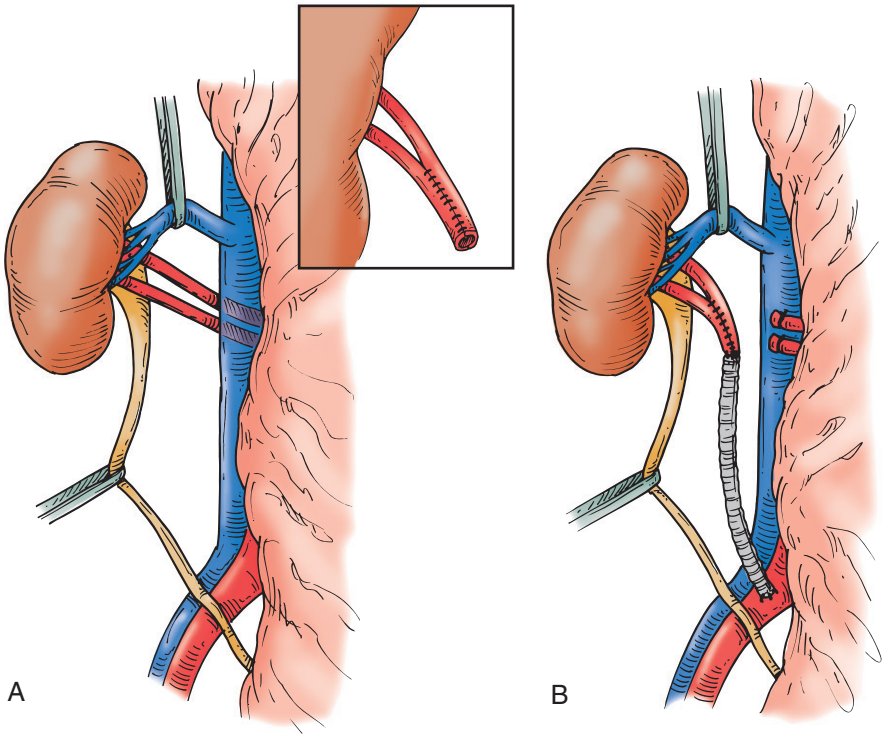

FIGURE 2 **A,** Right retroperitoneal dissection is shown, with kidney having two small diseased arteries. A circumferentially dissected left renal vein is retracted cephalad. The two arteries are surgically combined into one main trunk. **B,** Completed right ileorenal bypass with PTFE is shown.

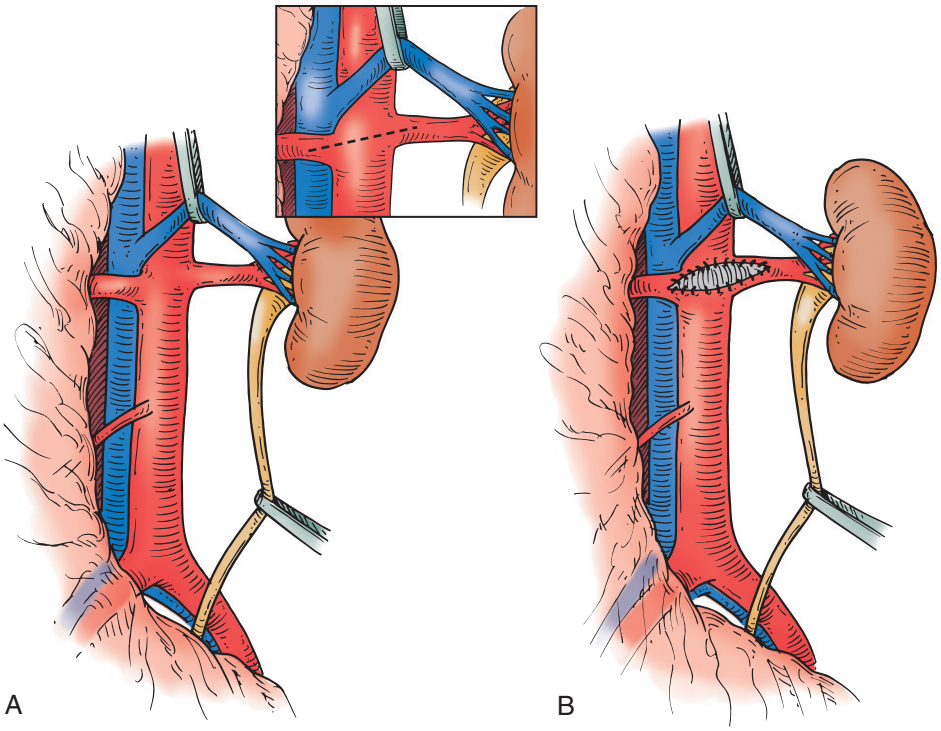

FIGURE 3 **A,** Exposure of the juxtarenal aorta and bilateral diseased renal arteries. Dashed line shows path of transrenal arteriotomy in preparation for endarterectomy. **B,** Completed patch angioplasty after endarterectomy is shown.

Endovascular Revascularization

While open surgical revascularization has excellent results in terms of outcomes and patency, there is a significant morbidity associated with repair. Also, many patients with advanced hypertension and progressive renal failure have concomitant comorbidities that preclude them from being open surgical candidates. Therefore, an alternative to open revascularization is percutaneous angioplasty and stenting (PTAS). While PTAS has excellent short-term results, restenosis rates can be as high as 60%. Contributors to increased rates of restenosis include small vessels, female gender, multiple lesions, and diffuse aortic atherosclerotic disease. Optimal renal artery size for stenting is greater than 5 mm with a single focal ostial lesion.

Renal Artery Stenting

The key to renal artery stenting is understanding that in most instances, renal artery lesions are ostial and are extensions from the aorta. Thus, the stent needs to be placed just outside the ostium in

order to provide a lumen from the encroaching aortic plaque. We use a 6F system. Once a diagnostic aortogram is performed using a pigtail catheter, the anatomy is assessed in order to see if the lesion is amenable to PTAS (size, length, accessibility). The patient is systemically heparinized, the renal artery is cannulated, and the lesion is crossed using a 0.018-inch wire and various catheters. Once the artery has been cannulated, the catheter is advanced into the renal artery and the 0.018-inch wire is exchanged for a stiffer, less traumatic J-wire. A sheath is then exchanged over the guidewire into the renal ostium, and a renal angiogram is performed to characterize the RAS, as well as perform measurements for PTAS. If deemed amenable to PTAS, the long sheath is advanced over the wire and through the lesion. The selected balloon-expandable stent is brought over the wire and placed in the appropriate location, making sure to extend slightly into the aorta. The sheath is retracted and the stent is deployed. Occasionally, predilation using a smaller balloon is necessary. The patient is started on antiplatelet therapy—namely, clopidogrel for 30 days—and aspirin is continued indefinitely.

Endovascular Results

Renal artery stents have a high technical success (>95%) in most series. Mortality and morbidity are low, but response to treatment has yet to be fully elucidated. While it does appear in some series to have some beneficial effects on hypertension, there is very little evidence that renal artery stenting prevents renal dysfunction in the face of unimpaired baseline renal function. Furthermore, PTAS has been implicated in worsening of renal function postprocedure. In fact, some series report that an equivalent number of patients have worsened renal function compared with those with improved renal function. Combining this with the high rate of restenosis (>10%) should dissuade practitioners from performing prophylactic renal artery stents in patients with angiographic lesions that are functionally silent.

SUMMARY

While frequently diagnosed, RAS is often treated in the modern era medically. Patients whose hypertension cannot be controlled and in the setting of worsening renal function may benefit from revascularization, but the "gold standard" remains open surgical techniques. Endovascular techniques should be reserved for patients who are unfit surgical candidates. Treatment of angiographic lesions without a functional component should not be performed because no current level 1 evidence suggests there is an improvement in outcomes compared with medical therapy.

RAYNAUD'S SYNDROME

Andy M. Lee, MD, and Elliot L. Chaikof, MD, PhD

OVERVIEW

Raynaud's syndrome (RS) is a condition that typifies an exaggerated vasoconstrictive response in extremities triggered by cold or emotional stimuli. First observed by Maurice Raynaud in 1862, characteristically, a triphasic color progression is observed in fingers and toes that is described as digital pallor due to arterial spasm, cyanosis as a consequence of reduced venous flow and pooling of deoxygenated blood, and a hyperemic response from warming reperfusion (Figure 1). This abnormal vascular response can also affect other sites, such as the tongue, nose, and cheeks, and can range in severity and presentation. Raynaud's is referred to as *primary Raynaud's syndrome* if an underlying disease process cannot be identified and is classified as *Raynaud's disease* or *secondary Raynaud's syndrome* if an associated underlying disease, such as systemic sclerosis or mixed connective tissue disease, is identified.

The distribution of RS is worldwide and its incidence varies from 3% to 14% in men and 3% to 20% in women. Populations in colder regions have greater prevalence of Raynaud's, which also contributes to a higher frequency of attacks. Raynaud's phenomenon can occur at any age, but onset typically begins at a younger age. Many risk factors have been suggested to contribute to primary and secondary forms of Raynaud's. However, definitive therapy is lacking and remains an area of evolving research.

Primary Raynaud's syndrome (PRS) is the most prevalent form in the general population, follows a benign course, and is characteristically a self-limited functional vascular defect with intervention seldom needed. Secondary Raynaud's syndrome (SRS) is rarer, is associated with an immunologically mediated systemic disease, and is characterized by episodes of intense pain with eventual progression in most patients to ischemic ulceration and gangrenous digits. SRS is associated with microvascular occlusive disease and the lack of a compensatory vasodilatory response. Because of the presence of more severe symptoms, patients that suffer from SRS will often need medical treatment and may require surgical intervention (Table 1).

PATHOGENESIS

The pathogenesis of Raynaud's is unclear. The disruption between vasoconstrictive and vasodilatory responses is associated with systemic, neural, and local structural vascular abnormalities. For instance, impaired endothelial production of nitric oxide and prostacyclin, as well as endothelin-1 and angiotensin II, have been postulated to contribute to impaired vasodilatory and vasoconstrictive responses, respectively. Abnormal expression of endothelial cytokines and growth factors is thought to elicit an inflammatory process leading to structural changes, including intimal fibrosis. Alternatively, impaired smooth muscle cell responses leading to abnormal production of the vasodilator, calcitonin-related peptide, or activation of the alpha-2 adrenergic receptor can also contribute to Raynaud's. Unopposed sympathetic vascular tone has also been proposed as a contributing factor. Lastly, hypercoagulable states, activated platelets and leukocytes, as well as diminished fibrinolysis, have been observed in both primary and secondary RS.

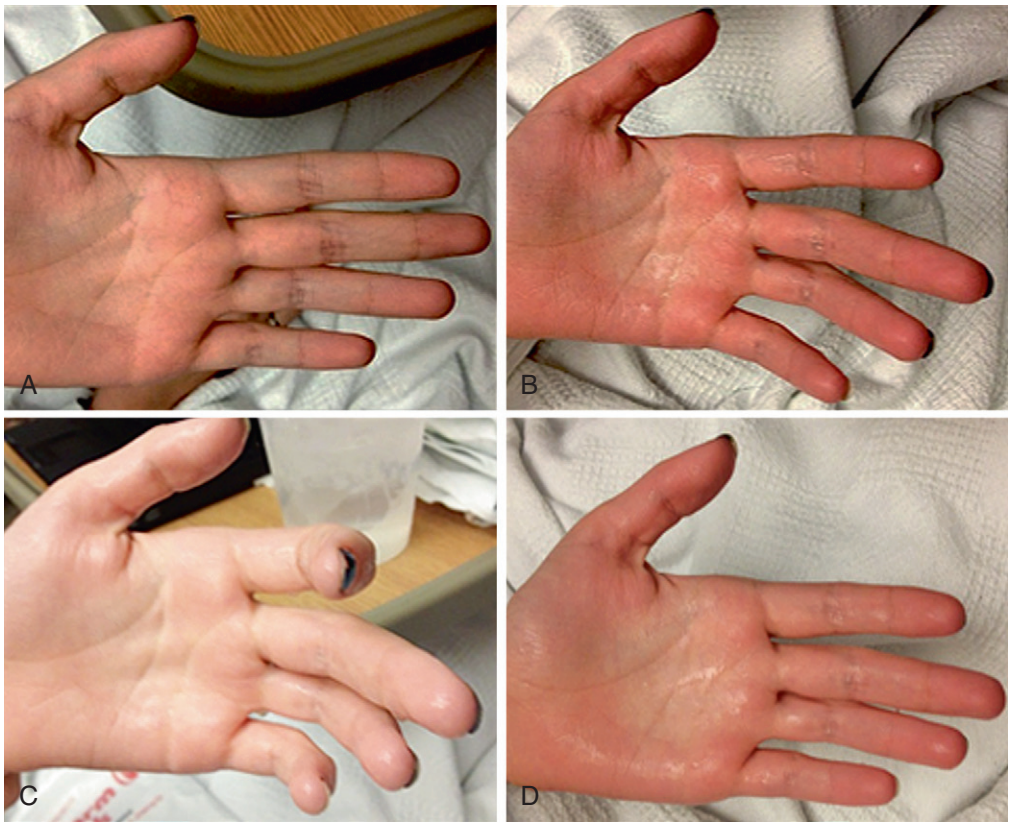

FIGURE 1 Raynaud's syndrome in patient with Ehlers-Danlos syndrome to illustrate the color changes associated with stressful stimuli. **A,** Normal appearing hand. **B,** After cold stimuli, the pallor from vasoconstriction can be seen. **C,** After 30 seconds, the hyperemic red appears in fingers with blood reperfusion. **D,** Hand after 3 minutes exposed to stimuli.

DIAGNOSIS AND PRESENTATION

The diagnosis of RS is based on history, including episodes of pain with notable color variation. It is important that triggers related to the onset of symptoms are noted. To exclude secondary causes, an occupational history, drug and medication use, family history, and current smoking status should be obtained (Box 1). A thorough vascular exam should exclude underlying symptomatic aneurysmal or atherosclerotic arterial occlusive disease that could mimic the presentation of RS. Thoracic outlet obstruction could produce unilateral upper extremity symptoms that could be mistaken for RS. The presence of pitting scars or healed digital ulceration should be noted, as well as flexion deformities, joint effusions, skin pigmentation, or ulcers that may be associated with scleroderma or systemic lupus erythematosus.

Routine blood work should include a complete blood count, immunologic and inflammatory markers for autoantibodies, antinuclear antibodies, Sjögren factors (SS-A and SS-B), rheumatoid factor, thyroid hormone levels, and an erythrocyte sedimentation rate. Specialized diagnostic tools can be used to assess the digital vascular response. Temperature-dependent digital plethysmography is obtainable in most noninvasive vascular laboratories. Infrared thermography and nailfold videocapillaroscopy may also be helpful in confirming the diagnosis of RS.

Angiography should be considered in the presence of severe hand ischemia or gangrene, primarily to exclude multilevel atherosclerotic occlusive disease or an embolic source due to a proximal aneurysm in the subclavian artery or distal ulnar artery aneurysm observed in hypothenar hammer syndrome. Comprehensive evaluation of the arterial supply of the hand, including the radial and ulnar arteries, as well as the palmar arch and digital vessels, can facilitate surgical planning to prevent further tissue loss.

Nailfold video capillaroscopy is performed with an ophthalmoscope or dermatoscope to assess capillary changes in the nail bed. Capillaries appear normal in PRS, whereas distorted, hemorrhagic, enlarged, and avascular capillary loops are characteristic of patients with scleroderma. If available, capillaroscopy is recommended for diagnosing scleroderma.

TREATMENT

The distinction between primary and secondary forms of Raynaud's is important in deciding on treatment. In PRS, episodes are self-limited and respond to supportive measures, changes in lifestyle, and avoidance of factors that can trigger symptoms. In SRS, treating any underlying disease, in addition to conservative measures and pharmacologic therapy, is often required. In the presence of digital ulceration and gangrene, local wound care and surgery may be needed to prevent further ischemic progression and avoid amputation. Severity of disease will dictate treatment and need for pharmacologic or surgical intervention (Table 2).

Conservative Treatment

Through avoidance of cold exposure and other triggers, milder Raynaud symptoms can be effectively controlled, minimizing the frequency and severity of attacks. The entire body should be covered and well insulated to protect exposed skin. Discontinuation of smoking is also recommended to reduce the severity of symptoms. Medication with vasoconstrictive potential, such as beta-blockers, sumatriptan, and ephedrine, should be avoided. Other substances with vasospastic properties include caffeine, decongestants, cocaine, and amphetamines.

Patients are advised to reduce stress with coping and relaxation techniques. Although biofeedback has been reported to minimize

TABLE 1: Characteristics of primary and secondary Raynaud's syndrome

	Primary	Secondary
Age	Younger (<30 years)	Older (>30 years)
Gender preference	Female	Male (depending on secondary cause)
Incidence	Most common	Less common
Familial predisposition	Yes	Yes
Combination with other disease	No, idiopathic	Associated with systemic disease
Vascular defect	Functional dysregulation of autonomic nervous system	Structural changes in connective tissue and/or vessels
Associated signs	None	Arthritis, sclerodactyly, cardiopulmonary abnormality, rash
Frequency	Precipitated by stimuli	Periodic and stimuli trigger
Severity of symptoms	Long history of mild attacks	Severe and disabling pain
Distribution	Symmetric	Asymmetric
Duration	Self-limited	Need for additional treatment (pharmacologic/surgery)
Critical complications	None	Ischemia and ulcers
Capillaroscopy	Normal (symmetric, thin, and uniform)	Abnormal (dilated, irregular, elongated, and tortuous vessel)
Vascular exam	Normal pulses	Abnormal pulses
ESR	Normal	Elevated
Serologic studies	Negative	Antinuclear antibody, autoantibodies
C-reactive protein	Normal	Elevated

ESR, Erythrocyte sedimentation rate.

symptom severity, a meta-analysis by Malenfant and colleagues (2009) of five randomized controlled trials showed no difference in severity, frequency, or symptom duration. Use of vibration-proof tools may also decrease the occurrence of RS.

Pharmacologic

Calcium Channel Blockers

For symptoms that are not responsive to conservative methods, calcium channel blockers are the drug of choice in the medical management of RS. Nifedipine has been studied most extensively and reduces vascular tone through an effect on the voltage gated calcium channel. Dihydropyridine-derived calcium channel blockers, including amlodipine, nicardipine, and felodipine, are currently favored because of their selectivity for peripheral vascular smooth muscle cells. Treatment is initiated at a low dose that is slowly increased to avoid hypotension, reflex tachycardia, headache, and flushing. In several meta-analyses of randomized control trials, Thompson and colleagues (2001) and Thompson and Pope (2005) noted that nifedipine decreased the frequency and severity of attacks (35%). Sustained release preparations are better tolerated and exhibit longer acting effects.

Prostaglandins

Prostaglandins (PGEs) have several beneficial effects for both primary and secondary forms of Raynaud's, including vasodilatory and antiproliferative effects in smooth muscle cells and the capacity to inhibit platelet aggregation. PGEs are used in the absence of a response to other vasodilators. Iloprost, an intravenous prostacyclin analogue, has been used in severe RS. In a multicentered randomized trial, Wigley and colleagues (1994) demonstrated that 5-day administration of iloprost decreased the frequency of attacks and healed 50% more lesions compared with placebo. In a randomized study of 30 patients, Milio and colleagues (2006) administered iloprost therapy over 3 to 18 months, which led to a reduction in the duration and frequency of attacks with improved quality of life. Compared to nifedipine, iloprost demonstrated improved long-term skin and functional scores. Adverse effects of iloprost include headache, flushing, and nausea. PGEs should be used with caution in patients with congestive heart failure because of the risk of exacerbating pulmonary edema. Controversial results exist for oral PGE analogues, and currently only the intravenous formulation is recommended in severe cases.

Alpha-2 Adrenoreceptor Blockers

The alpha-2 adrenergic pathway regulates sympathetic peripheral vascular tone. In a randomized, double-blinded, placebo controlled

study of 24 patients with RS, Wollersheim and colleagues (1986) observed a reduction in frequency and duration of attacks. Pope and colleagues (2000a) have demonstrated that prazosin was effective in treating Raynaud's secondary to scleroderma. Side effects of alpha-adrenoreceptor blockers include nausea, dizziness, headache, and hypotension. Drug resistance may occur with prolonged use. Despite some evidence of utility in Raynaud's, at this time sympatholytic agents cannot be recommended as first-line agents.

Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers

Angiotensin-converting enzyme (ACE) inhibitors inhibit the synthesis of angiotensin II and prevent the degradation of bradykinin, which is a potent vasodilator. Nonetheless, ACE inhibitors have a limited role in RS. In a randomized controlled study of losartan and nifedipine, Dziadzio and colleagues (1999) observed that losartan decreased symptoms and the severity of attacks. In contrast, Gliddon and colleagues (2007) treated patients who had Raynaud's with quinapril for 2 to 3 years and noted no change in symptom frequency or severity or occurrence of digital ulcers. Although angiotensin inhibitors have an acceptable side effect profile, there is insufficient evidence for their clinical use in RS.

Phosphodiesterase Inhibitors

Phosphodiesterase inhibitors increase cyclic guanosine monophosphate (cGMP) in circulation that decreases vascular smooth muscle tone. In several randomized trials, these inhibitors decreased the frequency and severity of attacks in primary and secondary RS and had a favorable effect on ulcer healing. In a randomized double-blinded trial, Fries and colleagues (2005) reported that a 4-week regimen of sildenafil reduced attacks and improved ulcer healing, but recurrence was observed when treatment was halted. Similar results were observed by Shenoy and colleagues (2010) in a 6-week trial of tadalafil. Common side effects include headache and nasal congestion. As these drugs are well tolerated, phosphodiesterase inhibitors represent a promising therapy for Raynaud's.

Endothelin-1 Receptor Antagonist

Endothelin-1 is a vasoconstrictor found at increased levels in patients with systemic sclerosis. Recent studies indicate a role for endothelin-1 receptor antagonist in patients who have severe RS with ulceration not responding to other therapies. Endothelin-1 receptors are found in both endothelial (ETa) and smooth muscle (ETb) cells with distinct receptors mainly responsible for vasoconstriction (ETa) and vasodilation (ETb). Bosentan is a competitive antagonist to both receptors and is currently approved for clinical use in Europe. Korn and colleagues (2004) assessed the effects of bosentan in treating digital ulcers in 122 patients with systemic sclerosis. Bosentan showed a 48% reduction in the mean number of new ulcers but had no effect on ulcer healing. Likewise, in another randomized trial of 188 patients, after 20 to 32 weeks, bosentan decreased the number of new ulcers by 30% without affecting ulcer healing. Endothelin-1 has profibrotic activity, and two case reports suggest that bosentan may be

TABLE 2: Available treatment options for Raynaud's syndrome

Treatment	Indications		Comments
Conservative	First-line therapy with mild symptoms		Smoking cessation; avoiding stress, cold, vasoconstrictive stimulants and medications; biofeedback
Pharmacologic treatment	**Indications**	**Common adverse effects**	**Comments**
Calcium channel blockers (CCBs)	Conservative therapy ineffective	Hypotension, reflex tachycardia, flushing, headache	Nifedipine most studied; sustained long-acting CCB (amlodipine, nicardipine, and felodipine) gaining popularity
ACE inhibitors and ARBs	When CCBs ineffective, can substitute or add	Cough	Losartan preferred based on clinical data; quinapril provided no benefit based on randomized controlled trials
PDE inhibitors (sildenafil)	Severe ischemia and ulcer healing	Flushing, hypotension, dyspepsia	Used when not responding to other medical therapy; sildenafil and tadalafil benefit noted after 4 and 6 weeks, respectively
Alpha-adrenergic blockers	When CCBs ineffective, can substitute or add	Nausea, dizziness, headache, palpitations, hypotension	Pharmacologic tolerance; better tolerated for those sensitive to vasodilator side effects; prazosin effective in Raynaud's secondary to scleroderma
Endothelin receptor antagonist (bosentan)	Ulcer healing and prevention	Increased liver enzymes	Approved for clinical use in Europe
Prostaglandin analogue (prostacyclin, iloprost)	Ulcer healing and critical ischemia	Dose-dependent, headache, flushing, nausea; use with caution in patients with CHF	Intravenous form for severe Raynaud's; antiplatelet therapy required for procoagulant tendency in SRS; iloprost used in severe RS and with healing potential
Serotonin reuptake inhibitor	When CCB ineffective, can substitute or add	Nausea, gastrointestinal upset	Tolerated for those sensitive to vasodilator side effects
Interventional treatment	**Indications**	**Complications**	**Comments**
Débridement	Necrotic tissue, complicated wounds		Use with antibiotics and analgesia
Amputation	Gangrene		Careful assessment of vascular and infection status
Regional sympathectomy (cervicothoracic or lumbar)	Painful ulcers	Pneumothorax, Horner syndrome, anhidrosis with hyperhidrosis, denervation supersensitivity	Endoscopic sympathectomy better tolerated; can also perform radiofrequency ablation; durability not yet fully validated
Botulinum A injection	Severe ischemia	Hyperhidrosis	Case series demonstrate benefit
Digital sympathectomy	Painful ulcers	Anhidrosis, denervation supersensitivity	Periarterial sympathectomy, decompression (excise fibrosis); randomized control trials lacking

ACE, Angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *CHF,* congestive heart failure; *PDE,* phosphodiesterase; *RS,* Raynaud's syndrome; *SRS,* secondary Raynaud's syndrome.

effective even in the presence of underlying structural damage to small vessels. Clinical trials showed no benefit when bosentan was used to treat individuals with milder forms of Raynaud's disease. Bosentan may lead to liver injury.

Selective Serotonin Reuptake Inhibitors

Platelets release serotonin, which is a vasoconstrictor, but the mechanism of action in RS is unclear. Selective serotonin reuptake inhibitors (SSRIs) may cause nausea, insomnia, and tremors. In a randomized study, fluoxetine (an SSRI) reduced severity and frequency of attacks compared with nifedipine in patients with PRS. However, in a prospective trial, sarpogrelate (SSRI) administered over 4 to 8 weeks showed marked symptom improvement in 32 patients with SRS. However, in a meta-analysis, Pope and colleagues (2000b) reported limited benefit in patients with scleroderma. Currently, there are insufficient data to support routine use of SSRIs to treat patients with RS.

Surgical Intervention

Surgery is generally reserved for patients with severe and disabling symptoms that have not improved after pharmacologic intervention. Progression to critical ischemia or digital ulceration requires hospitalization and surgical evaluation, and patients typically have an underlying systemic disease. On admission, intravenous PGE (prostanoid) should be considered and antibiotics administered in the presence of a concurrent infection. Analgesia should be provided and local wound care instituted. Débridement and amputation may be necessary. An abnormal pulse exam may suggest the presence of a large vessel arterial lesion, which may necessitate initiation of anticoagulation with subsequent surgical revascularization.

Sympathectomy, which may be temporary or permanent, eliminates sympathetic tone to improve blood flow and reduce ischemic pain, improve oxygenation, and prevent further tissue damage. Temporary sympathectomy can be produced by injecting a regional anesthetic near the appropriate cervical or lumbar sympathetic ganglia or, more distally, in the course of a digital or wrist block. Interdigital injections of botulinum toxin have been shown to be effective in decreasing pain, healing digital ulcers, and improving blood flow in patients with primary and secondary Raynaud's. Van Beek (2007) noted immediate pain relief within 48 hours in 11 patients who received perivascular injections of botulinum toxin A, and these patients remained symptom free for several months. Nine of 11 patients also demonstrated improved ulcer healing. Neumeister (2010) observed that botulinum toxin A (50 to 100 units) improved pain and perfusion in 28 out of 33 patients.

Surgical sympathectomy has been reserved for refractory patients with digital ulceration, with more favorable outcomes found in patients who have primary RS. Various methods have been described, including chemical ablation, resection, clipping, and stripping of the thoracic sympathetic chain. Cervicothoracic sympathectomy via supraclavicular, transaxillary, or thoracoscopic approaches is associated with an attendant risk of Horner's syndrome, pneumothorax, compensatory truncal sweating, persistent neuralgia, or phrenic nerve injury. de Trafford (1988) surveyed 140 patients who underwent sympathectomy and observed that only 18.6% claimed lasting benefit. Matsumoto and colleagues (2002) performed 54 endoscopic sympathectomy procedures without major complications and reported an initial improvement in 93% of patients but recurrence in 82% within 60 months. Similarly, Coveliers and colleagues (2011) performed a review of available studies and noted long-term benefit after endoscopic sympathectomy for only 58% with PRS.

Digital or palmar sympathectomy was first described in 1980 and does not have the major side effects associated with either a thoracotomy or thoracoscopy. The periarterial adventitia is stripped off the digital arteries of the involved finger. Depending on the appearance of the artery, especially in vessels with structural damage from scleroderma, open decompression with resection of the fibrotic layer is needed to remove the external compression and may be extended to include the radial and ulnar arteries of the wrist. Several case studies report successful outcomes, but randomized controlled trials are not available. In a retrospective review of six patients, Tomaino (2000) noted that five patients claimed significant improvement in quality of life after 6 months, including reduced ischemic digital pain and moderate improvement in cold intolerance. In a systematic review of 16 different retrospective and prospective studies that included 156 patients, Kotsis and Chung (2003) observed that 14% of patients eventually required amputation and 18% of ulcers failed to heal despite digital sympathectomy. Likewise, in a prospective study, Hartzell and colleagues (2009) reported that after 90 to 113 months, 26% of digits with an underlying autoimmune disorder and 59% of digits with associated atherosclerosis ultimately required amputation. This approach provides early symptomatic relief and may enhance ulcer healing, but additional studies to assess long-term benefit are needed.

CONCLUSIONS

Raynaud's is a challenging condition with an ill-defined pathogenesis. Distinguishing between primary and secondary forms is critical to formulating appropriate management. Presentations are similar in both forms, but critical ischemia with tissue loss is most common in secondary Raynaud's. Diagnosis is suggested by history and thorough physical exam to exclude other pathologies; digital plethysmography, nailfold capillaroscopy, and serologic testing are helpful in differentiating between primary and secondary forms.

Mild Raynaud's symptoms can be managed by conservative lifestyle changes such as avoiding stimuli that exacerbate symptoms and wearing appropriate protective garments. However, pharmacologic treatment may be necessary, and calcium channel blockers are the initial agent recommended. Depending on the progression of symptoms, other medications, including PGE, phosphodiesterase inhibitors, ACE inhibitors, or SSRIs, may be considered, although clinical studies have shown variable results. For those with severe vasospastic ischemia and ulcers that fail to respond to medical and conservative measures, sympathectomy may be appropriate although long-term effectiveness has not been confirmed.

Thoracic Outlet Syndromes

Brandon W. Propper, MD, and
Julie A. Freischlag, MD

OVERVIEW

Thoracic outlet syndrome (TOS) refers to the anatomic compression of one or more of the neurovascular structures as they exit the chest. Classically, each syndrome is described by the neurovascular structure that is compressed: subclavian vein TOS (vTOS), subclavian artery TOS (aTOS), and nerve root TOS (nTOS). Although controversy exists with regard to diagnosis, careful evaluation and clinical workup can help to identity those patients most likely to benefit from surgical treatment.

ANATOMY OF THE THORACIC OUTLET

Comprehensive treatment relies on a solid understanding of the thoracic outlet and the surrounding structures. Think of the thoracic outlet as a triangle with the apex facing the manubrium. The lower and upper edges are defined by the first rib and clavicle, respectively (Figure 1). Moving anterior medial to posterior lateral, the first structure encountered is the subclavius muscle. The tendon from the subclavius inserts onto the superior portion of the first rib, and the muscle hugs the inferior surface of the clavicle. The subclavian vein lies next to the subclavius tendon and can often be partially compressed. Separating the subclavian vein and artery is the anterior scalene. The relationship between the subclavian vessels and the anterior scalene is key to a safe surgical treatment. Posterior lateral to the subclavian artery are the nerve roots of the brachial plexus, then the middle scalene muscle.

Special anatomic consideration should be given to patients with cervical ribs. Previous autopsy data revealed that about 0.5% of the population has a cervical rib; furthermore, the rib can be fully formed or partially developed. When present, a bony or a fibrous connection exists between the cervical rib and the first rib (Figure 2). The presence of cervical ribs in the TOS population is reported between 10% and 65%. If a cervical rib is causing compression of the neurovascular structures, the cervical rib and fibrous connections should be removed during resection. The structure at greatest risk is the subclavian artery, which lies closest to the cervical rib attachments. In the authors' practice, all patients with TOS are screened for a cervical rib with routine chest radiographs.

ARTERIAL COMPRESSION

Subclavian artery compression is the least common of the three syndromes. Repeated compression over time can lead to a wide array of presentations. These patients are often young and are involved in activities or work that require repeated motion. The presenting symptoms can be subtle, including hand fatigue, mild edema, or temperature sensitivity. More obvious presentations include color changes from embolic events and digital ischemia. Repeated compression on the artery can lead to intraarterial scarring or wall weakening and development of a subclavian artery aneurysm. On physical examination, patients may display diminished radial pulses or disparate blood pressures in the upper extremities. Aneurysmal changes may be apparent on examination as a pulsatile mass in the clavicular region. More advanced testing has been advocated, including elevated arm stress testing (EAST) and abduction and external rotation test (Adson's). Both are noninvasive and are useful to perform during physical examination, but the examiner must be aware that neither test is diagnostic because multiple other disease processes can produce a positive test.

Arterial compression is relatively uncommon; as such, there is no standard complement of testing. The authors suggest further

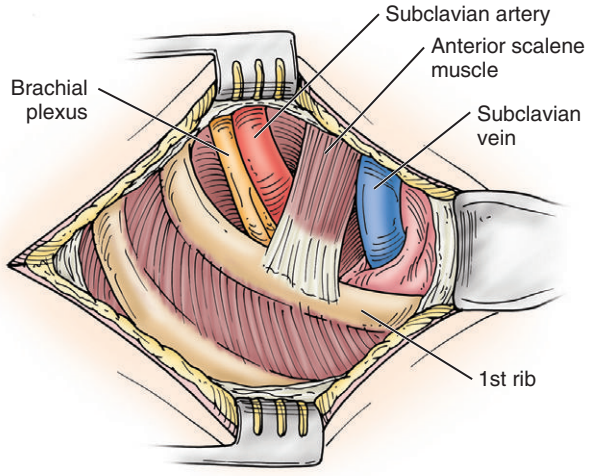

FIGURE 1 Anatomy of the thoracic outlet.

evaluation with imaging. At a minimum, standard chest radiographs should be done to evaluate for cervical ribs or other bony abnormalities. Dynamic ultrasound scan is a reasonable second step because flow changes in the subclavian artery can be seen with abduction and adduction of the arm. In addition, ultrasound scan can illustrate whether aneurysmal development has occurred. Computed tomographic (CT) scan is another imaging modality that can give clear visualization of arterial anatomy with regard to the proximal subclavian artery. It is not the authors' standard practice to use CT scan with most patients; however, if concern exists for proximal arterial disease or aneurysmal change, this modality is used. Finally, arteriography is helpful when the diagnosis is unclear. Dynamic imaging with the arm in abduction and adduction can elucidate arterial compression; however, it is rare that this modality is required when true arterial compression is present.

Treatment of aTOS depends on the clinical presentation and attributed symptoms. Compression without concomitant aneurysm formation can be treated with transaxillary rib resection; however, for those patients that need arteriotomy and reconstruction, the supraclavicular approach is favored. When complex reconstruction is necessary, an infraclavicular incision can be added for more distal exposure.

VENOUS COMPRESSION (PAGET-SCHROETTER SYNDROME)

Venous compression is the second most common form of TOS. Presentation is often in young healthy patients with a history of repetitive motion (swimming, pitching, manual labor) or an active lifestyle. These patients present with a painful swollen extremity and distinct color changes (rubor or cyanosis). Color change may be confused with infection, which can delay diagnosis. Edema of the arm into the fingers is substantial and often triggers patients to seek early medical attention. A history of arm fatigue or a feeling of heaviness may precede dramatic swelling but is usually unnoticed until advanced axillosubclavian compromise is present. Long-standing disease may also reveal multiple collateral veins around the upper arm and shoulder. In younger patients, the surgeon must always consider an underlying hypercoagulable state; however, in the authors' series of patients with vTOS, only 8% were shown to have a prothrombotic disorder.

On presentation, treatment should not be delayed, and anticoagulation therapy should be initiated. Admission begins with 24-hour to 48-hour intravenous heparin therapy and arm elevation. Chest radiographs and dynamic duplex ultrasound scan are recommended to evaluate for venous compression. Findings on ultrasound scan include: (1) decrease in venous velocity by 50% with abduction; (2) presence of venous thickening suggestive of deep venous thrombosis (DVT); and (3) presence of acute or chronic thrombus. Patients are transitioned to low molecular-weight heparin and warfarin for discharge and scheduled for first rib resection and scalenectomy. Initial reporting advocated for a 3-month interval of anticoagulation therapy before surgery. Multiple reports have shown that earlier resection is safe with excellent outcomes. Some large centers advocate for urgent resection performed during the initial hospital admission. The authors' practice is to schedule surgery between 2 and 4 weeks after hospital discharge. Before surgery, the authors prefer arm swelling to have resolved; this short delay allows for venous remodeling and a decrease in swelling. Furthermore, it affords patients a chance to plan for surgery without any compromise in long-term outcome. Inpatient venography, venoplasty, and thrombolysis have been advocated previously and are still performed routinely in some institutions. A stronger argument can be made for thrombolysis for those patients who present with acute upper extremity thrombosis. The authors' practice has moved away from venography and thrombolysis in the preoperative setting because no benefit has been found in long-term patency when compared with initiation of low molecular-weight heparin. Furthermore, regardless of treatment, more than 90% of patients had a patent subclavian vein at the 16-month follow-up.

For definitive treatment, the first rib and anterior scalene are removed via the transaxillary approach. This technique is discussed subsequently in the chapter, but vTOS also requires cutting of the subclavius tendon located at the apex of the thoracic outlet. Other institutions advocate for a supraclavicular approach for surgical treatment. The surgery is more extensive and consists of full mobilization of the subclavian vein, venotomy, and patch venoplasty with saphenous vein. Specific centers have reported good long-term patency with this approach.

After the transaxillary approach, patients are admitted for 1 night, and systemic anticoagulation therapy is held for 3 days and then resumed. The authors schedule all patients with vTOS for venogram 2 weeks after surgery. Venogram serves to identify those patients in whom anticoagulation therapy can be stopped. At venogram, the subclavian vein has recanalized in half of the patients. Fifty percent have a flow lumen amendable to venoplasty and are continued on anticoagulation therapy until follow-up at 1 month. In a small subset, wire access cannot be gained through the subclavian vein and these patients are continued on anticoagulation therapy without subsequent venogram. Figure 3 shows the treatment algorithm for vTOS at the authors' institution.

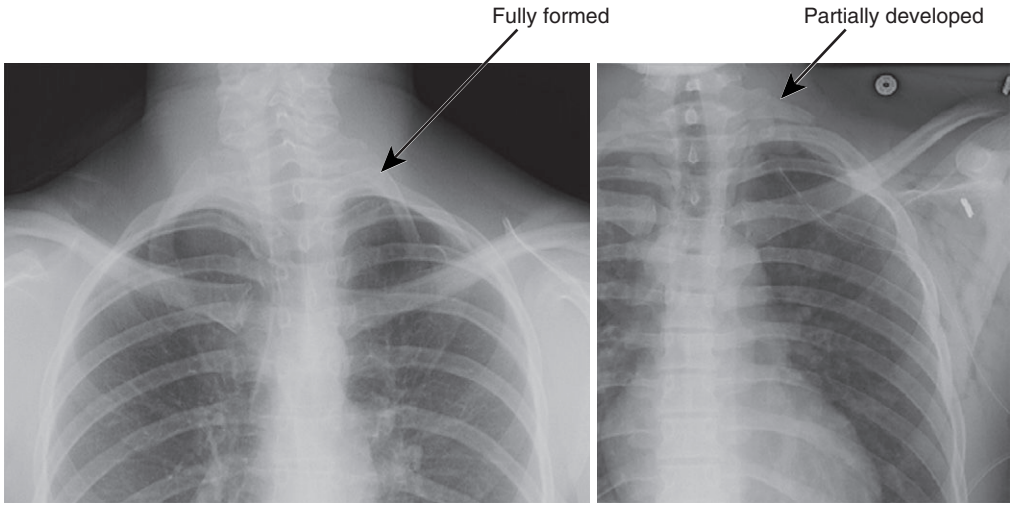

FIGURE 2 Radiographs show both a fully formed and a partially developed cervical rib.

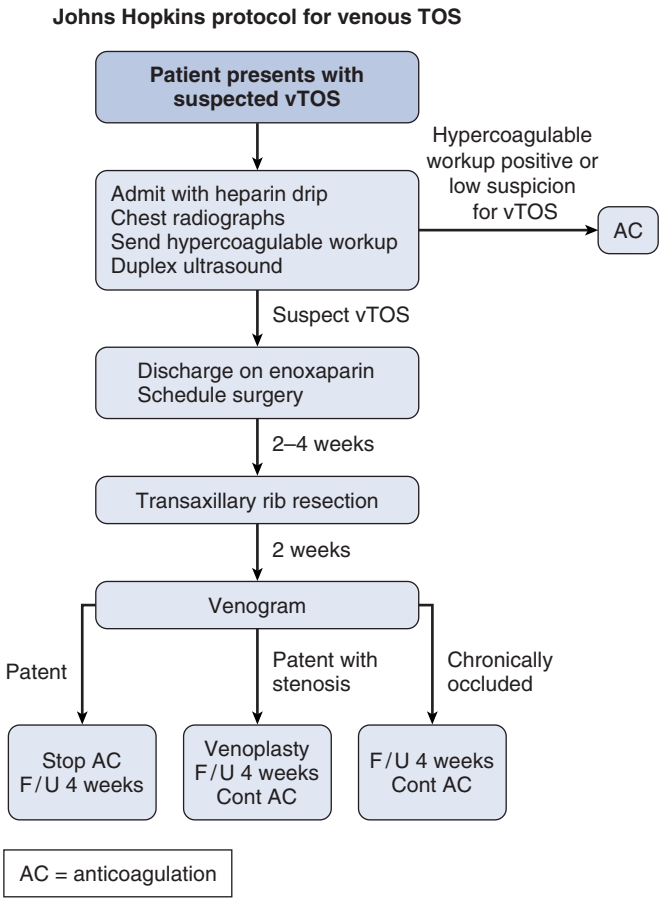

FIGURE 3 The Johns Hopkins algorithm for subclavian vein thoracic outlet syndrome *(vTOS). AC,* Anticoagulation; *F/U,* follow-up.

NERVE COMPRESSION

Nerve compression remains the most common form of TOS, although this is also the most controversial. Patients can present with a wide array of symptoms, including pain (back, arm, and shoulder) and headaches. However, the most common presenting symptom, which is present in 90% of patients, is arm paresthesias. Often the symptoms follow a traumatic event such as a motor vehicle crash or are found in patients who engage in repetitive upper extremity activity.

On physical examination, subtle findings of muscle atrophy or a winged scapula may be present. Tenderness with palpation over the anterior scalene may be present; palpation of this region may reproduce arm paresthesia or pain. As with aTOS, EAST and Adson's test may reproduce symptoms but should not be used as diagnostic for nTOS.

Patient selection and further evaluation are highly recommended in the nTOS population. All patients should undergo a period of observation and physical therapy to see whether symptoms can be alleviated without surgery. In addition, patient age should be taken into consideration. Recent data have illustrated that patients less than 40 years of age are more likely to have pain relief after rib resection and scalenectomy. Scalene injection or scalene block should be considered in patients over 40 years of age. Those over 40 years who experience pain relief with scalene block are more likely to benefit from surgical resection. Botulinum toxin injection continues to be a controversial topic. Although many patients experience temporary pain relief, current literature suggests no benefit over placebo injection. Ongoing studies are in progress, but no current evidence suggests long-term benefit from botulinum toxin injection. In patients who are deemed suitable for rib resection, resection is carried out via the transaxillary approach.

TABLE 1: Preferred surgical approach for thoracic outlet syndrome

TOS syndrome	Surgical approach
aTOS	Supraclavicular
vTOS	Transaxillary
nTOS	Transaxillary
Recurrent disease	Supraclavicular or posterior high thoracoplasty

aTOS, Subclavian artery thoracic outlet syndrome; *nTOS,* nerve root thoracic outlet syndrome; *TOS,* thoracic outlet syndrome; *vTOS,* subclavian vein thoracic outlet syndrome.

TRANSAXILLARY APPROACH

Table 1 illustrates the authors' preference for surgical approach based on underlying pathology.

Preparation and Position

Before the procedure, a discussion with the anesthesia team is appropriate to ensure that the operative arm is free from intravenous lines and that no long-term paralytic agents are used. General anesthesia is induced, and once complete, the patient is positioned and clipped free of hair. A suction beanbag is preferred to help maintain the lateral positioning. In addition, an axillary pad should be placed between the patient's chest wall and the bed to protect the contralateral axilla. Once positioned, the chest wall, axilla, and arm are prepped into the sterile field. The arm is flexed at the elbow and secured into the Machleder retractor (Koros, USA, Inc.) with elastic wrap. It is important to protect the ipsilateral arm and pad the retractor (Figure 4). Use of at least one lighted retractor is recommended, and the operating surgeon should wear a headlight.

Operative Approach

Once positioned, the border of the pectoralis major and latissimus dorsi are identified and marked as the anterior and posterior border. A line between these marks is made as the inferior edge of the hair baring area. This line is used for the incision. Dissection is carried out down to the level of the chest wall, with care taken to stay superior to the axillary fat. Potential structures encountered include the intercostal brachial nerve, which should be preserved if possible but can be sacrificed if necessary. Once the chest wall is indentified, palpation of the first and second rib can be achieved. Typically, the second rib protrudes further and is easily palpable. The first rib is flat and more difficult to identify. At this point, the Machleder retractor is raised to open the axillary space. Loose areolar tissue often can be bluntly dissected while the surgeon identifies the subclavian vein and artery. For patients with vTOS, the vein may be thrombosed and difficult to identify. Once the artery and vein are identified, the anterior scalene muscle is visualized and bluntly dissected free from the vein and artery. Sharp dissection is cautioned against because injury to the vein or artery is difficult to repair. The inferior border of the first rib is cleared of muscular tissue with a combination of blunt

FIGURE 4 Operative photograph of setup.

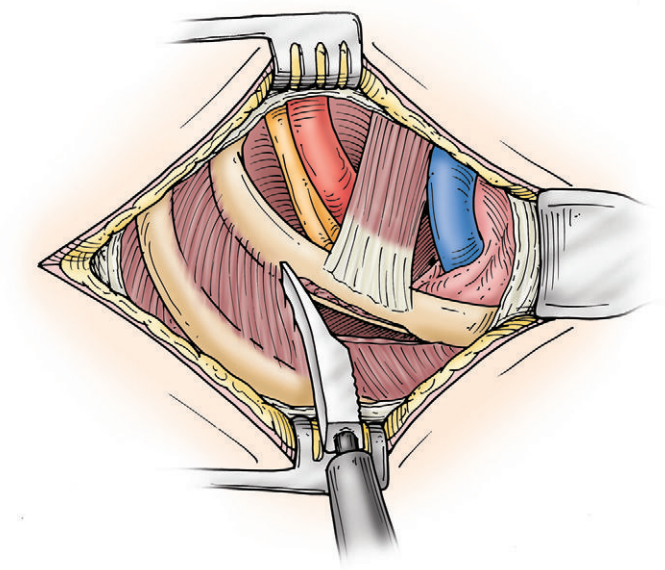

FIGURE 5 Use of the periosteal elevator to remove tissue from the first rib.

dissection and a periosteal elevator (Figure 5). The dissection of the first rib includes removal of all muscle tissue from the rib surfaces. This maneuver often causes bleeding of the dissected muscle, and periodic packing and lowering of the Machleder retractor are recommended for hemostasis. The surgeon should isolate the anterior scalene with a right angle instrument, while the assistant sharply divides the muscle fibers (Figure 6). Once the anterior scalene is divided, the rib can be divided with bone cutters. The anterior side should be cut first, with care taken not to damage the subclavian vein.

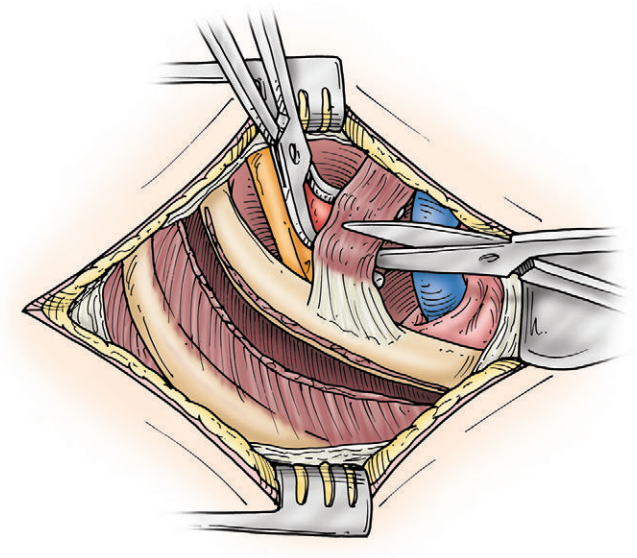

FIGURE 6 Transection of the anterior scalene muscle with a right angle clamp and scissors.

Subsequent dissection of additional muscle fibers helps to facilitate posterior rib transection. Posteriorly, the rib should initially be cut anterior to the nerve root. The rib specimen can be removed from the field. Rongeurs can be used to remove additional post anterior to the vein and posterior to the nerve root. Once complete, irrigation is instilled into the field, and Valsalva's maneuver is used to check for a pneumothorax. If pneumothorax is present, a small chest tube is placed.

The Diabetic Foot

Gilbert Aidinian, MD, FACS, RPVI,
Patrick R. Cook, DO, FACS, RPVI, and
Todd E. Rasmussen, MD, FACS

INTRODUCTION

The prevalence of diabetes mellitus worldwide has reached epidemic proportions and the myriad of complications that result from this disease cannot be overstated. In the United States alone, the diabetic population continues to grow exponentially, affecting an estimated 24 million people. Approximately 15% of patients with this disease will develop some form of foot complication and despite ongoing improvements in care, the annual cost associated with diabetic foot infections, tissue loss, and amputations exceeds $10 billion.

Up to 10% of patients with diabetes will develop a foot ulcer or tissue loss on the foot in their lifetime. In those patients who have other specific risk factors, such as peripheral arterial occlusive disease and altered foot architecture, the percentage rises to nearly 30%. The ideal management of patients with diabetes involves preemptive education and an awareness of the clinical manifestations of diabetes as well as routine surveillance of the foot surfaces. Patients at high risk for development of foot pathology are best cared for in a multidisciplinary setting that includes medicine, surgery, wound care, and rehabilitation specialists. Should a patient with diabetes mellitus experience a break in the integument of the skin, referral to a surgical specialist for evaluation is appropriate for optimal results.

PATHOPHYSIOLOGY

There are three categories of foot ulcers that can occur in those with diabetes mellitus: neuropathic, ischemic, and those that arise from mixed neuropathic and ischemic components. Understanding these categories and recognizing the etiology of a given ulcer is necessary for efficient and effective management. Conversely, failure to understand and recognize the categories of foot ulceration may lead to unnecessary tests and procedures or delays in recognition and treatment.

The first category is a result of diabetic peripheral neuropathy affecting the surfaces of the toes and feet of patients with long-standing diabetes. Even in the setting of normal arterial perfusion, diabetic neuropathy represents a frequent cause of foot injury, infection, and subsequent tissue loss. Neuropathic ulcers are also referred to as traumatic and originate because of abnormal or absent sensation to the toes and feet. In the setting of neuropathy, activity or injury that would otherwise be uncomfortable and prompt examination, behavioral adjustment, or treatment goes unnoticed or neglected. An example is repetitive irritation or abrasion from poor fitting shoes, which may go unrecognized in patients with neuropathy until the trauma results in a break of the skin integument and initiation of an ulcer. Similarly, a puncture wound or laceration to the foot, which would normally prompt examination and medical attention, may go unnoticed in patients with diabetic neuropathy. In addition to abnormal sensation, chronic diabetic neuropathy may lead to malformation of the joints of the foot and toes, which, in turn, leads to a condition termed *neuropathic arthropathy* or *Charcot's foot* (Figure 1). In this condition, joints and surfaces of the foot not otherwise prone to injury become abnormally positioned and exposed to surface trauma and ulceration. Finally, chronic diabetic neuropathy affects autonomic innervation of the skin of the foot and toes, which leads to abnormally dry surfaces. Dry skin associated with chronic neuropathy leads to scaling, cracking, or other breaks in the integument and predisposition to ulceration, infection, or both.

Chronic lower extremity ischemia from arterial occlusive disease may also affect those with diabetes who have normal sensation to the surfaces of the foot and toes. In these instances, the ulceration is referred to as *ischemic tissue loss* or *ischemic ulceration.* Ischemic ulcers of the foot or toes arise from multilevel arterial occlusive disease, meaning that more than one arterial level between the aorta and the foot is affected by significant stenosis or occlusion. Most commonly, patients with chronic diabetes have severe occlusive disease of one or more of the tibial arteries in combination with aortoiliac occlusive disease, femoral-popliteal artery occlusive disease, or both (Figure 2). Finally, depending on the duration and severity of diabetes, patients may have foot or toe ulcerations that are of a mixed neuropathic and ischemic component. These cases are typically the most severe and prone to significant tissue loss that leads to amputation.

From the standpoint of pathophysiology, it is important to keep in mind that a common pathway to ulceration and infection in diabetic patients is reduced local and systemic immune defense. This phenomenon increases significantly the propensity for any breaks in the skin integument, whether due to trauma or ischemia, to progress to complications. The abnormal local inflammatory response in patients with diabetes is due to alterations at the cellular level, including thickening of the endothelial basement membrane of the microvessels of the foot. Thickening of the basement membrane impairs leukocyte migration to the site of injury and the local cellular capability to defend against pathogens. Diabetes mellitus also impairs the function of circulating inflammatory cells through variations in blood glucose levels and as a result of chronic insulin administration, which interacts with circulating hormones (e.g., growth hormone) to negatively affect the immune response.

PRESENTATION

Whether from neuropathy, ischemia, or both, skin breakdown typically occurs on the pressure-bearing surfaces of the foot, such as hard calluses or bony prominences. The chronicity of any foot ulceration is important to discern, as is the history of other healing or nonhealing ulcers on the same foot. These factors often provide insight as to whether or not there is a significant ischemic component to the situation at hand. For example, a patient who presents with a chronic nonhealing ulcer that has been stagnant or indolent over a number of weeks or months is less likely to have a profound ischemic component. Likewise, a patient with a recurrent ulcer or a new ulcer on a foot on which healing has occurred in the recent past is less likely to have severe ischemia. In these cases, the fact that the ulcer has not progressed or may have healed in the past suggests that there is adequate blood flow to support tissue stabilization and ward off gangrene. In these scenarios, the ulcer most likely is caused by recurrent trauma to an area of surface pressure or injury. In contrast, first-time foot ulcers that show significant necrosis, deep space infection, or both, are more likely to have a significant ischemic component with or without neuropathy.

The presentation of foot ulcerations range from superficial blisters or chronic wounds to painful, erythematous or necrotic ulcerations with deep space infection. As mentioned previously, the intrinsic muscles of the foot may atrophy as a result of chronic neuropathy, resulting in a condition known as neuropathic arthropathy or Charcot's foot. This condition is recognized easily on examination and creates abnormal pressure points on the foot. The degenerative arthropathy associated with Charcot's foot also leads to loss of normal foot architecture and collapse of the arch, also referred to as a "rocker bottom" deformity. Examination of the foot frequently reveals dry and cracked skin and forefoot; erythema, edema, or

tenderness is suggestive of a more extensive deep space infection. Of particular importance in this patient population is the presence of unexplained hyperglycemia. Elevation in circulating blood glucose levels in patients with diabetes, and especially those with foot ulceration, should prompt an aggressive search for infection. In these instances, one should suspect undrained fluid collections or osteomyelitis or deep space forefoot infections.

The contribution of ischemia to a foot ulcer can be gauged quickly by performing an assessment of perfusion to the extremity, beginning with an assessment of peripheral pulses. This aspect of the physical exam begins with palpation of the femoral pulse, which may be compared in strength to that of the pulse in the opposite groin. Similarly, palpation for the popliteal and pedal pulses should be performed comparing their strength with those in the opposite extremity. Completing the pulse exam is most useful in determining the ischemic component to a foot ulcer at the two ends of the clinical spectrum: normal versus severe ischemia. A patient who has normal palpable pulses throughout an extremity, including the foot, on the initial examination is much more likely to have an isolated neuropathic ulcer. Conversely, a patient who has absent femoral, popliteal, and pedal pulses on the initial exam has an ischemic component and should be managed accordingly. Patients in whom the pulse exam is difficult or equivocal require further noninvasive testing, beginning with use of the continuous wave Doppler.

Continuous wave Doppler is an extension of the physical exam and used to determine the presence and quality of arterial signals in the foot. Normal signals are strong and biphasic, whereas weak monophasic signals are indicative of arterial occlusive disease and ischemia. The ankle brachial index (ABI) is the ratio of the occlusion pressure of the arterial signal at the ankle or foot compared with that in the arm. This aspect of the exam is performed using a manual blood pressure cuff and a continuous wave Doppler to assess the pressure at which the signals of the dorsalis pedis and posterior tibial arteries of the foot and the brachial artery of the arm occlude as the cuff is inflated. The normal index is 0.9 or greater while an index of 0.4 or less is diagnostic of critical limb ischemia.

It is important to note that chronic diabetes may result in medial calcinosis of the tibial arteries, also referred to as *Monckeberg's arteriosclerosis*. In patients with this condition, occlusion of the tibial vessels with the cuff is not possible, even at high pressures; thus, it is impossible to measure ABI. Noncompressible ABI occurs mostly in patients with long-standing, insulin-dependent diabetes, and this condition necessitates other types of noninvasive vascular testing to assess perfusion.

One test that is similar to ABI and that can be used to assess perfusion to the foot in the diabetic patient is the toe brachial index (TBI). Interestingly, the digital vessels of the toes are spared from medial calcinosis and are therefore compressible with small specialized cuffs and a form of plethysmography. While the upper values do not correlate well with ABI, a TBI of less than 0.4 is indicative of critical limb ischemia. Whether it is ABI or TBI, measured values of less than 0.4 is indicative of severe ischemia. Patients with indices of 0.4 or less are unlikely to heal a foot or toe ulceration or any débridement of the affected area.

FIGURE 1 Lateral foot film demonstrating loss of foot architecture resulting in classic neuropathic arthropathy.

TREATMENT

Treatment of the diabetic foot ulcer and any associated infection should be accomplished with a multidisciplinary approach. An important initial step that should not be overlooked is blood glucose control with an hemoglobin A_{1c} target level of less than 6.5% to 7.0%. Local infection control is also paramount and requires débridement of nonviable tissue and opening of any deep space or forefoot infection. In the case of toe ulceration with gangrene or infection, amputation of the digit with or without proximal extension to include the metatarsal head (i.e., Ray amputation) may be necessary. If more than one toe is affected or there is suspicion for a more extensive forefoot infection, a transmetatarsal amputation may be required. In cases involving digit, Ray, or transmetatarsal amputations, we favor starting the incision distally at the infected ulcer and extending proximally with the goal of exposing all of the relevant plantar spaces. The surrounding tissues should be carefully palpated for unrecognized and undrained abscess, especially along tendon sheaths, which can disguise and facilitate spread of infection (Figure 3).

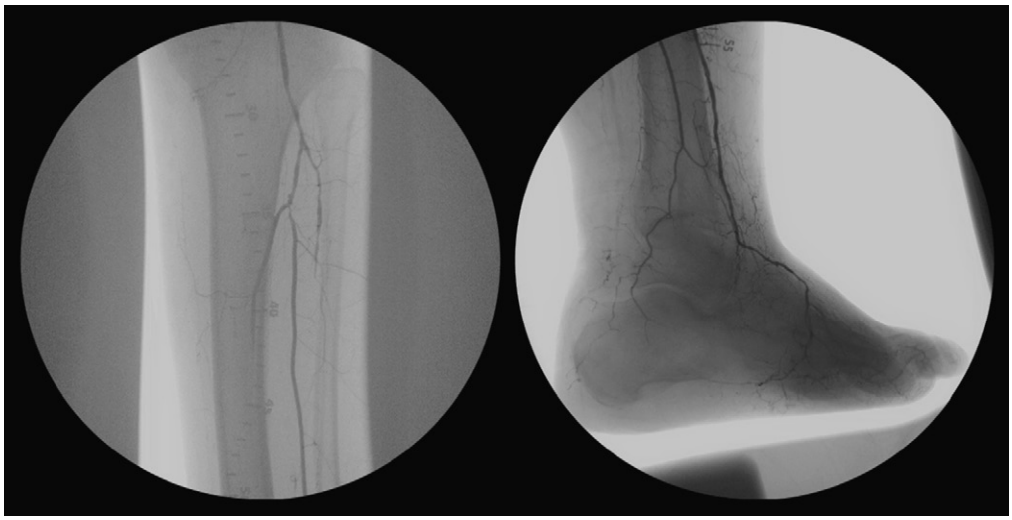

FIGURE 2 Tibial occlusive disease showing proximal anterior tibial artery and posterior tibial artery occlusion with peroneal artery runoff. At the level of the ankle, the anterior tibial artery reconstitutes and retrograde fills via perforating branch of the peroneal artery.

FIGURE 3 Left medial forefoot deep space infection necessitating wide débridement with first and second toe amputation.

Chronic or indolent ulcers without soft tissue or deep space infection can be treated without an extensive operation. These ulcers may have elements of surrounding cellulitis and often have necrotic tissue with polymicrobial colonization. In these cases, initial antibiotic therapy should be broad-spectrum, based on institutional culture and sensitivities and include coverage for methicillin-resistant *Staphylococcus aureus*. The antibiotic regimen should be modified and focused based on the results of the cultures obtained during the initial evaluation and débridement. Antibiotic therapy for chronic ulcers is continued until the cellulitis or superficial infection is resolved (7-10 days) and is not necessary until the wound is healed. Long-term intravenous antibiotic therapy is no longer recommended for diabetic foot ulcers with osteomyelitis given the high recurrence rate in this patient population.

Offloading of or minimizing trauma to the affected area of the foot is also paramount. This strategy may include bed rest, foot elevation, and restricted weight bearing to decrease edema and prevent further mechanical damage of tenuous tissue. Specialized orthotics are available to assist the provider and patient in this strategy, including custom-fit shoes for neuropathic or malformed feet. Although offloading and surface protection should be started during the initial evaluation of any foot ulcer, this strategy should be approached in combination with comprehensive foot care measures as a life-long requirement for patients with diabetes mellitus.

Correction of arterial ischemia will be required for ulcers that fail to heal despite conservative and local wound care and for those with critical ischemia (i.e., ABI or TBI <0.4). Diabetic patients with nonhealing ischemic foot ulcers should be evaluated first for the merit of limb salvage, as some already immobile or debilitated patients may be better served with a primary amputation. This overall assessment for limb salvage should be made in patients with acutely septic ulcers as well as those with more chronic or indolent, nonhealing ulcers.

If a patient is deemed a candidate for limb salvage, a vascular operation should be undertaken after control of associated foot infection and performance of vascular imaging. Revascularization for ischemic ulceration or tissue loss should be undertaken with the goal of restoring in-line or pulsatile flow to the foot. In other words, direct arterial flow is required, through recanalization of an existing artery or with a bypass conduit, to a tibial artery below the extent of occlusion. The arterial target in these cases is free of distal stenosis or occlusion and therefore provides direct flow to the affected foot. In most cases, distal bypass or recanalization for ischemic tissue loss is performed to the anterior or posterior tibial artery, either of which provides direct flow to the plantar arch of the foot. In contrast, the peroneal artery ends at the ankle and provides perfusion to the foot only through collateral branches. While collateral perfusion to the leg and foot may be adequate to relieve claudication or even ischemic rest pain, in-line pulsatile flow is typically required to meet the metabolic demands needed to heal an ischemic foot ulcer.

Lower extremity revascularization options can be considered in two categories: open surgical and endovascular. Regardless of the chosen approach, revascularization must begin with assuring or establishing adequate inflow to the extremity at the level of the common and deep femoral arteries. Options to establish flow from the femoral artery level to the foot will depend on the extent of occlusive disease. As previously discussed, nearly all diabetic patients with ischemic foot ulcers have multilevel arterial occlusive disease that includes the tibial vessels. Because endovascular procedures are yet to be established as effective or durable in the tibial vessels, bypass to a reconstituted tibial artery is most common in this scenario. In most instances, this is performed using autologous saphenous vein as the conduit and either the common femoral or popliteal artery as the inflow vessel. Prosthetic grafts (i.e., expanded polytetrafluoroethylene) can be used for conduit in distal bypass procedures, but they have not been shown to be as durable as saphenous vein. Although distal bypass with saphenous vein as a conduit is superior to endovascular therapy in terms of primary and secondary patency, there is no difference in limb savage rates between the two modalities. In some cases, endovascular therapy and bypass surgery are complementary techniques (i.e., hybrid procedures) for the treatment of ischemic, nonhealing diabetic foot ulcers.

Numerous adjunctive methods are available to aid healing of diabetic ulcers. These methods include hyperbaric oxygen therapy, which has been shown to facilitate wound granulation, contraction, and healing but has not been shown to be cost-effective given the lack of evidence for optimal duration of therapy. One adjunct that has been shown to result in faster rates of wound healing in diabetic patients with adequate perfusion is the negative pressure wound therapy device or VAC. Appropriately applied, closed negative pressure wound therapy results in fewer dressing changes and outpatient wound care visits and improved quality of life. The vacuum-assisted wound closure (VAC) dressing adjunct has also been shown to improve local wound oxygenation, granulation, and contraction.

One of the most difficult decisions in managing a chronic, nonhealing, or septic diabetic foot ulcer is whether to use leg amputation as the primary procedure. Certain patients will not be candidates for staged surgical revascularization and attempted limb salvage because of their preexisting immobility or severe comorbidities. In general, bedridden and wheelchair-bound patients with little potential for ambulation should have an amputation as the initial procedure to reduce complications and speed any chance for recovery. Patients with significant medical comorbidities such as advanced chronic kidney disease may also benefit from primary amputation instead of revascularization and attempted limb salvage. Finally, it should be noted that diabetic foot ulcers heal at a slow rate, even after revascularization. Ulcers over the calcaneus are particularly slow to contract and close because of a relatively lower arterial perfusion and their exposure to pressure or trauma. On average, only one quarter of foot ulcers treated with revascularization are healed within 6 months of surgery. Two thirds of such ulcers are healed within a year of operation, and freedom from amputation ranges from 80% at 1 year to 70% at 3 years.

CONCLUSION

The number of people with diabetes mellitus has reached epidemic proportions, and therefore a firm understanding of the etiology, presentation, and management of foot ulcers is increasingly important.

If present, gangrene or forefoot infection must be débrided or drained in the acute setting along with pursuit of tight glucose control. Chronic or indolent diabetic foot ulcers may be managed more conservatively initially, although failure to heal should prompt a detailed examination of arterial perfusion. The presence of critical limb ischemia will press a decision on the merits of limb salvage, including the potential for revascularization or preference for primary leg amputation.

GANGRENE OF THE FOOT

Louis Lewandowski, MD, Joseph Caruso, MD, and Mark E. Fleming, DO, MC(FS/FMF), USN

OVERVIEW

Critical limb ischemia can lead to gangrene, which in turn can lead to localized coagulative or liquefactive necrosis. This process is further complicated by superimposed bacterial infection and subsequent accelerated tissue decay. Gangrene can affect any part of the body, most commonly the distal extremities; however, when present in a location such as the perineum (Fournier's gangrene), the rates of associated mortality and morbidity are dramatically increased.

Gangrene is classified as either "dry" or "wet." Both disease processes are based on arterial occlusion and loss of perfusion. Dry gangrene occurs in the absence of bacterial infection and is characterized by mummification and desiccation of the necrotic tissue (Figure 1, *A*). In these cases, emergency amputation is not indicated; the natural course of the disease will result in autoamputation. Autoamputation is the process of spontaneous detachment of the desiccated necrotic tissue. Wet gangrene (Figure 1, *B*), however is associated with superimposed bacterial infection that can lead to overwhelming sepsis and multisystem organ failure. Patients presenting with gangrene with a superimposed infection need to be evaluated on an emergency basis for adequate infection control, through either amputation and aggressive débridement or revascularization procedure.

RISK FACTORS AND EPIDEMIOLOGY

Critical limb ischemia is estimated to affect 2 million patients in the United States, and that number is predicted to grow to 2.8 million by 2020. The number of patients with diabetes—a known risk factor for critical limb ischemia—is estimated to expand from 16.8 million currently to more than 24.5 million in the next 10 years; hence the prevalence of critical limb ischemia could be closer to 3.5 million by 2020.

Fortunately, the number of patients with diabetes who require lower extremity amputation has been nearly halved to 4.6 per 1000 within the last decade. Despite these improvements, the mortality rate remains as high as 30% at 1 month after amputation and 50% at 1 year after amputation, according to a study of 96 patients who underwent non–trauma-related amputations of the lower extremity. It is also estimated that more than 60% of nontraumatic lower amputations of the extremity are a result of diabetic complications; 25% of diabetic patients with foot infections require amputation.

Smoking continues to be an important risk factor for the development of peripheral artery disease and its progression to critical limb ischemia. In the TransAtlantic Inter-Society Consensus report, smoking was recognized as a greater risk factor for the development and progression of peripheral artery disease than for coronary artery disease. Heavy smokers with intermittent claudication are statistically more likely to require revascularization procedures and major amputations than are nonsmokers.

Gangrene is traditionally viewed as a unilateral phenomenon because of the conditions just described. In critically ill patients, however, disseminated intravascular coagulation can lead to symmetric gangrene. Other conditions leading to peripheral gangrene in critically ill patients include hypercoagulable states and use of vasoactive drugs. The mortality rate associated with symmetric peripheral gangrene is estimated to be approximately 35%; almost half of affected patients require amputation of at least one lower extremity. In the absence of ischemic arterial disease, other conditions that cause arterial occlusion and thereby lead to peripheral ischemia and gangrene include myeloproliferative disorders and vasculitides or vasospastic conditions such as Raynaud's syndrome.

EVALUATION

Clinical Presentation

The patient's evaluation begins as always with a thorough history and physical examination. The physician should look for risk factors and preexisting comorbid conditions that can complicate medical and surgical management of the patient. In patients with superimposed infection, it is of the utmost importance to determine the extent of the infection. Patients with sepsis have significant metabolic abnormalities and hemodynamic instability that necessitate immediate surgical and intensive care management.

The level of the amputation required can be approximated empirically by a thorough physical examination and through the clinical judgment of an experienced surgeon. Physical examination findings of critical limb ischemia include changes in skin temperature, loss of hair, muscle atrophy, presence of arterial bruit, and diminished pulses. Strong palpable pulses proximal to the anticipated level of

FIGURE 1 Dry and wet gangrene. **A,** Dry gangrene with evidence of autoamputation. **B,** Acute wet gangrene.

amputation are a good indicator of healthy wound healing. Numerous noninvasive tests provide valuable data for the adequacy of tissue perfusion and oxygenation to further determine the patient's ability to heal.

Diagnostics

The evaluation should proceed with noninvasive vascular studies to confirm the clinical diagnosis and further define the level and extent of arterial disease. Various noninvasive examinations help assess presence and severity of arterial disease, defining both the adequacy of inflow from large vessels and the quality of microcirculation. Physiologic tests include calculation of pressure index values (e.g., ankle-brachial index [ABI], toe-brachial index, blood pressures in segmental limbs) and measurement of transcutaneous partial pressure of oxygen ($TcPO_2$). Imaging can be used to determine whether a lesion is amenable to revascularization and to assist with decisions on surgical approach (e.g., endovascular versus open, choice of conduit). Ultrasonography is the mainstay of vascular imaging with each mode, providing specific and useful information. Other frequently employed techniques include computed tomographic scan and magnetic resonance imaging. Contrast arteriography (digital subtraction arteriography) is the "gold standard" of imaging tests and can be the primary imaging modality because it enables intervention if the anatomy is amenable.

Ankle-Brachial Index

The ABI is the ratio of the systolic blood pressure in the dorsalis pedis or posterior tibial artery to that in the brachial artery. Continuous-wave Doppler mode is used to listen to the arterial signal, and a manual blood pressure cuff is inflated until the sound disappears. The pressure at which the sound returns is recorded. The higher of the two pressures from the dorsalis pedis or posterior tibial artery is used. An ABI of 0.9 or lower is diagnostic of occlusive arterial disease; a value below 0.4 suggests multilevel disease and is predictive of poor wound healing. ABI values above 1.3 suggest calcification of vessels and the need for additional vascular studies.

Toe-Brachial Index

The toe-brachial index is a more reliable indicator of limb perfusion, particularly in patients with diabetes, because the small vessels of the toe are usually spared of calcifications. A photoelectrode is used to obtain an arterial waveform with infrared light. As in ABI measurement, the toe cuff is inflated until the arterial waveform flattens. The cuff is then deflated until the baseline waveform returns. A pressure gradient of 20 to 30 mm Hg is normal between the toe and the ankle, and so a normal toe-brachial index is 0.7 to 0.8. An absolute pressure of more than 30 mm Hg is favorable for wound healing, but pressures higher than 45 to 55 may be required for healing in patients with diabetes.

Segmental Limb Pressures

Segmental limb pressures are obtained with a series of four cuffs on the lower extremity: proximal and distal thigh, calf, and ankle. Pressures at each level are compared with the brachial pressure. With these comparisons, the level of arterial occlusion can be localized. A 20–mm Hg reduction in pressure between segments in the same leg or in comparison with the same level in the opposite leg is abnormal and suggests a significant lesion.

Transcutaneous Oxygen Measurement

$TcPO_2$ measurements can provide supplemental information regarding local tissue perfusion. Electrodes are placed on the chest wall and legs or feet. The absolute value of the oxygen tension in a location, or a ratio of that value to the chest wall, can be used. A normal value at the foot is 60 mm Hg, and a normal chest/foot ratio is 0.9. Local edema, skin temperature, inflammation, and pharmacologic agents can limit the accuracy of this test, and so the level of $TcPO_2$ that portends poor tissue healing remains controversial. A value of 40 mm Hg is generally accepted as adequate for healing (in the absence of edema or diabetes). Values lower than 20 mm Hg indicate severe ischemia, and revascularization is needed for wound healing. A meta-analysis of four studies revealed more than a threefold risk of healing complication in patients with a $TcPO_2$ below a threshold of 20 to 30 mm Hg (odds ratio, 3.26; 95% confidence interval: 1.07 to 9.69).

Duplex Ultrasonography

In real-time ultrasonography, reflected sound waves are used to produce images and assess blood velocity. *Duplex* refers to the use of two modes: B-mode (brightness) and Doppler mode. Ultrasonography does not require intravenous contrast or ionizing radiation and can provide precise anatomic location and accurate grading of lesion severity. It is, however, highly operator dependent.

Multidetector Computed Tomographic Angiography

Multidetector computed tomographic angiography (MDCTA) allows rapid acquisition of high-resolution, contrast agent–enhanced arterial images. It is more expensive than ultrasonography and involves the use of ionizing radiation and contrast agent. According to a meta-analysis of 20 studies in which MDCTA was compared with digital subtraction angiography, the sensitivity and specificity of MDCTA in detecting stenosis of more than 50% were 95% and 96%, respectively.

Magnetic Resonance Angiography

In magnetic resonance angiography, rapid three-dimensional imaging sequences are obtained with gadolinium contrast agents. This method is becoming a more time-efficient and cost-effective means for evaluation of arterial disease in the lower extremity. It has the advantage of employing nonionizing radiation, but it lacks the small vessel spatial resolution of MDCTA. Gadolinium, however, is contraindicated in patients with renal insufficiency.

Assessment of Metabolic Status

Evaluations of a patient's serum glucose and hemoglobin A_{1C} levels provide a starting point for a laboratory evaluation of diabetic control. It is also important to ensure that the total serum protein level is higher than 6.2 g/dL and that the serum albumin level is higher than 3.5g/dL to predict a patient's ability to heal. A total lymphocyte count higher than 1500/mm^3 is also a predictor of healing potential.

MANAGEMENT

Antibiotics and Medical Management

Current recommendations from the infectious disease literature warn against the use of empiric antibiotics before optimal wound cultures are obtained. Proper cultures should be obtained after initial débridement of deep tissue through biopsy or curettage, not by swab specimens, to increase accuracy of results. Antibiotic-resistant organisms continue to proliferate, especially methicillin-resistant *Staphylococcus aureus;* highly resistant *Pseudomonas* organisms and extended-spectrum β-lactamase bacilli are also increasingly isolated. With this rising risk of resistant organisms, tailored antibiotic regimens are increasingly important for clearing infections.

The choice of therapy is based largely on the severity of the infection; severe and some moderate infections necessitate parenteral therapy. However, highly bioavailable oral antibiotics alone are sufficient in most mild and many moderate infections. The length of antibiotic therapy is based on the extent of the infection: for mild soft tissue infections, treatment must continue for approximately 2 weeks, and for moderate to severe infections, 3 weeks.

Débridement

Débridement is the key step in the treatment of moderate to severe infection, with the removal of devitalized tissue that provides a substrate for bacteria. Devitalized tissue is poorly vascularized and therefore is not penetrated appropriately by systemic antibiotics. The most commonly used method of débridement is a sharp, surgical procedure. Sharp débridement can be augmented in the operation room with the addition of hydrodébridement devices to help débride nonviable tissue while maintaining healthy tissue. Techniques that continue the effects of surgical débridement between procedures are mechanical or pharmacologic, involving wet-to-dry dressings or topical enzymes. Negative-pressure wound therapy can also be used between débridements to decrease contamination of the wounds, remove wound debris, and promote granulation and microvascular ingrowth. Protease scavengers and biologic wound matrices will also aid in wound healing between operative interventions. In conjunction with local wound care, these agents have been shown to reduce healing times and increase overall healing rates, which lead to reduced amputation rates.

Revascularization

In patients with an ulcer caused by arterial insufficiency, intervention is necessary to optimize the potential for the wound to heal or, at the very least, to optimize the healing potential of an amputation wound. Arterial lesions are graded from A to D on the basis of complexity; type A ulcers are the simplest lesions, and type D ulcers are the most complex. Endovascular therapy is the treatment of choice for type A lesions and preferred for type B lesions. Open surgery is the treatment of choice for type D lesions and preferred for type C lesions. Nonetheless, technological advancements allow increasingly complex lesions to be addressed in endovascular approaches, which gives patients who are otherwise poor surgical candidates an opportunity for limb salvage.

For patients of an acceptable surgical risk, controversy exists as to the best initial approach. In the Bypass versus Angioplasty in Severe Ischemia of the Leg (BASIL) trial, investigators compared a surgery-first approach (with autogenous vein) with an angioplasty-first approach for infrainguinal disease. There was no difference between the two procedures in the rate of amputation-free survival 1 year after the procedure or at the end of follow-up. There was no difference in overall survival at 30 days or by the end of the study (mean follow-up period, 3.7 years). However, for patients surviving at 2 years after the procedure, the surgery-first approach was associated with a lower subsequent mortality rate, with a hazard ratio of 0.61 (95% confidence interval: 0.50 to 0.75). In view of this outcome, current American College of Cardiology/American Heart Association guidelines recommend endovascular intervention for patients if life expectancy is less than 2 years and bypass for patients expected to live longer than 2 years (provided that an autogenous vein is available).

Improvements in endovascular techniques have allowed for increases in attempted limb salvage in patients at high risk for limb loss who would have otherwise been candidates only for primary amputations. With these improvements, there have been decreasing rates of primary amputation; however, the incidence of limb loss despite patent revascularization is increasing in this patient population. Patients at high risk for limb loss after revascularization are those with diabetes, renal insufficiency, and gangrene. In such patients, inability to control primary or recurrent infection and inability to reverse ischemia are major factors contributing to limb loss despite intervention. Even with improved techniques and early intervention, a number of studies have demonstrated that the clinical durability of limb salvage in the setting of significant soft tissue infection is often limited.

Amputations

The initial goal in the treatment of severe infections of the lower extremity is the thorough débridement of all devitalized tissue and infectious material. The viability of muscle is determined according to its ability to contract when stimulated, capacity to bleed when débrided, color, and consistency. In order to ensure débridement is adequate, the wound can often be left open with a negative-pressure wound dressing in order to return to the operating room for a second-look procedure. Once the surgeon is satisfied with the débridement, the goal is preservation of the greatest amount of viable tissue for reconstruction. It is important to note the increased energy

requirements for ambulation that are associated with lower extremity amputation because these requirements, combined with the patient's preexisting comorbid conditions, dramatically decrease postoperative ambulation.

Although some authorities advocate the use of a proximal tourniquet when amputation of an infected hyperemic limb is required, no trials have yielded supportive evidence of improved healing rates with intraoperative tourniquet use. A tourniquet may be used to control blood loss while the affected limb is removed, but it should be released later to ensure adequate perfusion and viability of the skin flaps. One important consideration in applying a pneumatic tourniquet for any lower extremity amputation is the presence of an underlying vascular graft.

Wound closure in dysvascular amputations is arguably the most important component of the procedure. Careful attention should be paid to ensure that wounds are not closed under tension in order to ensure the greatest perfusion of the skin flaps. Also, monofilament suture should be used whenever possible to decrease infection risk; antibiotic sutures can also be used. For distal amputation, full-thickness flaps can be closed with nonabsorbable 2-0 or 3-0 suture. Major lower extremity amputation should be closed in layers with #0 nonabsorbable sutures to approximate deep fascia, augmented with 2-0 absorbable suture. All cutaneous sutures should be placed in a mattress or Allgower-Donati style to ensure placement of the knot on the proximal flap.

Postoperative dressing of the residual limbs should account for the decreased vascularity of these extremities. Either incisional negative-pressure dressings or fluffed gauze should be held in place with loosely wrapped elastic dressings. Tight compression wraps, although traditionally used in traumatic amputations, should be avoided because they can increase the risk of wound dehiscence.

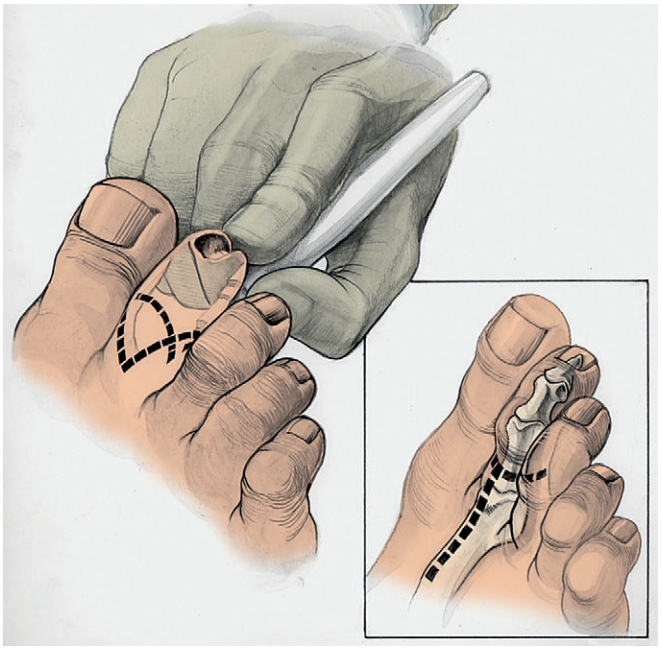

FIGURE 2 Ray amputation. Skin incision for a ray amputation is made with equal sagittal or dorsal and plantar flaps to ensure adequate blood supply. A racquet-like incision encircles the base of the toe and extends proximally over the dorsum of the metatarsal head. *(Modified from Barnes RW, Cox B:* Amputations: an illustrated manual, *Philadelphia, 2000, Hanley & Belfus, p 17.)*

Toe Amputation

Gangrene that is limited to the middle or distal phalanges, not involving the metatarsal head, is often amenable to simple toe disarticulation. This provides adequate treatment of the infection without affecting the patient's ambulation. Digit amputation should not be performed if ischemia of the forefoot is present or if infection involves the metatarsal head.

Great Toe Amputation

If amputation of the great toe is required, it is advantageous to preserve the base of the proximal phalanx rather than perform a complete metatarsophalangeal disarticulation. The first metatarsal head is important for balance and gait, and preservation of the proximal phalanx allows for better distribution of weight and pressure. This is particularly important in diabetic patients, who are susceptible to development of mal perforans ulcers. A curvilinear incision at the base of the toe is carried down to the level of the bone in a circumferential manner. Skin incisions can be created in a fish-mouth configuration, which involves the use of dorsoplantar or mediolateral skin flaps, or in a racquet-like manner. The choice of incision is based on viable tissue that is available to cover the remaining end of the proximal phalanx. An oscillating power saw is used to transect the distal phalanx, and the proximal phalanx (at least 1 cm) is preserved. Bone edges are smoothed to a bevel with a saw, rasp, or rongeur. Finally, full-thickness skin flaps are approximated.

Lesser Toe Amputations

The metatarsophalangeal joint is identified by flexing and extending the toe. A circumferential racquet-like or fish-mouth incision is made at the midpoint of the proximal phalanx (Figure 2). The incision is carried down to the level of the bone, and the joint capsule is opened. Resection of the cartilage at this time is not recommended; however, if viable skin flaps are present, cartilage ischemia is rarely a problem. The distal end of the affected phalanx is resected with the use of an oscillating power saw.

Ray Amputation

Ray amputations involve complete resection of the phalanx and partial resection of the corresponding metatarsal. Ray amputations are indicated when there is not enough viable tissue to provide coverage for a disarticulation as described previously. First and fifth ray amputations are often referred to as *border amputations* and are the easiest to perform. However, ray amputation to remove two adjacent toes is also possible.

For border ray amputations, a racquet-like incision is carried out in a circumferential manner and extended onto the dorsal aspect of the foot. For amputation of the second, third, or fourth toe, a racquet-like incision that extends over the metatarsal is also used (see Figure 2). Nerves and tendons are resected under tension, and the distal aspect of the metatarsal is transected with an oscillating saw; the metatarsal head is left intact.

Transmetatarsal Amputation

Transmetatarsal amputation is indicated for gangrene that results in significant forefoot tissue loss. A slightly curved dorsal skin incision is made in a mediolateral direction (Figure 3). The medial and lateral aspects of the dorsal skin excision are extended distally to ensure adequate skin coverage over the bone ends. The corresponding plantar flap is created slightly longer than the dorsal flap, and the tendons are resected under tension to the proximal edge of the wound and are allowed to retract.

Next, the metatarsals are resected with the use of a power saw with a 15-degree bevel in relation to the transverse axis. Each metatarsal should be cut successively shorter than the adjacent metatarsal in a mediolateral fashion. Next, the amputated forefoot is resected away from the plantar flap. Before approximation of the plantar and dorsal

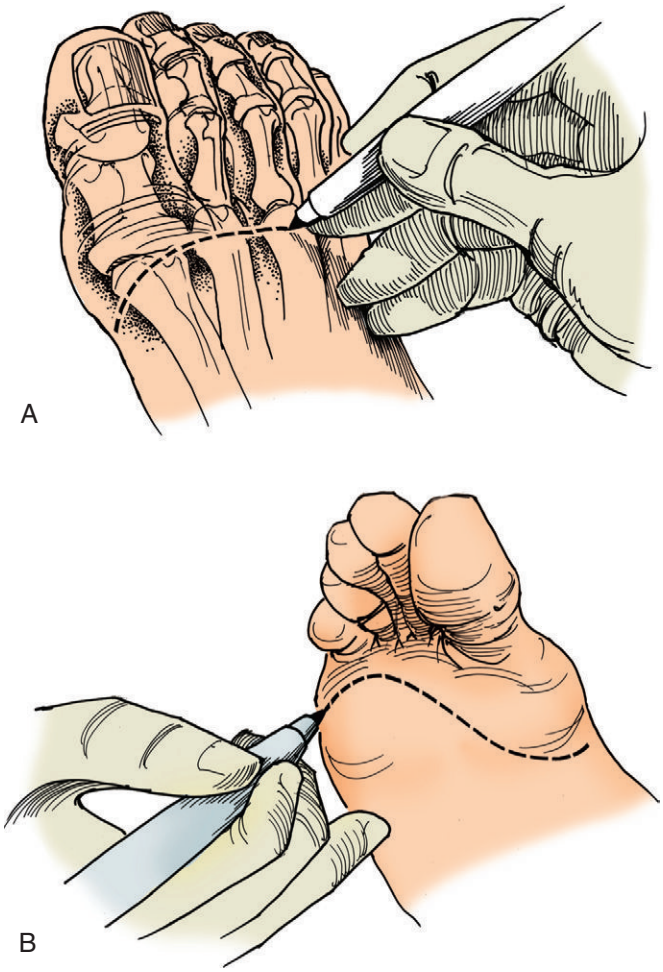

FIGURE 3 Transmetatarsal amputation. A transverse dorsal incision is made proximal to the metatarsal heads **(A),** and a curvilinear plantar incision is made at the base of the toes **(B)** to create a long plantar flap. *(Modified from Barnes RW, Cox B:* Amputations: an illustrated manual, *Philadelphia, 2000, Hanley & Belfus, p 39.)*

skin flaps, the plantar flap often requires thinning to avoid undue tension on the closure, which threatens viability.

Syme Amputation

The chief indication for a Syme amputation is forefoot necrosis not amenable to a transmetatarsal amputation with a healthy, viable heel pad. The Syme amputation allows for preservation of limb length and a partially weight-bearing residual limb. The sole vascular supply to the heel pad is the posterior tibial vessels, which should be carefully preserved. A transverse anterior incision that connects the anterior points of each malleolus is carried down to the bone. The corresponding dorsal incision is made down to the level of the calcaneus. The anterior tendons are identified and dissected under tension and allowed to retract (Figure 4).

The anterior tibial artery is identified and ligated, and the collateral ligamentous attachments of the talus are divided. After the medial neurovascular bundle is identified, the calcaneus is dissected away from the surrounding soft tissues, while traction is applied on the talus to facilitate dissection. During this aspect of the dissection, careful attention must be paid to avoid any injury to the subcutaneous attachment of the Achilles tendon, which would compromise the integrity of the heel pad and cause the amputation to fail. Subperiosteal dissection is carried out until the calcaneus is completely free from the soft tissue. Next, the malleoli are dissected flush with the joint surface, and the remaining bones are trimmed to avoid potential pressure points. The remaining soft tissue envelope is reapproximated with a three-layer closure. The plantar and deep fascias are approximated over the anterior portion of the tibia, followed by closure of the subcutaneous tissue and skin.

Transtibial Amputation

In patients whose necrotic tissue is not amenable to foot salvage, a transtibial amputation is indicated. An important consideration in major lower extremity amputations is what constitutes adequate débridement of necrotic tissue with maximal soft tissue preservation. Care should be taken to avoid creation of inadequate tissue flaps; such flaps may mandate a more proximal amputation than originally planned. Also, as a result of a guillotine-style amputation for the initial procedure, the residual limb may need to be shortened in order to provide adequate soft tissue coverage.

In the most commonly performed procedure for transtibial amputation, a longer posterior flap technique is used. The risk in using a true long posterior flap in patients with critical limb ischemia is poor perfusion of this distal flap, which needs to be monitored closely. If the extent of limb ischemia or gangrenous tissue precludes

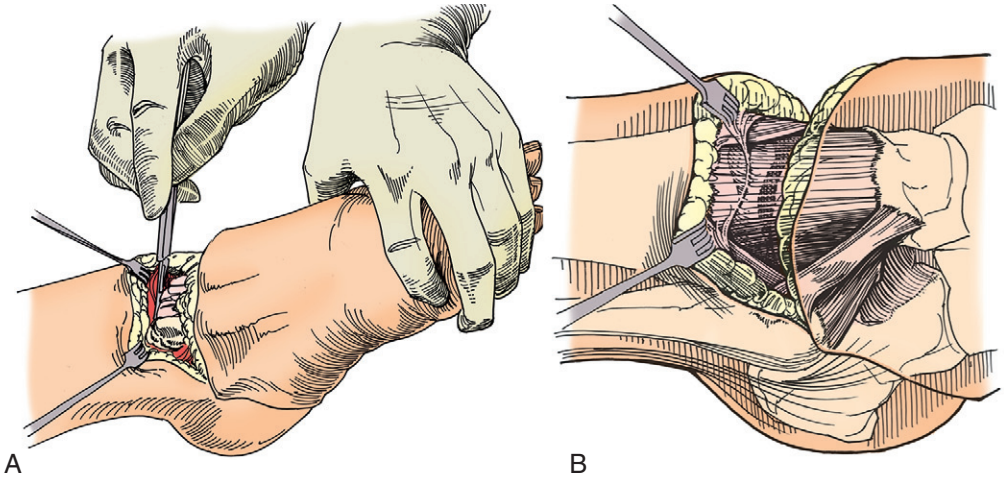

FIGURE 4 Syme amputation. *(Modified from Barnes RW, Cox B:* Amputations: an illustrated manual, *Philadelphia, 2000, Hanley & Belfus, p 53.)*

creation of a viable long posterior flap, numerous alternative techniques can be employed, including equal anteroposterior flaps, unequal anteroposterior flaps, and sagittal flaps. The anterior skin incision to create a long posterior flap is made approximately 10 cm distal to the tibial tuberosity and extended medially and laterally approximately two thirds of the way across the circumference of the calf (Figure 5). The incision is extended distally to create a posterior flap that extends 9 to 13 cm beyond the anterior flap. The distal aspects of the medial and lateral incisions are created in a curved manner and joined on the posterior surface of the calf, and the skin incision is carried down to the level of the fascia.

Next, the muscles of the anterior compartment are dissected sharply with a scalpel or electrocautery. As the muscle is further divided, the anterior tibial artery and vein are often encountered in the more posterior aspect of the anterior compartment; these vessels should be ligated and transected. The tibia and fibula are circumferentially cleared of the periosteum and are transected with an oscillating power saw. The anterior tibia is beveled approximately 1 cm proximal to the skin incision, and the fibula is transected 1 cm proximal to the tibia. A bone hook is used to apply traction on the tibia, and the muscles of the posterior compartment are carefully divided until the posterior tibial and peroneal neurovascular bundles are encountered; these bundles are then suture ligated and divided. The remaining muscles in the deep and superficial posterior compartment are divided, and the crural fascia is left in place with the posterior flap. At this time, the thickness of the posterior flap is evaluated and debulked as necessary to achieve a tension-free closure when it is approximated to the anterior flap.

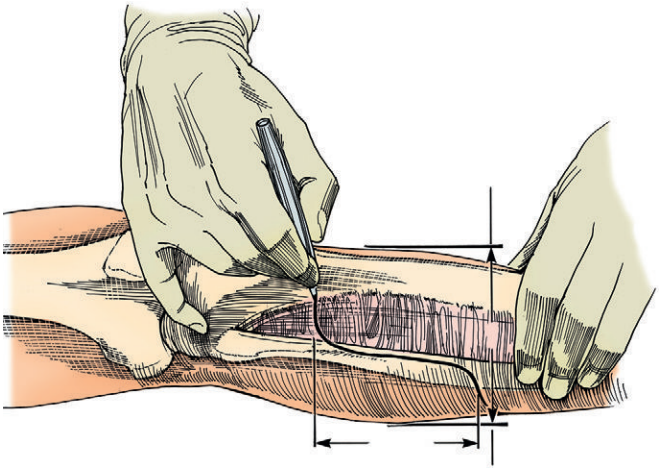

FIGURE 5 Below-the-knee amputation. The anterior skin incision is made at the level of maximal girth of the calf, approximately 3 to 4 fingerbreadths distal to the tibial tuberosity. *(Modified from Barnes RW, Cox B:* Amputations: an illustrated manual*, Philadelphia, 2000, Hanley & Belfus, p 68.)*

Transfemoral Amputation

A transfemoral amputation is indicated for patients with ischemic limbs that are nonreconstructable or with extensive infection that precludes healing at a more distal amputation site. In addition, patients with a fixed knee contracture or a nonfunctional distal limb should also be considered for transfemoral amputation. In these patients, the postoperative energy cost of ambulation increases 60% to 100%, in comparison with 30% to 60% in patients who have undergone transtibial amputation. Increased energy costs have been shown to reduce postoperative ambulation to approximately 40% in patients with diabetes and occlusive arterial disease.

A suprapatellar fish-mouth incision is carried down to the level of the deep subcutaneous fascia to create equal-sized anterior and posterior skin flaps. The skin and subcutaneous tissue are retracted in a proximal manner, and the deep muscle fascia is sharply incised. After division of the quadriceps muscle, proximal traction is placed on all mobilized skin, subcutaneous tissue, and muscle to allow for periosteal elevation of the femur 2 to 3 cm proximal to the skin incision. The femur is transected with an oscillating or manual saw at the proximal level of the periosteum and is then beveled. The transected femur is retracted anteriorly, and the posterior muscle bundle is sharply divided. As major vessels and nerves are encountered, they should be clamped, transected, and ligated with an absorbable 2-0 suture. Wound closure is performed in multiple layers by approximating the anterior and posterior deep subcutaneous and muscle fascia to a cuff of periosteum. This myoplasty effectively stabilizes the anterior and posterior muscle bundles.

SUMMARY

Lower extremity gangrene is a devastating disease process that accounts for a majority of nontraumatic lower limb amputations. The rates of morbidity and mortality from gangrene can best be reduced through a multidisciplinary approach and early treatment, beginning with local wound care and infection control. Vascular assessment and possible repair are critical for preoperative planning and attempted limb salvage, when suitable.

Buerger's Disease (Thromboangiitis Obliterans)

Carl Magnus Wahlgren, MD, PhD, and Bruce L. Gewertz, MD

INTRODUCTION

Thromboangiitis obliterans (TAO), or Buerger's disease, is a nonatherosclerotic, segmental, inflammatory disease that affects the small- and medium-sized arteries and veins of the extremities. Patients are mostly young male tobacco smokers who present with distal extremity ischemia, ischemic ulcers, or gangrene. Buerger's disease has a worldwide distribution, but it is more prevalent in the Mediterranean, the Middle East, and Asia. Recently, the prevalence of disease seems to have declined in the United States and Europe. In the United States, an eightfold decrease was found in the prevalence rate of disease between 1947 and 1986 (104 to 12.6 cases per 100,000 patient registrations). The disease also decreased in Japan between 2000 and 2006. Whether this represents a true decline attributed to the decline in smoking or an adoption of more uniform stricter diagnostic criteria is unclear. An increase has been seen in the incidence in women, who now constitute up to 20% of patients in certain series. This relative rise in incidence in women is undoubtedly a result of the increase in cigarette smoking among women.

Although the etiology of Buerger's disease is unknown, the condition is strongly associated with heavy tobacco use. Smoking is considered by most to be an absolute requirement for diagnosis, and progression is closely linked to continued use. However, a causal relationship has not been conclusively shown. Reports have been made of the presence of TAO in cigar smokers and in users of smokeless tobacco, such as chewing tobacco and snuff. The disease is classified pathologically as a vasculitis. Features that distinguish TAO from other types of vasculitis include highly inflammatory thrombus with relative sparing of the blood vessel wall, normal acute phase reactants, and no serum markers of immunoactivation.

CLINICAL PRESENTATION

Buerger's disease typically begins with involvement of the distal small arteries and veins. More proximal arteries may be involved when the disease progresses, but involvement of large arteries is unusual. The onset of symptoms usually occurs before the age of 40 to 45 years. Patients may present with claudication of the feet, legs, hands, or arms. Two or more limbs are always involved; all four limbs are affected in about 40% of patients. Intermittent symptoms are initially localized to the forefoot or the arch of the foot because of the distal nature of the disease, as opposed to patients with peripheral atherosclerotic disease who first experience symptoms located to the calves. Progression of the inflammatory disease leads to development of ischemic rest pain and ulcerations in the distal portion of toes or fingers. In most series, about three fourths of patients present with ischemic ulcers. Raynaud's phenomenon and superficial migratory thrombophlebitis are manifestations that are commonly encountered.

Although Buerger's disease predominantly affects the vessels of the extremities, a few instances of aortic, cerebral, coronary, mesenteric, pulmonary, and renal involvement have been reported in the literature. Mesenteric Buerger's disease is extremely rare and is associated with a poor prognosis. For this reason, patients with known Buerger's disease who present with gastrointestinal manifestations should be urgently evaluated for bowel ischemia; early surgical intervention is recommended.

DIAGNOSIS

Several criteria have been proposed for the diagnosis of TAO. The common clinical criteria can be summarized as:

- Age younger than 45 years
- Current or recent history of tobacco use
- Distal extremity ischemia documented with noninvasive vascular testing
- Findings suggestive of TAO on conventional angiography or magnetic resonance imaging.
- Exclusion of autoimmune disease, hypercoagulable states, diabetes mellitus, proximal source of emboli, trauma, and local lesions (popliteal entrapment syndromes, adventitial cystic disease)

The physical examination often reveals cyanotic and erythematous extremities. Sensory abnormalities (burning, hypoesthesia, numbness, and tingling) as a result of ischemic neuropathy are common as is cold sensitivity that may be related to ischemia or to increased muscle sympathetic nerve activity. Absent distal pulses in the presence of normal proximal pulses are typical in patients with the disease. Ankle-brachial indices should be included in the vascular examination. Involvement of both the upper and the lower extremities is common. Dry punctuate ischemic lesions are often seen on both the hands and the feet. Although nonspecific, a positive Allen's test in a young smoker with digital ischemia is strongly suggestive of the disease.

A definitive diagnosis of TAO can only be made with a vessel biopsy that shows cellular thrombus and the classic acute phase lesion, but the physical examination and history are often classic. As a consequence, biopsies are rarely needed unless a patient presents with unusual characteristics, such as large artery involvement or an age of more than 45 years.

No specific laboratory tests confirm the diagnosis, but several serologic tests should be included in the workup to rule out other diseases that mimic TAO, including scleroderma, calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia (CREST) syndrome, mixed connective tissue disease, systemic lupus erythematosus, and hypercoagulability disorders. A complete blood count is routinely obtained with differential, electrolyte, renal and liver function tests, fasting blood glucose, urinalysis, sedimentation rate/C-reactive protein, and a complete hypercoagulability screen, including antiphospholipid antibodies. Serologic markers that should be obtained are antinuclear antibody, rheumatoid factor, complement measurements, and serologic markers for CREST syndrome and scleroderma (SCL-70 and anticentromere antibody). Patients with giant cell arteritis or Takayasu's arteritis usually present with more proximal vascular involvement and more frequently have elevations of acute phase reactants.

Standard arteriography is not essential for the diagnosis. Noninvasive imaging methods such as magnetic resonance angiography (MRA) and computed tomographic angiography (CTA) are good alternatives. Four-limb segmental arterial pressures and digital plethysmography (waveform or digital pressure measurement) are useful to document distal occlusive disease. When suggested by unilateral involvement, a proximal source of emboli should be excluded with echocardiography or CTA/MRA.

Arteriography should be performed in those patients with threatened limb loss. Although a number of angiographic findings are

highly suggestive of TAO, there are no pathognomonic findings (Box 1 and Figures 1 and 2). The angiographic appearance of TAO may be identical to other types of small vessel vasculitis or toxic arterial responses related to amphetamine, cannabis, or cocaine abuse. If a nonsmoking patient presents with signs consistent with Buerger's disease, a toxicology screen for the previously mentioned drugs is advisable.

Because of the relatively young age of most patients, the possibility of popliteal artery entrapment syndrome, cystic adventitial disease, or popliteal artery aneurysm should be considered in patients with lower extremity symptoms. The presence of diabetes mellitus, end-stage renal disease, or significant risk factors for atherosclerosis argues against a diagnosis of Buerger's disease.

BOX 1: Angiographic findings in thromboangiitis obliterans (Buerger's disease)

- Involvement of small and medium-sized vessels
- Palmar, plantar, tibial, peroneal, radial, and ulnar arteries and digital arteries of fingers and toes (see Figure 1)
- Normal extremity arteries proximal to the popliteal and distal brachial levels
- Absence of proximal atherosclerosis and vascular calcification
- No source of thrombus
- Abrupt transition from a normal and smooth proximal artery to an area of occlusion
- Symmetric and segmental arterial involvement
- Tortuous "corkscrew" collaterals that are suggestive, but not pathognomonic, of Buerger's disease (see Figure 2)

TREATMENT

The main and most effective treatment for Buerger's disease is the total abstinence from tobacco products. Smoking is closely related to exacerbation and remission of the disease. Even a few cigarettes a day or use of smokeless tobacco or nicotine replacement may keep the disease active. Smoking cessation was initially thought to not be possible in patients with Buerger's disease. The authors' experience and that of others suggest that this is unduly pessimistic; up to one third of the authors' patients have successfully discontinued tobacco use with proper counseling and support.

A correlation is found between continued smoking and limb amputation. If patients discontinue tobacco use, they can be reassured that the disease often remits and that amputation can be avoided as long as ischemic ulcers have not already occurred. That said, patients with already significant occluded arterial segments may continue to experience intermittent claudication or Raynaud's phenomenon.

In patients with disease progression despite smoking cessation, effective therapeutic options are limited (Box 2). Initial enthusiasm for infusion of the prostaglandin analogue iloprost has not been borne out by further trials or experience. Anticoagulants, antiplatelet drugs, and rheologic agents seem to be ineffective. Calcium channel blockers are only helpful if significant vasospasm is present. Intraarterial thrombolytic therapy is not effective and has not been used in the authors' practice. Therapeutic angiogenesis, including intramuscular gene transfer of vascular endothelial growth factor and bone marrow–derived stem cell therapy, seems promising and beneficial, although further studies are needed to evaluate safety and efficacy.

Unfortunately, arterial reconstruction is usually not an attractive option because of the diffuse segmental involvement and distal nature of the disease. Also, the concomitant inflammatory venous

FIGURE 1 Hand angiogram of a patient with Buerger's disease showing involvement of the digital arteries with several occlusions and collaterals.

FIGURE 2 Lower extremity angiography of a patient with Buerger's disease showing multiple occlusions and "corkscrew" collaterals.

BOX 2: Treatment options in thromboangiitis obliterans (Buerger's disease)

1. Cessation of tobacco products
2. Local wound care
3. Arterial reconstruction with vein graft or endovascular therapy
4. Therapeutic options
 a. Prostaglandin analogue iloprost or treprostinil sodium
 b. Cilostazol
 c. Hyperbaric oxygen therapy
 d. Calcium channel blockers (i.e., amlodipine or nifedipine), if vasospasm
 e. Intermittent pneumatic compression pump
 f. Implantable spinal cord stimulator
 g. Therapeutic angiogenesis with gene-based or cell-based therapies
5. Amputation

disease often renders the saphenous veins unsatisfactory for use as conduits. However, if conservative treatment fails in patients with severe ischemia and nonhealing ischemic ulcers of the lower extremities, revascularization should be considered. The distal arteries must be thoroughly evaluated with arteriography for optimal preoperative planning. If surgical exploration reveals a diminutive receiving vessel, bypass should be abandoned.

Although less invasive endovascular approaches might be attractive in this population, the diffuse, distal, and segmental involvement of the lesions confounds available catheter-based techniques, and their role is likely to be similar to that of surgery. Extended endovascular interventions down to the foot have shown to be technically feasible in a limited number of patients with TAO, but long-term data are lacking. More proximal femoropopliteal lesions in patients with advanced disease should be addressed to maximize inflow to collateral vessels.

As with many interventions for occlusive vascular disease, limb salvage rates usually exceed graft patency rates. Although the patency rate for distal bypass is no more than 50% even in the small number of patients with Buerger's disease who can undergo bypass, limb salvage rates frequently exceed 75%. In these well-selected patients, even limited periods of revascularization provide a sufficient interval to heal ischemic ulcers in the feet.

Sympathectomy as a primary or adjunctive treatment option has been tried in a large number of patients with Buerger's disease without encouraging results. This lack of success reinforces the obstructive rather then vasospastic nature of the disease. Still, in some patients, spinal cord stimulation can have a salutary effect through pain reduction.

Amputations are inevitable in patients with extensive gangrene or sepsis. The goal is to remove all nonviable tissue, preserve optimal residual function, and minimize surgical morbidity. Application of these principles may result in unconventional amputation levels with a preponderance of multiple digital or distal amputations.

PROGNOSIS

In general, the prognosis for many patients with Buerger's disease is surprisingly good and depends largely on the ability to discontinue tobacco use. Despite the considerable morbidity, life expectancy for patients approaches that of an age-matched population. This could possibly be explained by the young age of presentation and the lack of coronary involvement in the disease process.

Even though ischemic ulcers are already present in most patients presenting for medical care, the overall limb amputation rate is less than 50%. It seems that occurrence of necrotic lesions subsides in patients older than 60 years. Still, follow-up of patients with TAO shows frequent hospitalization and surgical procedures. Major amputation and prolonged hospitalization markedly influence quality of life, with many patients losing any opportunity for productive employment.

SUMMARY

Thromboangiitis obliterans or Buerger's disease is a nonatherosclerotic, segmental, and inflammatory disease. It is characterized by the development of segmental thrombotic occlusions of the medium-size and small arteries and veins of the extremities.

It occurs in young smokers who present with distal extremity ischemia, ulcers, or gangrene. The most important diseases to exclude are atherosclerosis, emboli, and autoimmune diseases. The only effective treatment is complete and permanent abstinence from tobacco products. Several medical, endovascular, and surgical therapies are palliative.

Acute Mesenteric Ischemia

Charlie C. Cheng, MD, Lorraine Choi, MD, Zulfiqar Cheema, MD, and Michael B. Silva, Jr., MD

OVERVIEW

Acute mesenteric ischemia is a relatively uncommon condition that can potentially have fatal outcomes. Despite advances in diagnostic imaging, perioperative management, and treatment modalities, mesenteric ischemia remains a challenging clinical dilemma. It is estimated that about 1 per every 1000 hospital admissions in the United States is for mesenteric ischemia. The 30-day mortality rate remains high, at 32% to 80%, because of delay in diagnosis and treatment. The prevalence is likely to increase because the population is aging and because of the comorbid conditions of elderly patients. A high index of suspicion with early diagnosis and treatment is essential for improving outcomes.

ANATOMY AND COLLATERALIZATION

The arterial perfusion to the gastrointestinal system is provided by three branches of the abdominal aorta: the celiac artery (CA), the

superior mesenteric artery (SMA), and the inferior mesenteric artery (IMA; Figure 1). The CA originates from the ventral surface of the aorta near the level of T12 to L1. It provides arterial circulation to the foregut (distal esophagus to duodenum), spleen, and the hepatobiliary system. The SMA originates just distal to the CA near the level of L1 to L2 and supplies the midgut from the jejunum to midcolon. The IMA originates from the left lateral surface of the aorta near the L3 level, about 10 cm distal to the SMA. It supplies the hindgut from the midcolon to the rectum.

There is rich collateral circulation between these mesenteric arteries (Figure 2). Chronic mesenteric ischemia from the occlusion of one or even two mesenteric arteries is usually well tolerated if time is allowed for enlargement and development of these uninvolved mesenteric collateral circulations. In acute mesenteric ischemia, however, there may be profound ischemia as a result of the lack of these collateral networks. The collateral circulation between the CA and the SMA is via the superior and inferior pancreaticoduodenal arteries from the gastroduodenal artery. The communication between the SMA and the IMA is via the arch of Riolan centrally and the marginal arteries of Drummond near the periphery of the colon. There is also important collateralization between the IMA and the internal iliac artery to supply the hindgut.

PATHOPHYSIOLOGY

There are four primary causes of acute mesenteric ischemia. The most common cause is embolization to the SMA (Figure 3), which accounts for approximately 50% of all cases. Most emboli originate from left atrial or ventricular mural thrombi or from valvular lesions. The emboli then travel to the SMA preferentially because its course is a nearly parallel course to the aorta and because of its high flow rate. Most emboli lodge 3 to 10 cm distal to the SMA origin, in the tapered segment just past the branching of the middle colic artery. The result is that the proximal midjejunum is spared from ischemia.

Mesenteric thrombosis accounts for about 20% of cases of acute ischemia and is located at the origin of the vessel in a preexisting atherosclerotic lesion (Figure 4). Because of this preexisting lesion, most affected patients have a history of symptoms of chronic mesenteric ischemia that include postprandial pain and "food fear," which leads to weight loss. The thrombosis occurs at the origin flush with the aorta. If the SMA is involved, the result is ischemia of the entire midgut.

Nonocclusive mesenteric ischemia accounts for about 20% of cases and is caused by a low-flow state resulting from any type of shock or the use of vasoconstrictors. The underlying medical condition and delay in diagnosis result in high rates of mortality, regardless of treatment.

Mesenteric venous thrombosis accounts for about 10% of cases and is caused by thrombosis of the veins draining the intestine (Figure 5). These veins include the inferior mesenteric, superior mesenteric, splenic, and portal veins. Venous thrombosis leads to decreased venous outflow, edema, distension, and decreased mesenteric perfusion. The thrombus is located in the superior mesenteric vein in 70% of patients, and in the portal and inferior mesenteric veins in approximately 30%. Risk factors include hypercoagulable syndromes, such as protein C and S deficiency, and hypercoagulable states, such as cancer.

Regardless of the cause, decreased perfusion leads to anaerobic metabolism and acidosis. If these states are persistent, there is mucosal compromise, with release of intracellular toxin and influx of toxin from the bowel lumen into the splanchnic and systemic circulation. With advanced ischemia, there is full-thickness necrosis with resulting bowel perforation and peritonitis. If blood flow is restored, reperfusion injury may develop, and the inflammatory cascade may result in systemic effects, with cardiac, pulmonary, or renal dysfunction.

CLINICAL PRESENTATION AND DIAGNOSIS

The classic manifestation of acute mesenteric ischemia is sudden abdominal pain out of proportion to the physical examination. This

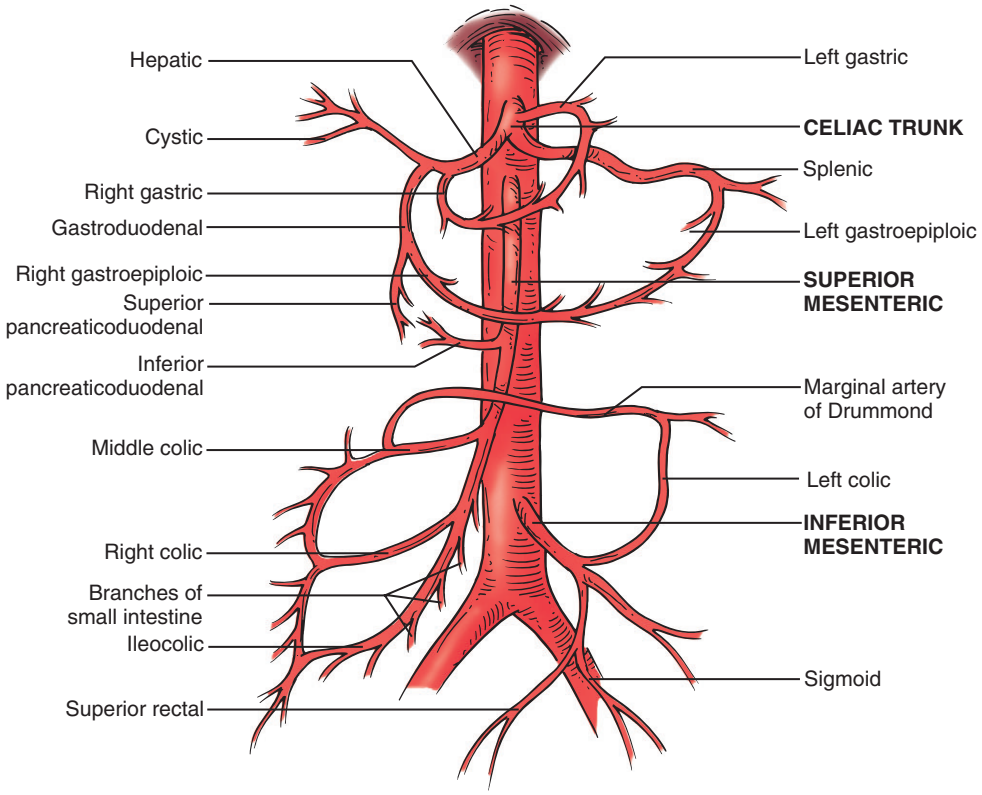

FIGURE 1 Mesenteric circulation, showing the celiac, superior mesenteric, and inferior mesenteric arteries.

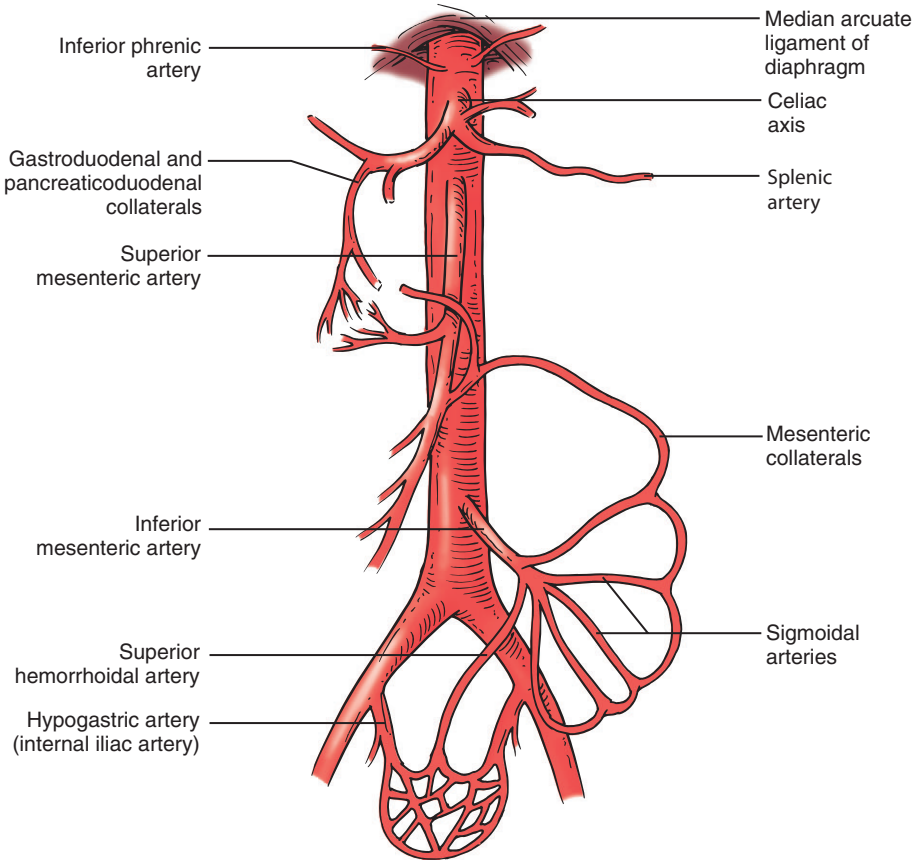

FIGURE 2 Collateral circulation between the three mesenteric arteries.

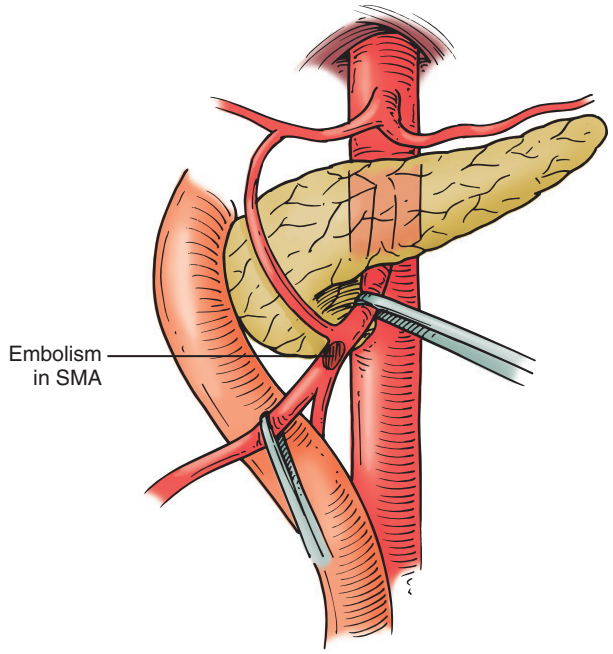

FIGURE 3 Embolization of the superior mesenteric artery (SMA).

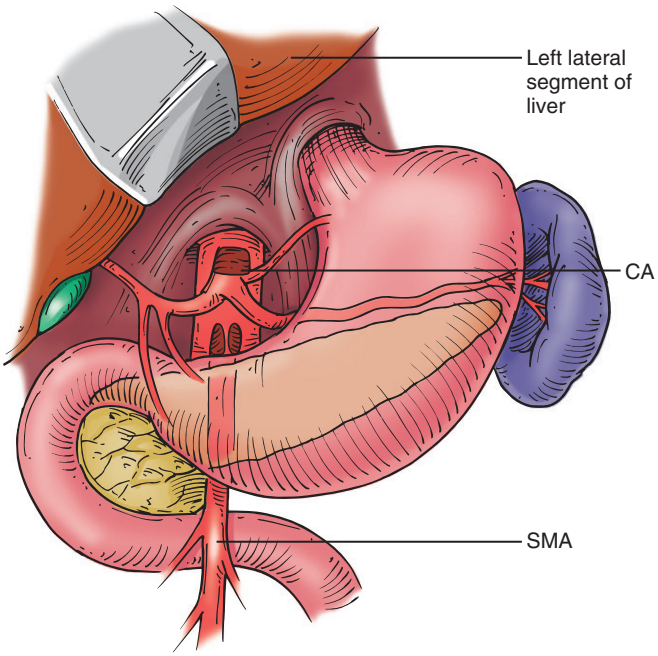

FIGURE 4 Mesenteric thrombosis. This usually occurs at the origin of the celiac artery (CA) or superior mesenteric artery (SMA).

occurs frequently after an embolic event in patients with a history of cardiac arrhythmia or recent myocardial infraction. The abdominal pain is often followed by bloody diarrhea with progression of mucosal sloughing. Common nonspecific symptoms also include fever, nausea, vomiting, and abdominal distension. Patients may present with either (1) acute mesenteric ischemia or (2) chronic mesenteric ischemia and a history of abdominal angina, food intolerance, and weight loss. The subacute presentation is characterized by a more gradual development of abdominal pain. In nonocclusive mesenteric ischemia, there may be severe pain that varies in intensity and

location. If abdominal pain is absent or if the patient in the intensive care unit is unresponsive, there is progressive abdominal distension with acidosis. There should be a high index of suspicion in elderly patients with a recent history of cardiogenic, hypovolemic, hemorrhagic, or septic shock.

No laboratory evaluation is specific for mesenteric ischemia. Complete blood cell count may show hemoconcentration with increased hemoglobin and hematocrit. There is also a leukocytosis with "left shift." With advanced ischemia and bowel necrosis, metabolic acidosis occurs, and amylase, lactic dehydrogenase, and alkaline phosphatase levels are elevated. Plain abdominal radiographs are used to exclude other causes of abdominal pain, such as perforation or intestinal obstruction. With bowel infarction in advanced ischemia, there may be pneumatosis intestinalis, portal venous gas, and pneumoperitoneum. Color Doppler ultrasonography can show stenosis or occlusion in the CA or SMA and is more specific than clinical evaluation. However, this tool may be difficult in patients with acute ischemia when bowels are dilated and filled with air. Computed tomographic scan of the abdomen and pelvis is helpful in diagnosing ischemia in patients with subacute symptoms, showing focal or segmental bowel wall thickening. In the mesenteric or portal veins, the appearance of thrombus or lack of contrast opacification indicates mesenteric or portal venous thrombosis. Upper endoscopy and colonoscopy do not provide any useful information, and barium contrast evaluation is contraindicated. The intraluminal barium can limit visualization of the mesenteric arteries during angiography.

The definitive diagnostic study for mesenteric ischemia is angiography (Figure 6). Angiography with multiple views is needed for adequate evaluation. The lateral views are used to assess the origin of the CA and the SMA, whereas the circulation of the distal CA and SMA is best evaluated with the anteroposterior views. In most cases, the IMA has been occluded by aortic atherosclerotic disease. Selective catheterizations of the CA and the SMA are also needed for complete visualization of the anatomy and to define the pathophysiologic process. In mesenteric embolization (usually in the SMA), the emboli that lodge at branch points create a "meniscus sign," with an abrupt occlusion of a normal proximal SMA several centimeters from its origin. In contrast, with mesenteric thrombosis, the lesion occurs near the origin and tapers off 1 to 2 cm distally. Usually, patients with thrombosis have a history of chronic mesenteric ischemia, and collateral circulations such as the arch of Riolan and the marginal arteries of Drummond can be visualized. In nonocclusive mesenteric ischemia, angiography shows a normal-appearing SMA with segments of vasospasm.

TREATMENT

Initial Management

The goal of treatment is to restore mesenteric blood flow to alleviate the mesenteric ischemia and to prevent bowel necrosis. Initial

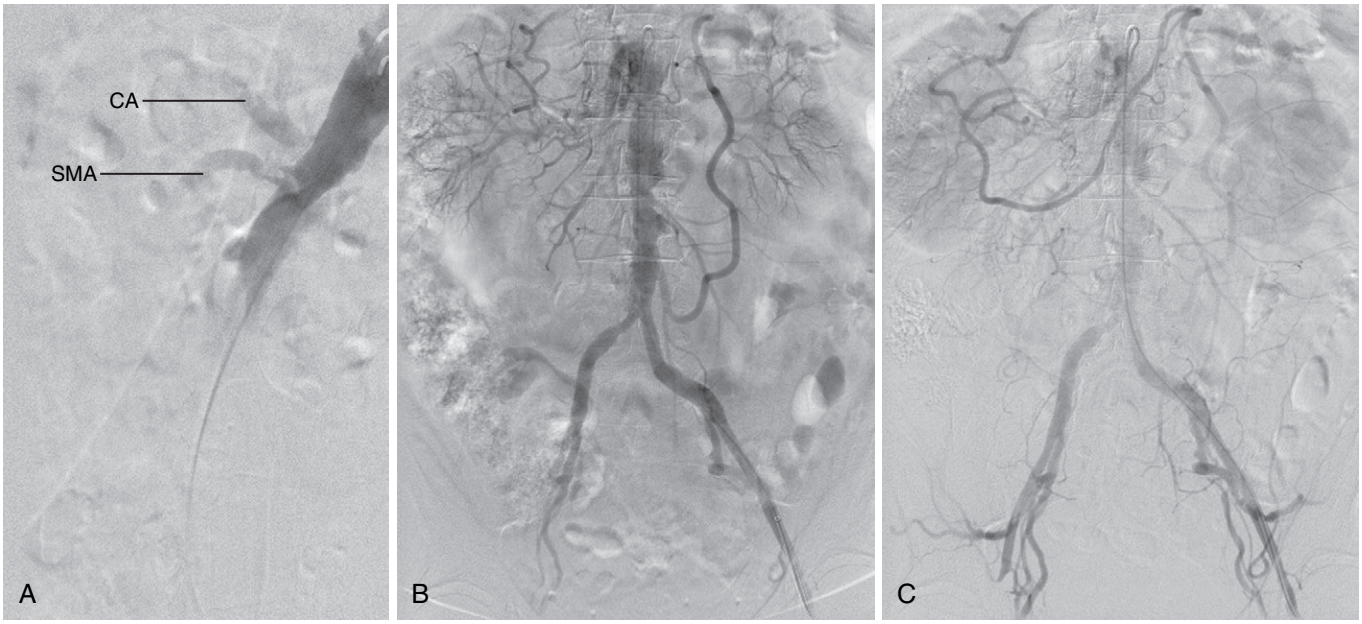

FIGURE 6 Angiography for mesenteric ischemia. **A,** Stenosis of the celiac artery (CA) and superior mesenteric artery (SMA). **B,** Retrograde filling of the SMA from the inferior mesenteric artery (IMA) via collateral vessels in the same patient. **C,** Delayed angiography showing retrograde filling of CA from the SMA.

treatment includes fluid resuscitation, correction of metabolic acidosis with sodium bicarbonate, and administration of antibiotics. Anticoagulation with heparin is used to prevent further propagation of thrombus. A central venous catheter, a peripheral arterial catheter, and a Foley catheter are placed to monitor volume and hemodynamic status. Mesenteric angiography is performed immediately to confirm the diagnosis and to plan for appropriate intervention according to the cause of the ischemia.

Embolism of Mesenteric Artery

In acute embolic mesenteric ischemia, the treatment is surgical removal of the embolus to restore arterial blood flow. As mentioned previously, the majority of the emboli are lodged in the SMA. A midline incision is made, and the extent of the mesenteric ischemia and bowel necrosis is assessed. There is usually variable bowel ischemia from the midjejunum to the transverse colon (Figure 7). Bowel resection is usually delayed until revascularization of the mesenteric artery. To expose the SMA, the transverse colon is reflected superiorly and the small bowel is retracted to the right upper quadrant. The ligament of Treitz is divided to mobilize the fourth portion of the duodenum. The SMA is palpated at the root of the mesentery over the junction of the third and fourth portions of the duodenum. Proximal and distal vascular control of the proximal SMA segment is obtained in the standard manner. A longitudinal arteriotomy is made, and an embolectomy balloon catheter is passed proximally and distally to ensure complete removal of the embolus. When proximal inflow and distal back flow are adequate, a vein or synthetic (polyester [Dacron] or polytetrafluoroethylene [PTFE]) patch is used for closure of the arteriotomy. If embolectomy is unsuccessful in reestablishing blood flow, this longitudinal arteriotomy can be used for distal anastomoses of the bypass graft. A longitudinal arteriotomy is recommended over a transverse arteriotomy (Figure 8).

After restoration of mesenteric blood flow, the viability of the bowel is assessed. Segments of bowel whose viability was equivocal previously may improve after revascularization. Intravenous fluorescein injection followed by Wood lamp inspection and Doppler imaging can assist in assessing the viability of the bowel. If bowel viability remains questionable, a second-look operation can be performed in 24 to 36 hours. This allows for bowel resection to be limited and to ensure that bowel anastomoses are performed with viable bowel.

Thrombosis of Mesenteric Artery

The management of mesenteric thrombosis is more challenging and differs from that of mesenteric embolism. The mesenteric artery is usually normal in mesenteric embolism. In mesenteric thrombosis, in contrast, there is disease progression from atherosclerosis that usually involves multiple mesenteric artery branches at their origins (Figure 9). Mesenteric bypass to a distal, uninvolved segment is needed for definitive revascularization. Single-vessel or two-vessel revascularization may be performed. The donor vessel for the mesenteric bypass can be the supraceliac abdominal aorta in antegrade bypass or the infrarenal aorta or the iliac artery in retrograde bypass. Advantages of antegrade bypass include the use of supraceliac aorta, which is usually free of atherosclerotic disease, and the use of a short bypass graft that avoids kinking when the bowel is returned to its anatomic position after revascularization. However, this bypass requires supraceliac aortic occlusion and the aortic exposure is more difficult, especially in obese patients. Advantages of retrograde bypass include the ease of infrarenal aortic or iliac exposure. However, there is higher risk for bypass graft kinking in retrograde bypass, and this requires the use of donor vessels that frequently are involved in atherosclerotic disease.

The graft material of choice is the saphenous vein. Prosthetic graft should be avoided in patients with nonviable bowel or in patients requiring bowel resection. In situations in which a prosthetic graft

can be used, a small-diameter woven or PTFE graft is used for single-vessel revascularization. For two-vessel revascularization, a bifurcated graft may be used to bypass to the CA and SMA.

In antegrade bypass, initial exposure is accomplished by dividing the gastrohepatic ligament and mobilizing the left lobe of the liver. The esophagus is retracted to the left, and division of the diaphragmatic crura and median arcuate ligament provides exposure of the distal 10 cm of thoracic aorta without division of the diaphragm. The origin of the CA has already been dissected during exposure of the aorta, and dissection is continued distally until a soft, patent distal target is reached. The SMA is dissected at the root of the mesentery as described previously. The vein graft is bypassed first to the CA and then sequentially to the SMA via a tunnel behind the pancreas. In patients without bowel ischemia or infarct, a synthetic graft can be used. If a bifurcated graft is used, the proximal aortic graft is beveled and sutured to the supraceliac aorta. The limbs are cut into appropriate lengths and anastomosed to the CA and the SMA (Figure 10).

In retrograde bypass, the most proximal SMA segment that is patent is exposed as it exits from behind the pancreas. This decreases the risk of kinking in the bypass graft. This anastomosis is completed first, and the bowel is returned to its anatomic position. The bypass graft is pulled and placed adjacent to the aorta. A soft spot on the infrarenal aorta or the iliac artery is located and used for the proximal anastomosis. Tension is maintained on the vein graft during anastomosis to avoid graft laxity and kinking (Figure 11, *A*). Revascularization to the CA is usually performed via the common hepatic artery (see Figure 11, *B*) or, less commonly, via the splenic artery. The distal anastomosis is again performed first, and the graft is pulled taut behind the duodenum and the head of pancreas. The graft is tunneled behind the tail of the pancreas, and if the distal anastomosis is to the splenic artery, anterior to the left renal vein.

Nonocclusive Mesenteric Ischemia

The primary treatment of nonocclusive mesenteric ischemia is catheter-directed infusion of vasodilatory agents. A catheter is placed into the CA and the SMA for selective mesenteric angiography, and a diagnosis is made when segments of vasospasm are seen in a normal-appearing mesenteric artery. A vasodilatory agent such as papaverine is directly infused into the mesenteric artery via the catheter at a dose of 30 to 60 mg/hour. System anticoagulation is achieved with heparin, given via peripheral intravenous catheter, to prevent thrombosis in the catheterized vessels. Vasoconstricting agents should also be stopped. The hemodynamic status of the patient is monitored for any hypotension that may signify systemic infusion of the vasodilator with migration of the infusion catheter into the aorta.

The patient's response and clinical status are observed closely. If abdominal symptoms improve, mesenteric angiography is repeated to ensure resolution of the vasospasm and perfusion of the bowel. If the patient develops acute peritonitis with rebound tenderness and involuntary guarding, there is continued bowel ischemia or infarction, and surgical exploration is needed to assess bowel viability. The room temperature is elevated, and the bowel is wrapped in warm, moist laparotomy pads to minimize vasoconstriction. Papaverine is continued perioperatively, and any nonviable bowel is resected. A second-look operation can be performed in 24 to 36 hours if bowel viability is questionable.

Mesenteric Venous Thrombosis

In addition to the initial management as described previously with fluid resuscitation and anticoagulation, patients need to be evaluated for hypercoagulopathies and hypercoagulable states such as cancer. Surgical exploration is indicated in a patient with signs of bowel ischemia and infarction. Surgery should be limited to bowel resection because venous thrombectomy has not been shown to be effective. Bowel resection is generous, and repeated surgical explorations may be necessary to ensure adequate bowel resection.

In patients who do not have peritonitis but continue to have abdominal pain despite resuscitation and anticoagulation, catheter-directed thrombolytic therapy is potentially useful. The thrombolytic agent is delivered to the mesenteric venous circulation via catheter-directed infusion of the splenic artery and the SMA (Figure 12). Bilateral common femoral arterial access is obtained for

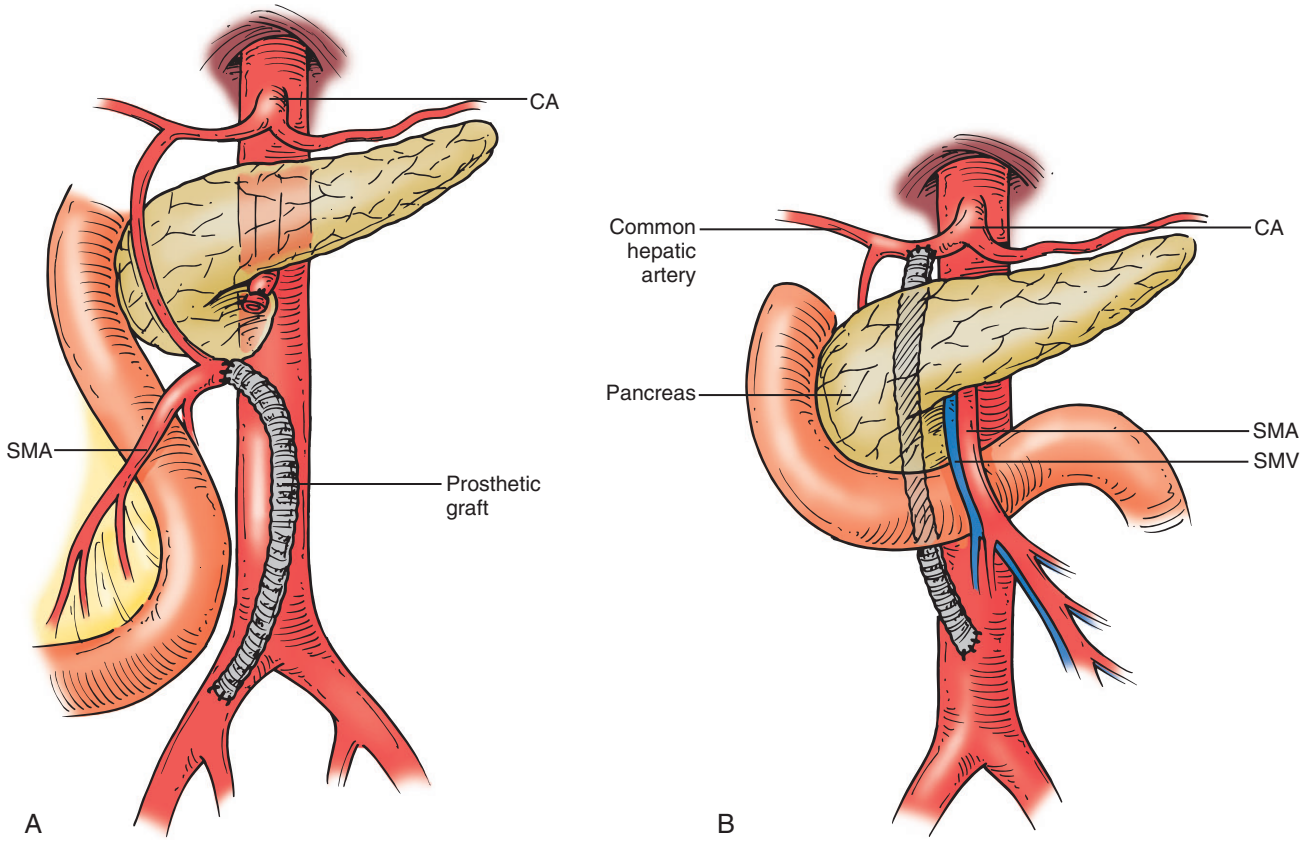

FIGURE 11 **A,** Retrograde bypass to the superior mesenteric artery (SMA). **B,** Retrograde bypass to the celiac artery (CA) via the common hepatic artery. *SMV,* Superior mesenteric vein.

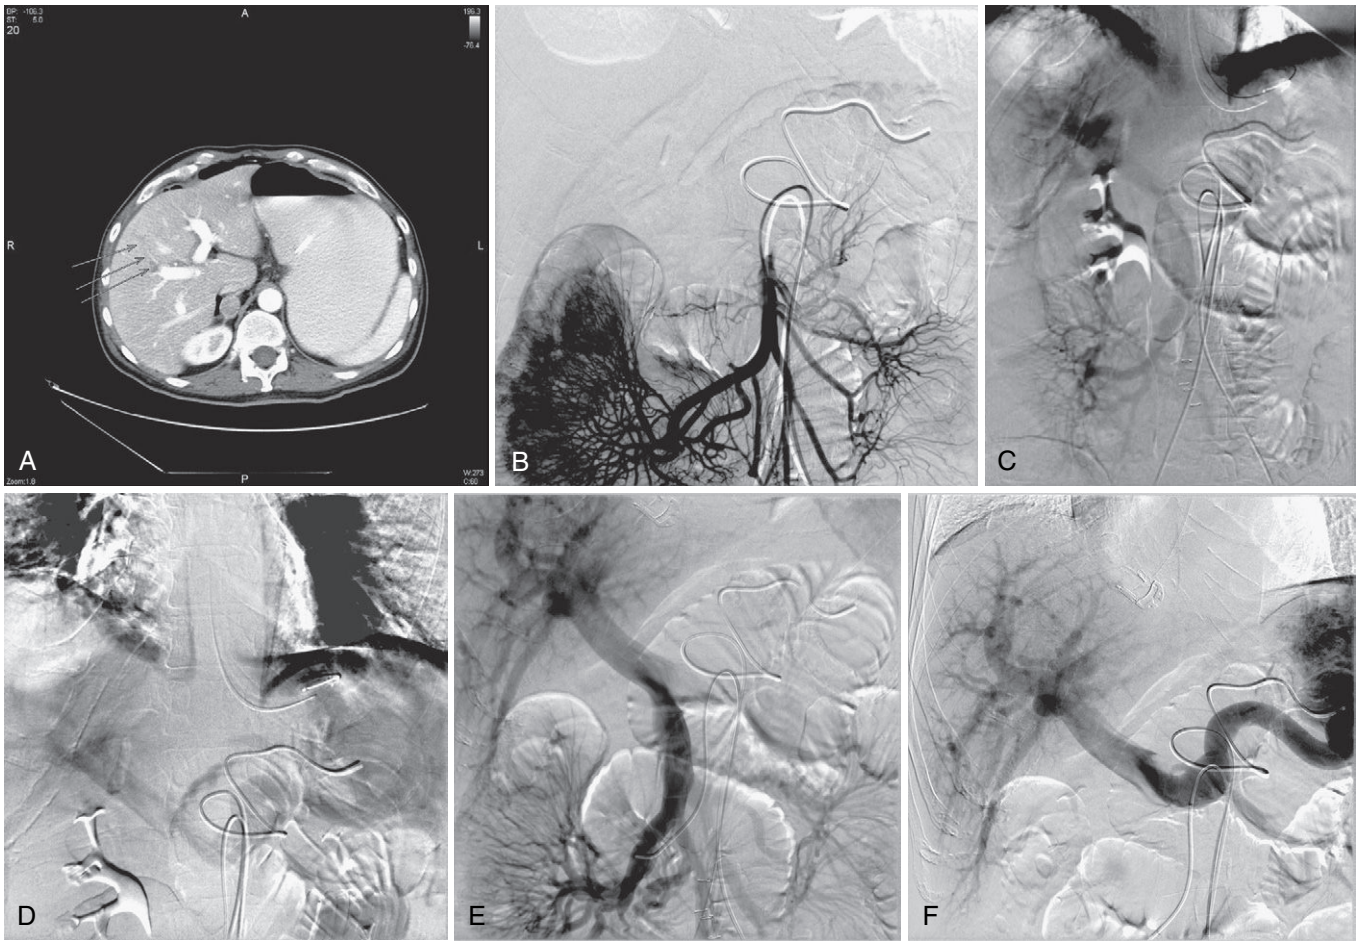

FIGURE 12 Hepatic venous thrombosis. **A,** CT scan showing thrombus. **B,** Angiogram of superior mesenteric artery (SMA). **C,** Catheter in SMA, delayed imaging showed patent mesenteric venous outflow. **D,** Catheter in splenic artery, delayed imaging showed patent splenic and portal veins, with poor visualization of hepatic veins. **E,** After thrombolytic therapy, angiogram from SMA catheter showed patent mesenteric and hepatic veins. **F,** Angiogram from splenic catheter showed patent splenic, portal and hepatic veins.

FIGURE 13 Endovascular treatment with stent placement in the stenosed superior mesenteric artery (SMA).

placement of two catheters for infusion of the two mesenteric arteries. The thrombolytic agent is infused slowly overnight, and angiography is repeated in 24 hours to assess for progress of lytic therapy. If there is residual thrombus, slow thrombolytic therapy is continued for another 24 hours. After a maximum of 48 hours of lytic therapy, sheaths and catheters are removed, and the patient is continued on anticoagulants. The patient's response and clinical status are monitored closely. Any signs of bowel ischemia or infarction necessitate surgical exploration to assess for bowel viability.

Endovascular Treatment

Mesenteric angiography used for the diagnosis of mesenteric ischemia can also be used for therapeutic interventions. Endovascular therapy involving catheter-directed delivery of pharmacologic agents was described previously for nonocclusive mesenteric ischemia and mesenteric venous thrombosis. This treatment modality can also be used for short-segment stenosis or occlusion, recurrent disease, or anastomotic stenosis from prior mesenteric intervention (Figure 13). In patients with medical comorbid conditions who are at high risk for open surgical interventions, endovascular therapy is a useful, less invasive treatment modality.

Arterial access is obtained in a common femoral artery. Left brachial arterial access may be needed in mesenteric arteries that branch in an acute angle from the aorta. A diagnostic catheter is placed in the proximal abdominal aorta below the diaphragm. Lateral aortography is used to assess the origin of the CA and SMA, and anteroposterior mesenteric angiography is used to assess the distal mesenteric circulation. An angled catheter is used to catheterize the CA and SMA, and selective mesenteric angiography is performed. When the location of the lesion is identified, a 6F working sheath is placed with the tip at the origin of the mesenteric artery, and the lesion is crossed with a wire. For occlusive lesions, a trial of lytic therapy is undertaken, whereby a thrombolytic agent is given via an infusion catheter that is placed across the length of the occlusive arterial segment. Any residual stenotic lesion identified on angiography can be treated with balloon angioplasty. Postangioplasty angiography is performed to assess for evidence of possible suboptimal angioplasty results such as dissection or residual stenosis. This is best treated with placement of a stent across the lesion. Stent placement should also be considered for mesenteric thrombosis because the lesion at the origin is caused by atherosclerotic disease in the aorta. It is important to maintain the wire across the lesion until the result appears satisfactory on completion angiography.

CONCLUSION

Long-term outcomes in patients with acute mesenteric ischemia are dependent on early diagnosis and prompt treatment. The prevalence is likely to increase among the aging population with multiple medical comorbid conditions. It is important to have a high index of suspicion in patients who present with abdominal pain and who have risk factors for mesenteric ischemia. With advances in treatment modalities involving less invasive endovascular revascularization, outcomes may improve in patients with acute mesenteric ischemia.

The Management of Chronic Mesenteric Ischemia

Linda M. Reilly, MD

Chronic mesenteric ischemia (CMI) results from inadequate arterial perfusion of the abdominal viscera. The postprandial pain that is the hallmark of symptomatic CMI prevents adequate nutrition, causing progressive and ultimately life-threatening weight loss. CMI is also believed to be a precursor to intestinal infarction, usually a lethal event because of the extent of viscera involved. Therefore, the goals of treatment are to restore normal tissue perfusion, to provide durable protection against visceral infarction, and to provide durable relief of pain so that normal nutrition can be maintained. Like most disorders of perfusion, visceral blood flow may be impeded by arterial obstruction, venous obstruction, or systemic conditions with a global effect on perfusion. Venous obstruction or systemic conditions that reduce mesenteric perfusion produce *acute* mesenteric ischemia, which is not discussed in this chapter.

ARTERIAL DISEASE

The most common cause of chronic visceral ischemia is atherosclerotic arterial occlusive disease. Arteritis may also cause CMI but is less common. The frequent observation of asymptomatic stenosis or even occlusion of a visceral artery in adults older than 65 years (about 20% of cases of CMI), and the abundant potential routes of collateral flow to the viscera have led to the belief that flow must be impaired through at least two of the three main visceral arteries in order to reduce perfusion sufficiently to cause symptom development. Although it is clear that compromise of flow in both the celiac artery and the superior mesenteric artery (SMA) can produce CMI, it is less predictable whether compromise of inferior mesenteric artery (IMA) flow and either celiac artery or SMA flow will produce symptoms of visceral ischemia. In the author's experience, all but one or two patients had involvement of both the celiac axis and the SMA. None of the author's patients developed symptoms with involvement of only the IMA and either the celiac artery or SMA. The pattern of the flow-reducing lesions is also important in the development of symptoms. The more diffuse the distribution of lesions, the more likely it is that all potential collateral routes are affected and that the patient will have symptoms.

Occlusion of the visceral arteries has three patterns: lesions involving the orifices of the visceral arteries, lesions involving long segments of the main visceral artery trunks (with or without orifice involvement), and lesions involving the branches of the visceral arteries (with or without proximal trunk/orifice involvement). These patterns of disease determine which treatment method is applicable, as well as the prognosis for a successful and durable reconstruction. The importance of establishing the arterial pathologic process is not so much in knowing the diagnosis as it is in understanding the implication of a given process for successful treatment. For example, typical visceral atherosclerotic lesions are located at the vessel origins; thus they actually represent aortic lesions that spill into the visceral artery orifice. The involvement of the visceral artery is usually limited to the 1 to 2 cm of the main trunk. The lesions of early-onset atherosclerosis more often involve longer segments of the main visceral arteries and may not have as much association with aortic disease. In contrast, unusual pathologic processes involving the visceral arteries, such as an arteritis, generally affect long segments of the arteries, involving both the main trunk and primary branches.

RECONSTRUCTION OPTIONS

Reconstruction options for visceral arterial occlusive disease take three forms: endovascular techniques (consisting of angioplasty with or without stents, either bare metal or covered stents), endarterectomy, and bypass.

Endovascular Techniques

As is the case with all atherosclerotic occlusive disease, intraluminal techniques are most suitable for the treatment of focal arterial lesions (Figure 1, *A* and *B*). Unfortunately, visceral occlusive lesions are rarely truly focal, and thus the effectiveness of endoluminal treatment is limited. As mentioned previously, typical atherosclerotic lesions represent aortic disease that extends into the mesenteric artery origins. Although the visceral involvement in this pattern of disease is focal, the aortic involvement is not. In general, orificial lesions are less optimally treated by angioplasty or stent placement, but the common approach of extending the visceral stent a few millimeters into the aortic lumen (Figure 2, *A*) and flaring the intra-aortic end of the stent (Figure 2, *B* and *C*) is successful in treating disease involving the visceral orifice. In addition, the very dense median arcuate ligament surrounding the celiac axis and (to a lesser extent) the SMA can be a mechanical barrier to achieving and maintaining an adequate lumen with endovascular treatment, even if adjunctive stents are placed. Extrinsic compression may be effectively managed by placement of one stent inside the other, so as to create a rigid artery (rifle-barrel) with a reasonable likelihood of resisting compression by the ligament (Figure 3). Nonetheless, stent fracture commonly results from extrinsic compression. These approaches have improved at least the initial success of endovascular treatment of orificial visceral lesions; however, when the lesions extend through long segments of the main trunk or into the branches (the other two patterns of visceral occlusive disease), even initial success is less likely.

Several key technical points are pertinent to endovascular treatment of visceral arterial occlusive disease. First is the choice of access site: femoral versus brachial. The femoral access site is more familiar to vascular interventionalists, but entry into the visceral artery involves at best a right angle and more commonly an acute backwards turn, resulting in unfavorable force vectors. In contrast, brachial access, although less familiar and carrying a slightly greater risk, provides an optimal angle of approach, as well as the support that might be needed to cross tightly stenotic lesions, heavily calcified lesions, or total occlusions. In fact, a parallel brachiofemoral wire may be necessary in some cases to provide sufficient sheath stabilization to allow the considerable pushing needed to cross a difficult stenosis or an occlusion. The risk of embolization during the treatment of visceral occlusive disease, particularly when total occlusions are recanalized, has prompted a gradual increase in the use of distal embolic protection devices (filters) to catch fractured plaque fragments or thrombus. This increases technical complexity, but it may improve procedural safety.

Because of the orificial nature of the lesions, the common finding of heavy calcification, and the likelihood of some extrinsic ligament compression, simple balloon angioplasty of the mesenteric arteries is rarely sufficient. Stent placement is necessary to treat the stenosis effectively, and balloon-expandable stents are almost always used because they exert greater radial force. Balloon-expandable covered stents have become the device of choice. The covered stent provides

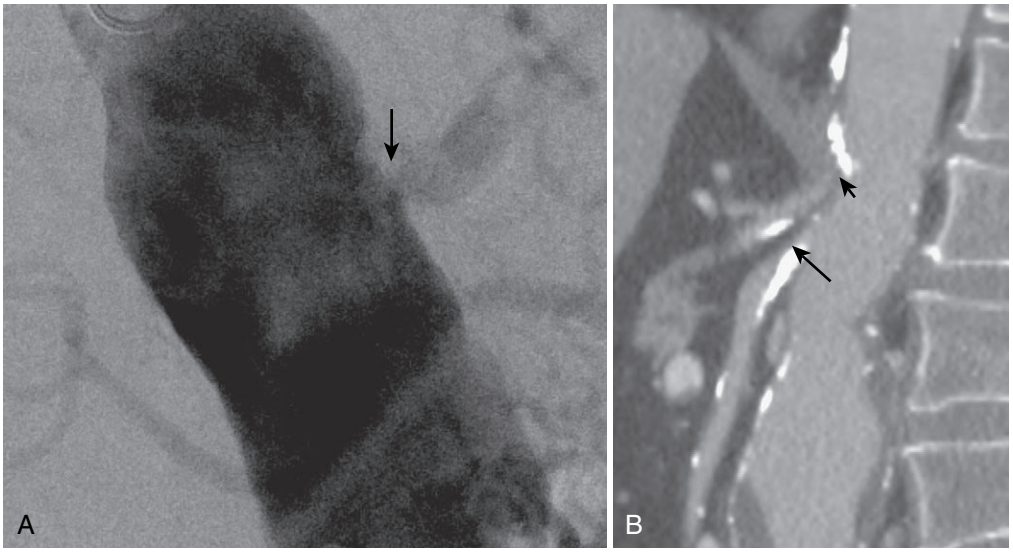

FIGURE 1 Focal stenosis in visceral arteries. **A,** Focal high-grade stenosis of the celiac axis *(arrow)* with poststenotic dilation. **B,** Focal stenosis of the celiac axis *(short arrow)* and superior mesenteric artery *(long arrow)*.

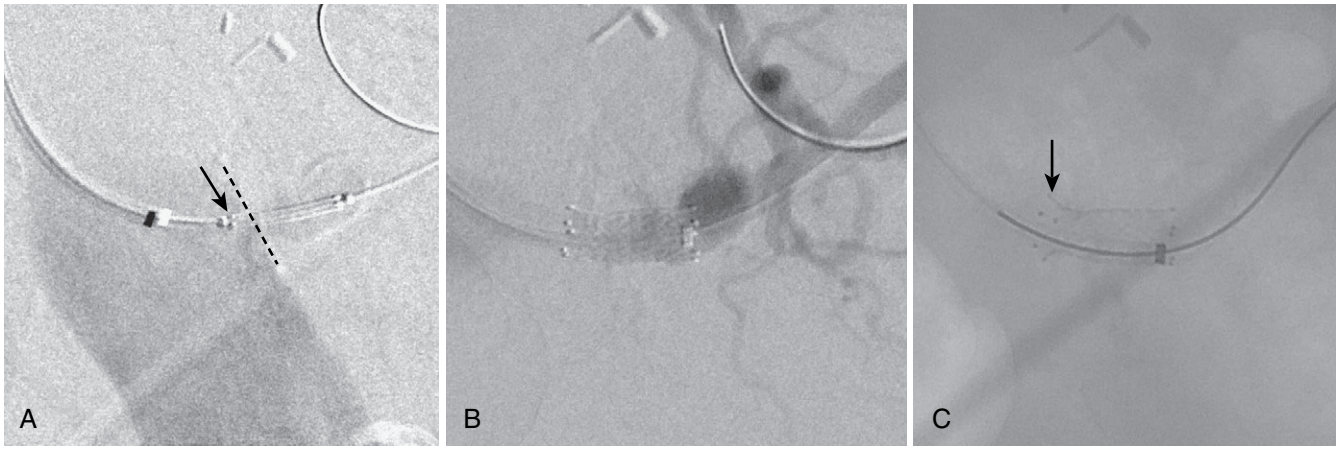

FIGURE 2 Placement of stents in a visceral artery. **A,** Intraprocedural angiographic image demonstrating optimal position of the celiac stent, extending a few millimeters into the aortic lumen. The *arrow* represents the proximal end of the stent; the *dotted line* represents the aortic wall. **B,** Angiographic image of the celiac stent after pressure-monitored balloon inflation and stent deployment. **C,** Angiographic image of deployed celiac stent, showing the flared proximal end *(arrow)*. The slight "waist" represents the location of the aortic wall.

some protection against inadvertent visceral branch or aortic injury from the high pressures that may be necessary to efface the stenosis. In addition, the covered stent traps plaque, protecting against distal embolization that might occur if an uncovered stent was used. The visceral arteries are also unique in the difference between the orifice segment and the rest of the artery. As described previously, the orificial visceral segments tend to be fixed, involved by dense, heavily calcified plaque and possibly extrinsically compressed, all features that necessitate stents with high radial force (balloon-expandable). The more distal celiac artery and SMA segments, however, are quite flexible and mobile, and thus a flexible (self-expanding) stent with lower radial force is a better choice.

In spite of the challenges associated with endovascular treatment of visceral arterial occlusive disease, technical success rates approach 100%, anatomic results are good, and initial clinical outcomes are comparable with or better than open surgical treatment (Table 1). However, the lower rates of mortality and morbidity and high rate of technical success come at the price of less durability. Outcomes from reviews of large data samples (meta-analyses, National Inpatient Sample) consistently show primary patency rates well below that achieved with open surgical mesenteric revascularization. Durability is therefore the issue to be resolved with endovascular treatment of the visceral arteries.

The author's experience with endovascular treatment of visceral occlusive disease is also favorable, with only one death among approximately 30 patients who underwent celiac or SMA angioplasty (or both) and stent placement. The single death resulted from a shower of atheroemboli in a patient with SMA occlusion and celiac stenosis. That patient had experienced a relatively recent symptom change, which, in retrospect, probably indicated progression of SMA stenosis to complete occlusion. At the time of intervention, this subacute occlusion probably contained thrombus, which embolized during placement of an uncovered stent. Whether this outcome would have been different if embolic protection or a covered stent were used is unknown, but the case highlights a critical factor in successful endovascular outcome: the potential for plaque or thrombus embolization.

The appeal of an endovascular approach to treating CMI is obvious. Patients with CMI are always nutritionally impaired and commonly have significant comorbid conditions. Endovascular procedures, even if a brachial approach is used, can be performed while the patient is under local anesthesia, which reduces procedural risk.

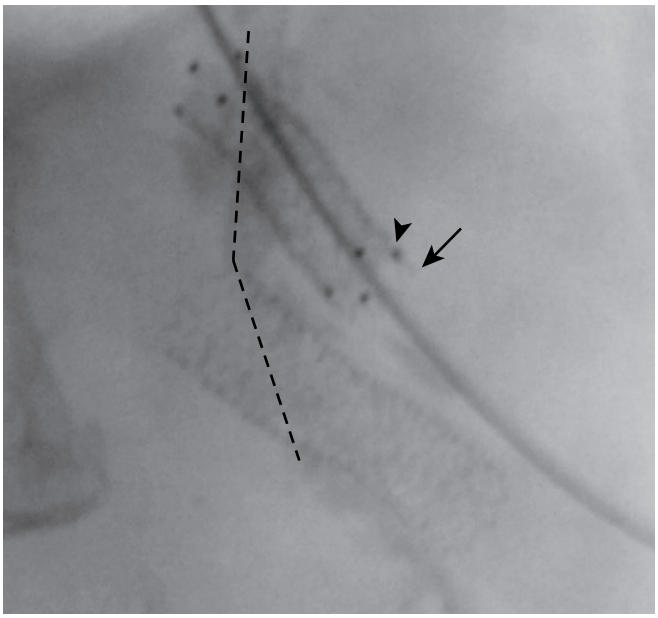

FIGURE 3 Angiogram obtained after placement of a balloon-expandable, covered stent into the celiac axis, lined with a balloon-expandable uncovered stent. The *arrow* indicates the distal end of the covered stent; the *arrowhead* indicates the distal end of the lining uncovered stent; and the *dotted line* indicates the aortic wall. Note complete resolution of the stenosis and slight extension of the stent into the aortic lumen.

Relief of symptoms is immediate, and patients can begin nutritional repletion without the additional interval of negative balance associated with open surgery. Many authorities now regard endovascular treatment of mesenteric occlusive disease to be the first choice for treatment, particularly for high-risk patient. Endovascular treatment can also serve as a bridge that allows nutritional repletion and optimization of comorbid conditions before definitive open operative repair. Because the price for a lower risk procedure is less durability, however, patients must be monitored regularly and indefinitely with appropriate imaging studies (duplex arterial imaging or computed tomographic angiography) to ensure continued patency and prevent catastrophic occlusion. Many authorities have reported that endovascular reintervention also has low mortality and morbidity rates, if performed electively.

Endarterectomy

Endarterectomy was the earliest operative technique applied to visceral artery occlusive disease. However, in the initial procedures, the transarterial retrograde approach, through either the celiac artery or SMA, or both, was used to remove the obstructing lesion. The use of this approach indicates the early failure to recognize the significance of the aortic involvement and was unsuccessful because it did not allow complete removal of the aortic portion of the lesion. Endarterectomy is currently performed through the aorta, and the lesions extending into the visceral artery orifices are extracted by eversion endarterectomy.

Aortic exposure is achieved through a transabdominal approach with medial rotation of the viscera from the left. Either a full-length

midline incision or a bilateral subcostal incision may be used; the author prefers the latter and to leave the left kidney in its anatomic position, while the plane behind the left colon, spleen, pancreas, and stomach is developed to allow displacement of these structures toward the midline (Figure 4). If necessary, the entire aorta, from the distal thoracic level to the bifurcation, can be completely exposed with this technique. During complete aortic occlusion, including control of any intervening intercostal branches, a U-shaped trapdoor aortotomy circumscribes the orifices of the celiac and superior mesenteric arteries, and an endarterectomy is performed to remove the aortic lesion and the extensions into the visceral orifices. In many cases, the significant aortic atheroma is confined to the ventral surface of the aorta immediately around the celiac artery and SMA orifices, and the aortic endarterectomy can be limited to the trapdoor segment itself. However, more diffuse aortic disease, frequently in the setting of associated renal artery occlusive lesions, necessitates extension of the aortotomy caudally to allow sleeve aortic endarterectomy and bilateral or unilateral renal artery endarterectomy. In this circumstance, the aortotomy takes the shape of a hockey stick rather than a trapdoor. After completion of the endarterectomy, the aortotomy is closed with a running suture or with a patch. If the disease extends well out into the visceral branches, it may be necessary to use a separate longitudinal arteriotomy in the visceral artery itself to allow complete removal of the disease. This visceral arteriotomy is then closed with a patch.

Endarterectomy is perhaps the most elegant approach to visceral artery occlusive disease, but surgeons must be aware of its limitations. It is most applicable to visceral artery lesions that are limited to the first 1 to 2 cm of the artery. Longer lesions may be successfully treated with transaortic endarterectomy; in the author's experience, however, endarterectomy in that setting is less durable. Endarterectomy is not applicable to lesions extending into branches of the visceral arteries. Transmural calcification of the involved portions of the aorta or visceral artery should generally be considered a contraindication to endarterectomy. Transmural lesions force the use of a very deep endarterectomy plane, which usually results in inadequate integrity of the adventitia. Attempting endarterectomy in this setting usually results in extensive bleeding through the porous adventitia and prolonged visceral ischemia as a consequence of attempts to repair the bleeding artery—an invariably fatal combination. Endarterectomy is particularly appealing when occlusive disease involves the renal arteries, because it is much faster than individual bypasses to all four arteries (celiac artery, SMA, and both renal arteries). If multiple renal arteries are present, endarterectomy is even more attractive. Endarterectomy is often the most appropriate technique for occlusive disease involving the IMA. Because of the smaller size of this artery and the less predictable location of the endpoint, however, the author favors a longitudinal incision that extends past the IMA to a disease-free segment. After the endarterectomy is completed, the arteriotomy is closed with a patch. In this location, the author prefers a vein patch.

Visceral flow must be restored—endarterectomy completed and the aorta closed—within 40 to 45 minutes. Longer intervals of total visceral ischemia, particularly hepatic ischemia, lead to coagulopathy that is usually impossible to reverse. In the author's experience, visceral flow was restored in 30.5 ± 15.5 minutes.

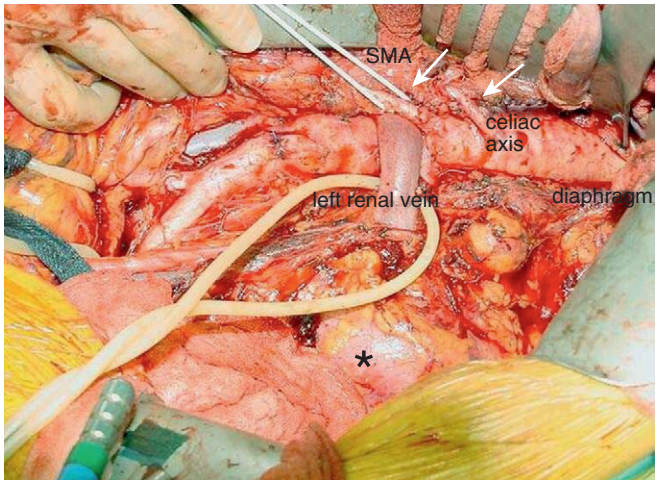

FIGURE 4 Aortic exposure provided by transabdominal approach with medial rotation of the viscera from the left. Note that the entire abdominal aorta from the diaphragm (under the narrow retractor blades at the right) to the bifurcation of the iliac arteries can be exposed. Note that the left kidney *(asterisk)* remains in its anatomic position. The large vessel loop encircles the left renal vein, which can usually be left intact. *SMA,* Superior mesenteric artery.

Bypass

At least theoretically, bypass is the only reconstruction technique applicable to all patterns of arterial visceral occlusive disease. Practically, the more extensive the disease and the more distal the branch involvement, the less feasible bypass becomes. Bypass to the mesenteric arteries may originate from the supraceliac portion of the aorta (antegrade bypass) or from the infrarenal portion of the aorta or iliac arteries (retrograde bypass).

Antegrade Bypass

Aortic exposure for antegrade bypass can be achieved through a transabdominal, transcrural approach (Figure 5) or medial visceral rotation from the left (as described previously). The transcrural approach is appealing because it is a less extensive exposure. Either an upper vertical midline incision or a bilateral subcostal incision can be used. The upper vertical midline incision yields a relatively small operative field, which may make creation of the aortic anastomosis awkward because both visibility and movement may be restricted. The author prefers to use a bilateral subcostal incision and, if the costal margin angle is narrow, to add a short superior midline extension. Graft length and alignment are easy to determine with the transcrural approach, but a retropancreatic tunnel may be needed for the SMA graft (Figure 6), depending on the extent of disease in the SMA. Medial visceral rotation provides a much larger operative field but at the cost of a larger operation. Graft length and alignment are more difficult to determine with medial rotation of the viscera because the viscera are retracted to the right. Prosthetic conduits are almost always used.

Regardless of the exposure, the proximal anastomosis of the antegrade bypass is placed in the disease-free supraceliac or distal thoracic portion of the aorta. The author prefers total aortic occlusion of the aortic segment for this anastomosis. When a partial aortic occlusion clamp is used, most of the time it occludes the aorta almost completely. Preserving a minimal amount of aortic flow does not warrant the disadvantages of limited visibility, increased technical difficulty, and longer periods of visceral ischemia. Circumferential supraceliac aortic mobilization is not routinely performed unless there is an intervening pair of intercostal arteries that need to be controlled. Historically, the author used a small, bifurcated prosthetic graft (12 mm × 6 mm) and excised a small, obliquely oriented ellipse of aorta at the site of the proximal anastomosis (see Figure 6). However, to reduce the risk of kinking, the graft must assume a low profile along the front of the aorta. This requires a lengthy graft bevel and a lengthy matching aortotomy. In many cases there is simply not enough disease-free aortic tissue to allow such a long aortotomy. Consequently, the author now creates a bifurcated graft from two limbs of smaller diameter (Figure 7). With this technique, less normal aortic tissue is required for the proximal anastomosis because the

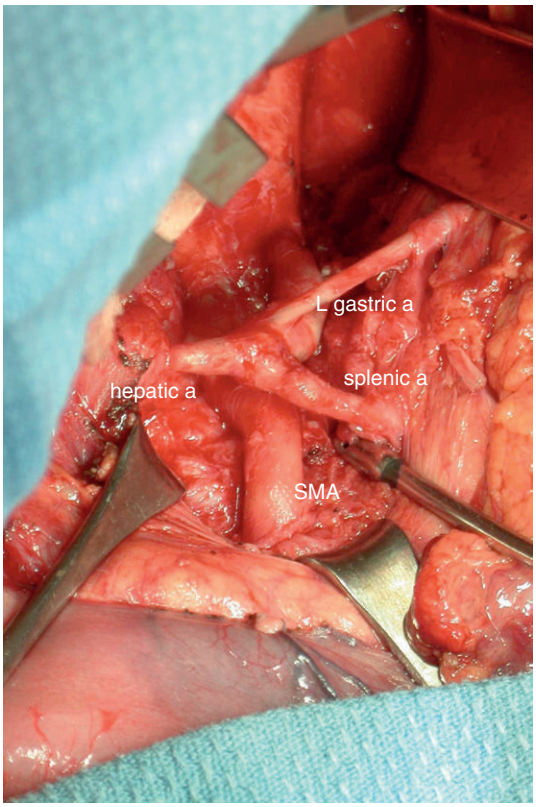

FIGURE 5 Transcrural exposure of the celiac axis and its branches (left gastric, hepatic, and splenic arteries) and the superior mesenteric artery (SMA). Note the caudal retraction of the stomach and pancreas. Note also the complete division of the median arcuate ligament and the complete removal of the celiac ganglion and plexus from around the anterior surface of the aorta and the proximal trunks of the celiac axis and the SMA.

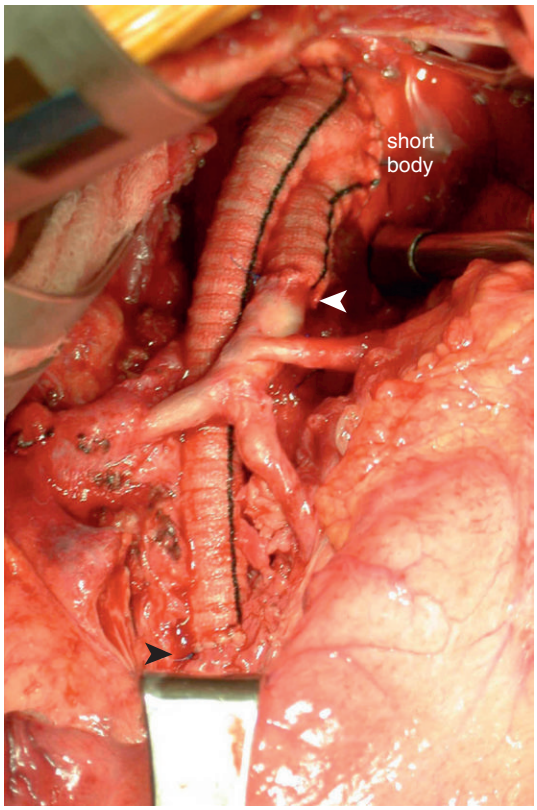

FIGURE 6 Completed antegrade bypass to the celiac axis and superior mesenteric artery. Note the very short body portion of the graft and, again, the inferior retraction of the stomach and pancreas. Note also that the orientation of the graft limbs prevents either limb from compressing the other. The *white arrowhead* indicates the celiac artery anastomosis; the *black arrowhead* indicates the superior mesenteric artery anastomosis.

aortotomy for the proximal anastomosis is shorter, and it is easier to ensure a low profile for the graft. After completion of the proximal anastomosis, aortic flow is restored, and an occluding clamp is placed on the graft. In the author's experience, this anastomosis can be performed and aortic flow restored in 26.0 ± 15.8 minutes. Operative times are shorter when the surgeon-created bifurcated graft is used.

If the transcrural exposure is used, the celiac axis and SMA are exposed above and behind the pancreas; this exposure requires careful and complete dissection of the visceral arteries from the surrounding celiac ganglion tissue and the median arcuate ligament (see Figure 5). Usually the left graft limb is anastomosed to the celiac axis and the right graft limb to the SMA (see Figure 6). However, it is always wise to check the relative positions of the two visceral arteries before committing to this arrangement. When the medial rotation of the viscera exposure is used, it may be better to perform the anastomosis to the SMA *first.* Usually the anastomosis to the SMA is performed more distally on that artery than the anastomosis to the celiac axis. This is particularly so when the SMA lesion is longer. As a consequence, the SMA anastomosis may actually lie *under* the graft limb to the celiac axis. Performing the SMA anastomosis first improves exposure and avoids the need for significant retraction on the celiac graft. The distal anastomoses can be performed either end to end or end to side, as determined by the disease pattern.

Retrograde Bypass

The infrarenal portion of the aorta, iliac artery, or a previously placed prosthetic aortic or aortoiliac graft can all serve as inflow conduits to the visceral arteries. For exposure of the aorta, the standard infracolic approach is used. Both the inflow (aortic, iliac, or graft) and outflow (visceral branch) anastomoses are performed end to side. If the SMA is the revascularization target, it is exposed beyond the diseased areas in the root of the mesentery. The celiac axis itself is rarely the target for a retrograde bypass, partly because it is too short to accommodate an end-to-side anastomosis and partly because the graft alignment would be awkward. More commonly, the bypass is anastomosed to a branch of the celiac artery, usually the hepatic artery, because hepatic and gastric perfusion are more important than splenic flow. Positioning and alignment are more difficult with retrograde conduits, and as a consequence they are more susceptible to twisting, kinking, and compression. Some authorities recommend that the conduit be constructed in the shape of a long, gentle backwards C-shaped curve. This orientation allows antegrade flow at both the proximal and the distal anastomoses, although flow through the conduit itself is still retrograde. The advantages of retrograde bypass are simpler exposure, no supraceliac aortic occlusion, and sometimes no aortic occlusion at all.

EXTENT OF VISCERAL ARTERY RECONSTRUCTION

Although it is generally agreed that at least two visceral arteries must be involved by the occlusive process to produce symptoms, there is more debate regarding the number of visceral arteries that need to

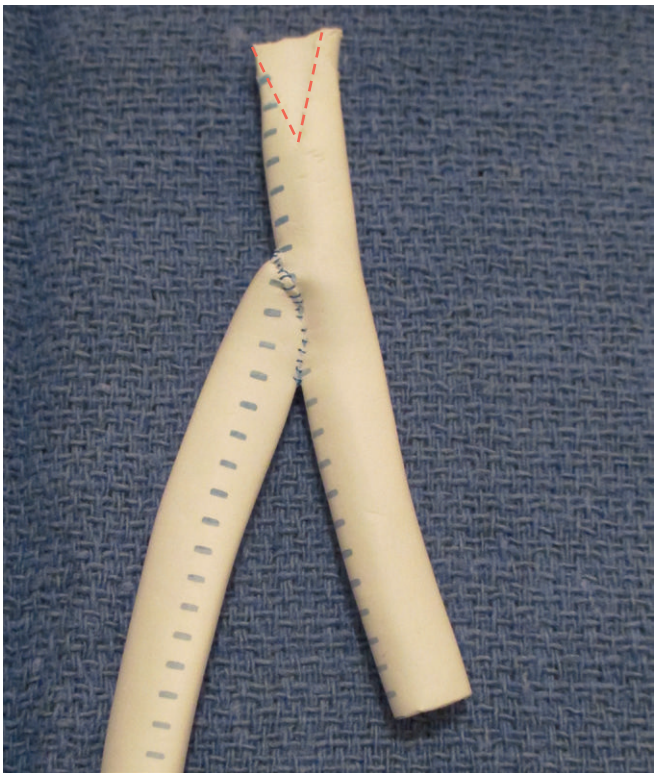

FIGURE 7 Bifurcated graft created for visceral revascularization. The *dotted line* indicates the much shorter flange for the proximal anastomosis, in comparison with a manufactured bifurcated graft. The length of each limb can be customized. Polyester (Dacron) can also be used.

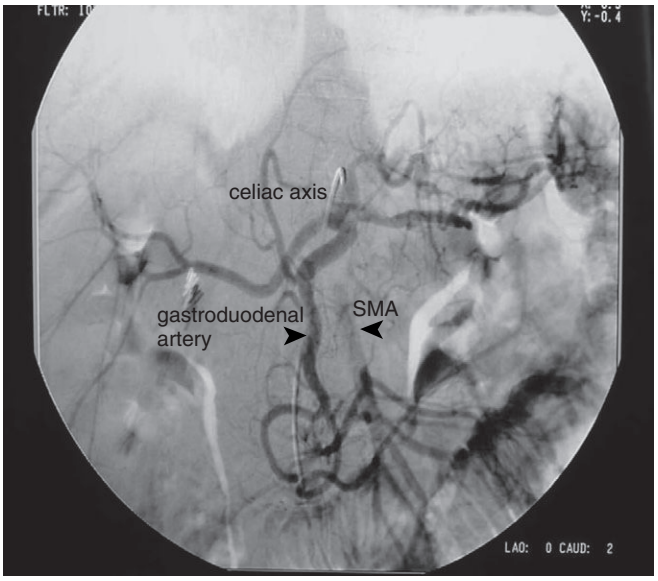

FIGURE 8 Selective injection into the celiac axis results in opacification of the superior mesenteric artery (SMA) via a very large gastroduodenal artery. In this case, reconstruction of either the celiac axis or the SMA provides perfusion to the entire visceral circulation.

be reconstructed to provide durable symptom relief and protection against visceral infarction. Some authorities have reported a correlation between durable symptom relief and "complete" visceral revascularization, whereas others have reported equivalent results with single-vessel revascularization. Among those who believe that single-vessel reconstruction is adequate, there is further debate about the optimal choice of the single vessel. In fact, if all of the collateral pathways between the three main visceral arteries are intact, revascularization of any single visceral artery should be sufficient for relief of symptoms (see Figure 7). Practically speaking, if single-vessel reconstruction is chosen, either the celiac artery or the SMA should be the target artery as long as this is technically feasible (Figure 8). Single-vessel reconstruction to the IMA should be performed only if neither the celiac artery nor the SMA can be repaired.

OUTCOME OF OPEN REVASCULARIZATION

Since 1990, the author and colleagues have performed open visceral reconstruction in more than 100 patients with an overall perioperative mortality rate of approximately 20%. The mortality rate in the last half of this time interval has been about half that experienced in the early half of the time interval. The author and colleagues attribute this improvement to the increasing proportion of patients managed with antegrade bypass, as well as to the routine performance of transaortic endarterectomy through an abdominal approach, rather than through a thoracoretroperitoneal approach. In general, the perioperative outcome achieved with the two standard open reconstruction options—transaortic endarterectomy and antegrade bypass—are equivalent.

Furthermore, in the author's experience, the long-term relief of symptoms is the same whether it is achieved with transaortic endarterectomy or with antegrade bypass. Approximately 80% of patients undergoing one of the two standard open operative treatments have remained symptom free. Factors that are correlated with increased probability of recurrent symptoms include very early age at first diagnosis, greater weight loss at the time of initial presentation, and intraoperative modification of the planned reconstruction technique. These factors are probably indicative of a more aggressive and extensive arterial process.

Of equal interest is the fact that two thirds of patients with recurrent symptoms can be rendered symptom free again by repeat visceral revascularization. This result is also durable, inasmuch as these patients have remained symptom free during an average further follow-up of 6 to 7 years. Thus, during this extensive follow-up interval, fatal recurrent visceral ischemia has occurred in only approximately 5% of patients.

Published results from the literature (see Table 1) also show improvement in comparison to earlier experiences. These series also demonstrate the better durability associated with open surgical visceral revascularization, in comparison to the durability of endovascular techniques.

Hemodialysis Access Surgery

Bonnie E. Lonze, MD, PhD, and
Thomas Reifsnyder, MD, FACS

INTRODUCTION

For the past decade, the overall prevalence of end-stage renal disease in the United States has increased at a rate of approximately 2% per year. In 2009, 116,395 patients initiated dialysis, and the overall number of Americans living on dialysis grew to exceed 397,000. For the vast majority of these patients hemodialysis is the preferred mode of renal replacement therapy. The ability to deliver this lifesaving therapy is dependent on the creation and maintenance of adequate vascular access.

HISTORICAL NOTES

Over the course of approximately a century, end-stage renal failure went from a universally fatal disease to a tolerable chronic illness with reasonable long-term survival. In the United States, a series of events involving science, medicine, and politics led to universally available and undeniable renal replacement therapy.

The concept of dialysis was introduced by the Scottish physical chemist Thomas Graham, whose experiments in the 1850s characterized the movement of water across semipermeable membranes and led to an understanding of the principle of osmosis. It was in fact Graham himself who first applied the term *dialysis* to describe the phenomenon of exploiting osmotic gradients to move solutes across a membrane separating two solutions.

Fifty years later, John Jacob Abel, a pharmacologist at Johns Hopkins Hospital, first explored the application of dialysis in a clinical setting. Abel, working with Leonard Rowntree and B. B. Turner, described in 1914 the construction of the "artificial kidney," an apparatus that consisted of 32 tubes connected in series and encased in a large glass container filled with a dialysate solution. Using hirudin as an anticoagulant to prevent clotting in the tubes, they tested the invention on anesthetized animals. Using arterial cannulae to channel blood into the narrow tubes of the circuit, they demonstrated that indeed blood could be dialyzed.

The first successful human use of dialysis is credited to Willem Kolff, a Dutch physician who had studied Abel's work. During the German occupation of the Netherlands in the 1940s, he designed and built, mainly from household items, a dialysis device he named the "rotating drum kidney." This device consisted of a large drum, covered with thin tubing that sat partly submerged in a large tank of dialysate. Blood passed through the series of tubes affixed to the drum that then rotated within the tank, facilitating dialysis of the blood across the tubing. Kolff's first surviving patient was a 67-year-old woman with acute renal failure secondary to sepsis. She endured an 11-hour dialysis session in which a measured 60 grams of urea were removed. He foresaw many possible applications of hemodialysis and was astutely aware that its implementation for chronic renal failure would require durable vascular access.

The first solution to the access problem was developed by Belding Scribner at the University of Washington. Having been introduced to a newly engineered material called polytetrafluoroethylene, or PTFE (Teflon; DuPont, Wilmington Del.), and recognizing its inert and noninflammatory properties, he conceived of using a U-shaped Teflon tube to create an external arteriovenous connection that could be accessed for dialysis. On March 9, 1960, the first dialysis by way of the "Scribner shunt" was performed. While this did establish an important proof of principle, Scribner shunts had unacceptably high rates of infection, thrombosis, and hemorrhage, and their functional patency rarely exceeded a few months. Seeking to improve upon this, James Cimino and Michael Brescia invented the radiocephalic arteriovenous fistula and described the technique in their landmark *New England Journal of Medicine* manuscript in 1966.

With safe and reliable vascular access technically feasible, widespread availability of hemodialysis had a final major obstacle: its prohibitive cost. Lobbying at local and national levels resulted in government funding for improvements in dialysis machine technology and the construction of more dialysis units. However, due to its cost, most people believed that without federal government support, access would remain limited to the privileged few. In November 1971, a chronic dialysis patient named Shep Glazer and his nephrologist demonstrated a dialysis session before a congressional committee in Washington, D.C. This had a tremendous impact on both the committee members and the press, leading Congress to take action. In October 1972, President Richard Nixon signed into law a bill authorizing Medicare coverage of dialysis.

In this chapter, we review and summarize our current practices for the evaluation, placement, and maintenance of hemodialysis

access. In 2002, the Society for Vascular Surgery and the American Association for Vascular Surgery published recommendations for standardized reporting of dialysis access techniques, procedures, and configurations. For purposes of brevity, however, we preferentially utilize common nomenclature throughout our discussion.

NATIONAL PRACTICES AND GUIDELINES

In 2009, the End-Stage Renal Disease Program alone consumed 6% of the overall Medicare budget—a total of $29 billion—and this staggering sum is rising annually. As health care cost containment has become a major national focus, there has been great motivation within the dialysis community to identify best practices that minimize costs and maximize patient benefit. Until recently, the majority of arm accesses placed had been prosthetic grafts. Certainly some of these grafts were placed out of necessity. Unfortunately, convenience, lack of surgeon experience, and the higher reimbursement rate for prosthetic grafts undoubtedly played a role in their preferential placement. Specifically, in 1990, ePTFE grafts were placed twice as frequently as autogenous arteriovenous fistulae. According to the Centers for Disease Control, in 1995, just over 20% of patients on dialysis were utilizing autogenous access. Clear evidence has since emerged that autogenous fistulae are associated both with better outcomes and lower costs, and this has drawn attention to the unacceptably low proportion of patients in the United States dialyzing through autogenous accesses. The disproportionate and often inappropriate use of prosthetic grafts fueled the National Kidney Foundation's Kidney Disease Outcomes and Quality Initiative (KDOQI). This is a comprehensive analysis of the best practices with regard to the management of end-stage renal disease. An offspring of KDOQI was the Centers for Medicare and Medicaid Services' Fistula First Breakthrough Initiative, which aimed to promote awareness among patients and physicians of the superiority of autogenous access. The current national goal is to place autogenous access in at least 65% of new dialysis patients.

Currently, the three main avenues for hemodialysis access are tunneled central venous catheters, arteriovenous prosthetic grafts, and autogenous arteriovenous fistulae. Clearly, the worst outcomes are associated with catheter usage, and therefore every effort should be made to avoid them. To this end, current KDOQI guidelines stipulate that all patients should be referred to a surgeon for the placement of autogenous access when they reach stage 4 chronic kidney disease (glomerular filtration rate [GFR] <30 mL/min/1.73 m^2). This allows sufficient time for fistula placement and maturation prior to the commencement of dialysis. The caveat to this scenario is that not all patients have a suitable vein for autogenous fistula creation. Only those with a suitable vein should have their access placed far in advance of the initiation of dialysis, and this access should be an autogenous fistula. The most common cause of prosthetic graft failure is stenosis at the venous anastomosis due to neointimal hyperplasia. This worsens with time, so if a prosthetic graft is required, it should only be placed when dialysis is imminent or has already begun.

The options for dialysis access are frequently impacted by treatment options instituted years before the patient reaches end-stage renal disease. Patients and physicians alike must be aware that for those with any degree of renal dysfunction, subclavian vein central lines and ports, PICC (peripherally inserted central catheter) lines, and even forearm intravenous catheters (intern's vein or distal cephalic vein) should be avoided whenever possible. PICC lines are the curse of the dialysis access surgeon. Not only do they frequently ruin a normally good access vein—the basilic vein—but they are also associated with rates of central venous stenosis or thrombosis estimated up to 85%, which renders the arm unusable for dialysis access of any type.

The algorithm for selecting which fistula to place is fairly straightforward. One should begin distally and work proximally in the nondominant arm: radiocephalic (Figure 1), brachiocephalic, and then upper-arm basilic transposition. We believe that the benefits of autogenous access are so great that many exceptions to the standard algorithm are permitted. Although use of the nondominant arm is preferable, frequently the veins are better in the more active dominant arm. In this circumstance, the dominant arm is used without hesitation for fistula placement. If a patient has no suitable vein for autogenous access, then a prosthetic graft may be used. A good prosthetic graft is better than a bad vein. Although prosthetic grafts may be placed between any artery with sufficient flow and any suitable vein with unobstructed outflow, it is best to begin as far distally as possible and reserve more proximal sites for the future. For example, we would consider these configurations in the following order: distal radial artery to brachial vein straight graft, distal brachial artery to distal brachial vein forearm loop graft, and finally, distal brachial artery to proximal brachial vein or distal axillary vein straight graft. With education and careful attention to best practices, autogenous accesses can be preferentially placed, and the use of prosthetic grafts can and should be limited.

PREOPERATIVE EVALUATION

End-stage renal disease is rarely an entity that exists in isolation, and dialysis patients have a higher incidence of significant comorbid conditions. According to the United States Renal Data System, among the cohort of new dialysis patients who were registered in 2006-2009, 84% had hypertension, 21% had coronary artery disease, 32% had congestive heart failure, 35% had insulin-dependent diabetes, 14% had peripheral vascular disease, 9% had a history of previous stroke or transient ischemic attack, and 7% were unable to ambulate. Briefly stated, these patients are poor operative candidates. The preoperative evaluation revolves around assessing cardiopulmonary reserve and selecting the anesthetic with the least risk.

Aside from a history of events relevant to cardiopulmonary status and prior dialysis access attempts, it is imperative to inquire as to all previous venous access procedures, including dialysis catheters, subclavian lines or ports, PICC lines, pacemakers, and defibrillators. Prior trauma to the upper extremities or clavicles should be noted. The physical exam should include auscultation of the heart and lungs and an evaluation of the extremities to determine the patient's best option for dialysis access. The radial, ulnar, and brachial pulses should be palpated bilaterally. Uncommonly, a radial pulse is present with an occluded brachial artery. An Allen's test to confirm adequacy of ulnar flow to the hand should be performed if a radiocephalic

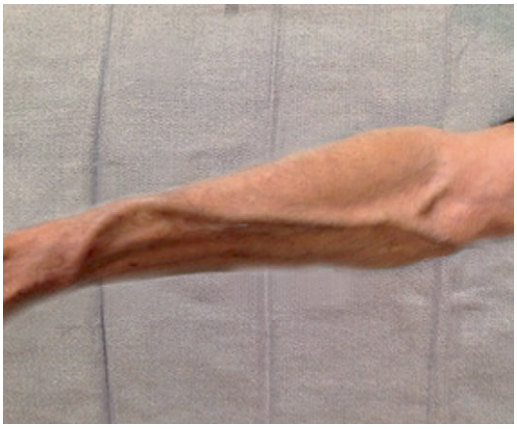

FIGURE 1 Mature radiocephalic arteriovenous fistula 6 weeks postoperatively.

fistula is contemplated. It cannot be overemphasized that the preoperative physical examination is incomplete unless a venous tourniquet is used to assess the superficial veins. To end up with a successful radiocephalic fistula, the forearm cephalic vein should be palpable from the wrist to the antecubital fossa. Otherwise, attention should be directed to the upper-arm veins.

Duplex ultrasound–based vein mapping prior to dialysis access surgery was essentially mandated by the KDOQI guidelines. We strongly disagree with this blanket recommendation. Although vein mapping at times may be helpful for operative planning, it is frequently unnecessary, adds cost, and may not always give valid information. In patients already on dialysis via a catheter, we rarely request a vein map. If no suitable vein is found at surgery (see operative techniques below), then the patient will require a prosthetic graft. In patients referred prior to the initiation of dialysis, vein mapping may be helpful in those who are obese, are intravenous drug abusers, or have had prior PICC lines. It may also be helpful in patients with normal-sized arms where neither an adequate basilic nor cephalic vein is palpable with a tourniquet in place. Lastly, with the ubiquity of portable ultrasound machines, surgeon-performed vein mapping in the preoperative area or intraoperatively is becoming more routine, and this option generally obviates the need for a formal vein mapping study.

Venography is an important component of successful dialysis access surgery. Its primary use is not to road map the arm veins but rather to confirm central vein patency. Our practice is to use it liberally in any patient with a history of arm swelling or prior central venous cannulation on the side of proposed access. In predialysis patients, carbon dioxide may be used as a contrast agent, thereby avoiding the risks of iodinated contrast-induced nephrotoxicity. If a hybrid endovascular operative suite is available, the venogram may be done at the beginning of the access case, allowing for a combined procedure that is more convenient for the patient. Lastly, for the safety of the surgical team, any patient with a history of intravenous drug use should have a plain radiograph of the upper extremity to evaluate for the presence of foreign bodies.

Prior to surgery, standard blood chemistries and a complete blood count are all that are necessary. The surgeon can assume that uremic platelet dysfunction will always be present, and we have found no utility in checking bleeding times preoperatively. Uncommonly, DDAVP (arginine vasopressin) at a dose of 0.3 μg/kg will be needed intraoperatively to control oozing. Additionally, aspirin use does not seem to impact bleeding significantly, and considering the cardiovascular risk profile of these patients, we routinely administer a dose of 81 mg in the preoperative area. Clopidogrel does seem to increase oozing in some patients, so this should be held for 5 to 7 days unless the patient has recently undergone coronary artery stenting. Many patients are also on warfarin. In general, we do not advocate holding warfarin and feel comfortable proceeding with access surgery with an international normalized ratio (INR) up to 2.5.

OPERATIVE TECHNIQUES

The best option for anesthesia depends on the patient's comorbid conditions, the anesthesiologist, and the proposed surgery. While local anesthesia is a viable option for many patients, it works best for patients undergoing radiocephalic or nontransposed brachiocephalic fistulas. While we have used it successfully for upper-arm basilic transpositions, it tends to be somewhat less than ideal for both patient and surgeon due to the relatively large area that must be anesthetized. More recently we have used infraclavicular regional nerve blocks. The blocks are placed in the preoperative area by a dedicated block team while the preceding case is underway. This helps to maximize efficiency and shorten turnover time. If the skin incision approaches the deltopectoral groove or the axilla, supplementation of the regional block with local anesthetic will be necessary. Our experience with supraclavicular blocks has been less satisfactory. Over the last year, three cases were canceled due to shortness of breath secondary to phrenic nerve paresis following this more proximal nerve block.

Autogenous Arm Fistulae

The patient is positioned supine, with the shoulder of the operative side near the edge of the bed. The arm board should be positioned such that the arm rests in the center of the board. A standard skin preparation including the shoulder and axilla is performed. If available, an arm board drape is most convenient, but an extremity drape will suffice.

Radiocephalic Fistula

A 3-cm to 4-cm incision is placed just proximal to the wrist along the lateral or radial aspect of the arm. Once the skin is incised, the surgeon and assistant both lift the skin with Adson forceps, facilitating easy identification of the cephalic vein after some gentle blunt dissection. The vein is encircled with a vessel loop and then sharply dissected out, tying all branches with 4-0 or 5-0 ties. The radial artery is dissected out circumferentially in a standard fashion and controlled with vessel loops. Any side branches are tied but not divided, which helps to maintain its orientation. The cephalic vein is divided distally, gently dilated with sequential coronary dilators, and then flushed with heparinized saline. After flushing the radial artery, a spatulated end-to-side anastomosis is performed using 6-0 or 7-0 polypropylene suture. Any large proximal vein branches are ligated through separate 1-cm incisions. Closure consists of 3-0 interrupted absorbable dermal sutures and a 4-0 running absorbable subcuticular suture.

Upper-Arm Fistula

If there is a potentially good cephalic vein, then a transverse incision is made in the antecubital crease (Figure 2, *A*), and the cephalic vein is identified (Figure 2, *B*). If the vein is of suitable size, it is dissected out to its confluence with the median cubital vein, ligated distally, and divided. Sequential coronary dilators are gently passed cephalad and should easily pass if there is no intraluminal scarring. Although a sufficient length of vein can be mobilized at this point to easily reach the brachial artery, we frequently convert the incision into a hockey stick–shaped incision (with the handle of the stick along the cephalic vein; Figure 2, *C*) and mobilize 10 to 15 cm or more of the vein (Figure 2, *D* and *E*). Not only does this allow ligation of the accessory cephalic vein and other small branches, but it also allows superficial tunneling of the vein (Figure 2, *F*), which is necessary in all but the thinnest of arms. With the vein transposed, accessing the fistula can be performed earlier (as soon as 4 weeks, depending on vein size), easier, and more consistently, enabling earlier removal of dialysis catheters.

Dissection of the distal brachial artery through the medial aspect of the antecubital incision is done in a standard fashion, with control obtained with vessel loops. If the brachial artery appears smaller than expected, the patient most likely has a high brachial bifurcation. In these cases, the more suitable donor artery almost always is the deeper of the two vessels and should be evaluated before proceeding with the anastomosis. The vein is tunneled just beneath the skin, making sure there is no kink or twist at the most proximal site of mobilization (Figure 2, *G*). Once an arteriotomy is made and the artery is flushed with heparinized saline, the vessel loops are replaced with baby bulldog clamps. This eliminates any vessel stretching and makes the end-to-side anastomosis easier to perform. Closure consists of 2-0 absorbable sutures in the subcutaneous tissue and 3-0 nylon vertical mattress skin sutures (Figure 2, *H*). In our experience,

FIGURE 2 Brachiocephalic arteriovenous fistula creation. **A,** Antecubital incision. **B,** Identification of cephalic vein in antecubital fossa. **C,** Hockey stick incision. **D,** Proximal dissection of cephalic vein. **E,** Ligation of cephalic vein branches, dissection of brachial artery in antecubital fossa. **F,** Superficial tunneling of mobilized cephalic vein. **G,** Completed arteriovenous anastomosis. **H,** Closure of skin with vertical mattress nylon sutures.

subcuticular closures in the upper arm have been associated with postoperative wound problems much more frequently than with interrupted nylon closures. In addition, patients are much more apt to keep their follow-up appointment if they have sutures that need to be removed. If the cephalic vein is not of adequate size or quality, then the median cubital vein is identified near the medial aspect of the incision. If the median cubital vein is adequate, it is ligated distally, divided, and flushed with heparinized saline. We then extend the medial end of our skin incision in a hockey stick fashion along the medial aspect of the arm nearly to the axilla. The vein is dissected circumferentially over its course toward the axilla as it joins the basilic vein, which subsequently joins the proximal brachial vein. If the median cubital vein is not adequate, then the basilic vein is used. In this instance we place two surgical towels under the upper arm to improve positioning and then make a new incision just anterior to the medial epicondyle of the humerus. Once the basilic vein is identified and found to be of appropriate size and quality, the incision is extended proximal and distally until enough vein for a transposition has been exposed. The brachial artery is then dissected out at the antecubital fossa either through a separate incision or through the medial aspect of the antecubital incision if that incision had already been made to inspect the cephalic vein. The vein is then tunneled and the anastomosis prepared and performed as described above. The fascia and subcutaneous layers are reapproximated with running 2-0 absorbable sutures. The skin is closed with interrupted 3-0 nylon vertical mattress sutures. At the end of the case, there should be a palpable thrill in the fistula. If there is not, then there is a technical problem and the incision should be reopened.

Prosthetic Arteriovenous Grafts

If there is no suitable vein, then a prosthetic graft must be placed. Although the most commonly used graft is 6-mm ePTFE, bovine carotid artery and polyurethane-urea (Vectra; Bard, Tempe Ariz.) grafts may also be used. A transverse incision is made over the brachial artery in the antecubital fossa. The brachial artery and vein (if at least 5 mm in diameter) are isolated and encircled with vessel loops. The vein should be generously dissected out to allow a long venous anastomosis. A second, smaller counterincision is made on the volar surface of the midforearm on the radial side. Placement of the counterincision in this fashion skews the graft toward the radial aspect of the forearm, and this affords the most comfortable arm positioning during dialysis. The venous anastomosis is performed first, particularly if the graft has a premade flared end. The graft is tunneled in a gentle arc to the counterincision and then back to the

antecubital fossa. Tunneling is best accomplished with a Kelly-Wick tunneler (IMPRA; Bard, Tempe Ariz.), although an aortic clamp may be used. The arterial anastomosis is then performed, and the incisions are closed. If the brachial vein is too small at the antecubital fossa, then a second incision is made on the proximal medial aspect of the upper arm, and the proximal brachial or distal axillary vein is used for the venous outflow. While this describes the two most common graft configurations, in reality any suitable artery and vein may be used. We strongly believe in fistula first and therefore do not agree with the use of forearm grafts to help mature upper-arm cephalic or basilic veins.

Special Considerations

Not uncommonly, patients present for dialysis access after many months of catheter usage and already have upper extremity central vein occlusion or stenosis. The thigh prosthetic graft is the next best access in most circumstances. Although we have extensive experience utilizing femoral vein and find it particularly useful for home hemodialysis patients who have no useful upper extremity veins, its use for a thigh fistula should be carefully planned and works best in thin legs. Saphenous vein may also be used as a thigh fistula (tunneled anteriorly as a straight fistula and anastomosed to the distal superficial femoral artery), but if the vein is not generous in size (at least 5 mm) at the time of surgery, failure to mature into a useful access is common. For a prosthetic thigh graft, an oblique skin line incision is made just distal to the groin crease, and either the deep femoral or proximal superficial femoral artery is used for arterial inflow. Through the medial aspect of that incision the proximal saphenous vein or saphenofemoral junction is preferentially used for venous outflow. The proximal femoral vein may be used, but the dissection is somewhat more difficult.

COMPLICATIONS AND MANAGEMENT

Infection is the most frequent complication of hemodialysis access and is a major cause of morbidity and mortality in the dialysis population (Table 1). Up to 30% of all deaths in dialysis patients are due to infections, and most come from vascular access sites. Compared to autogenous fistulae, the relative risk of infection-related death is 1.8 times greater in those dialyzing through catheters and 1.3 times greater in those dialyzing through prosthetic grafts. The cumulative probability of developing a catheter-related infection is over 50% after 2 months of dialysis through a catheter. Diabetes and human immunodeficiency virus (HIV) are also independent risk factors for greater infection rates among all access types. Staphylococcal species are the most frequently isolated organisms. Access-derived infections often lead to systemic complications, including bacterial endocarditis, osteomyelitis, septic emboli, and septic arthritis. For catheter-related bacteremia, management consists of culture-directed parenteral antibiotics and removal or exchange of the infected catheter. For infected ePTFE grafts, management must be guided by an attempt to balance the benefits of preserving a functioning access with the severity of infection. Some local infections can be successfully treated with aggressive intravenous antibiotic therapy combined with resection and replacement of a portion of the graft, though recurrent infection is not uncommon. Abscess formation, purulent drainage from the graft site, or the development of infected pseudoaneurysms all mandate removal of the infected portion or the entirety of the graft.

TABLE 1: Frequency of dialysis access–derived infections in a study of 1574 surgery patients

Overall incidence of infection, n (%)	132 (8.3%)
Category of Infection	
Dialysis center–derived infection (>30 days after surgery)	66 (50%)
Spontaneous infection in nonfunctional graft	30 (22.7%)
Infection in remaining stump of partly excised graft	22 (16.7%)
Operative site infection (<30 days after surgery)	6 (6.1%)
Postinterventional radiology thrombectomy	6 (4.5%)

The risk of access failure due to thrombosis is more common in prosthetic grafts than in autogenous fistulae. Early failure is generally due to technical factors but can also be related to hypercoagulability, low flow states, or use of inadequate vein. In mature accesses, most problems will be detected by the dialysis unit. High venous pressures, poor arterial inflow, recirculation, and diminishing effectiveness of the dialysis all indicate access problems. The anatomic location of the problem usually can be ascertained by physical examination. The lack of bruit and thrill indicates thrombosis. A weak thrill or bruit suggests inflow problems. Pulsatility in a fistula generally indicates an outflow problem. Early intervention can often salvage an otherwise threatened fistula or graft. A duplex scan can further pinpoint the area of the problem, but it is frequently unnecessary. Generally, the diagnostic test of choice is a fistulogram, at which time therapeutic interventions, such as thrombectomy, angioplasty, and stenting, can be carried out. Occasionally open revision is necessary, with many options available to improve either arterial inflow or to relieve venous outflow obstructions.

Almost all arm accesses create a steal syndrome, but significant steal occurs less than 15% of the time, with brachial artery–based accesses presenting the highest risk. Loss of a palpable distal pulse at the time of fistula creation indicates that a significant steal syndrome could develop. Manual compression of the fistula should result in restoration of the distal pulse. Options for improving distal perfusion include ligation, plication, banding, proximalization of the arterial inflow, and the distal revascularization with internal ligation (DRIL) procedure. The DRIL has the benefit of leaving the functioning fistula undisturbed and eliminates the physiologic pathway for the steal and restores downstream perfusion.

Other complications that occur with varying frequencies and degrees of morbidity include edema due to venous hypertension, seromas, wound problems, and carpal tunnel syndrome. Aneurysmal dilatation of mature grafts or fistulae generally does not need to be addressed operatively unless there is overlying skin breakdown. In general, having a low threshold to investigate and intervene on a fistula that is not performing optimally will minimize the need for repeated access surgeries.

CONCLUSIONS

1. Assume dialysis is forever, so when performing access surgery, do not jeopardize future options.
2. Try to avoid all catheters and, if possible, prosthetic materials—in other words, fistula first.
3. Fistula dysfunction mandates prompt investigation and intervention to maximize chances of fistula salvage.
4. Dialysis access preformed properly will be rewarding for the patient as well as the surgeon.

Venous Thromboembolism: Prevention, Diagnosis, and Treatment

Catherine G. Velopulos, MD, MHS, and Elliott R. Haut, MD, FACS

INTRODUCTION

Venous thromboembolism (VTE) disease, which encompasses deep vein thrombosis (DVT) and pulmonary embolism (PE), has become an increasingly recognized source of morbidity and mortality, particularly in surgical cases. The Agency for Healthcare Research and Quality (AHRQ) has suggested that appropriate VTE prophylaxis is the number one patient safety initiative that can be undertaken to prevent in-hospital death. In 2008, the Surgeon General issued "A Call to Action to Prevent Deep Venous Thrombosis and Pulmonary Embolism," and the U.S. Congress designated March as DVT Awareness Month in an effort to raise awareness for this disease that kills more than 100,000 and is diagnosed in more than 600,000 Americans per year.

In the setting of this potentially preventable disease, it is important to recognize the scope and impact of the problem, the risk factor profile of each patient, prophylaxis and prevention strategies, and appropriate screening and diagnosis. In patients who are identified as having disease, optimal treatment algorithms must be used to reduce morbidity and mortality.

IMPACT

Multiple patient populations treated by surgeons are particularly vulnerable because of physiologic derangements in the perioperative period. VTE is more prevalent, and more deadly, in patients with malignant disease; patients with gastrointestinal, pancreatic, and colorectal cancer are at highest risk. VTE is one of the most common and deadly complications among trauma patients, with reported rates as high as 50%. Patients who undergo orthopedic surgery (particularly hip or knee joint replacement) have been shown to be at a tenfold increased risk for VTE. Intensive care unit (ICU) admission is an independent risk factor for VTE, although this is often difficult to differentiate from other risk factors present in the same patients. Studies of patients on mechanical ventilation show an incidence rate of up to 25% for DVT and greater than 10% for PE even in patients who were given appropriate prophylaxis.

Economic evaluations have reported a doubling in the length of stay and hospital costs for patients with VTE, with estimated per patient added costs of $15,000 to $25,000, and increased hospital readmission rates. In the era of pay for performance and decreased reimbursements for preventable events, VTE prevention represents an area of significant potential improvement, particularly in the arena of patient safety and quality.

RISK FACTORS

Any disease process that augments Virchow's triad of venous stasis, endothelial injury, and hypercoagulability increases the risk of VTE. Factors such as trauma that leads to immobilization, paralysis (i.e., spinal cord injury, stroke, or pharmacologic event during surgery), indwelling venous catheters, and insufflation for laparoscopic surgery contribute to venous stasis. Any type of venous injury leads to endothelial damage and release of factors, whether traumatic or iatrogenic (i.e., central venous catheter placement). Disease states such as trauma, neoplasm, congestive heart failure, congenital disorders, and obesity, along with pregnancy and treatments such as hormone therapy and chemotherapy, contribute to a hypercoagulable state. Some of the commonly accepted risk factors for VTE are included in Box 1.

PREVENTION AND PROPHYLAXIS

In the years before routine VTE prophylaxis was adopted, general surgery patients who were untreated had rates of DVT and PE of 19.1% and 1.6%, respectively, with a remarkably high fatal PE rate of 0.87%. Even in the current era in which prophylaxis is more frequently used, VTE rates of more than 2% to 3% are reported after some major general surgery and surgical oncology cases. Numbers such as these should remind clinicians of the importance of VTE prevention.

All surgical patients should be evaluated for VTE risk factors and be offered appropriate prophylaxis, with the vast majority warranting pharmacologic prophylaxis. Well-researched evidence-based guidelines are routinely published by national societies to aid clinicians in determining the ideal prophylaxis for their patients. The American College of Chest Physicians (ACCP) updates their guidelines approximately every 4 years and is thought by many to be the definitive resource on VTE prevention. Other groups, such as The Eastern Association for the Surgery of Trauma (EAST) and The American Academy of Orthopedic Surgeons (AAOS) have guidelines for specific patient subgroups as well.

Nearly all surgical patients have at least some risk factors that warrant pharmacologic prophylaxis in the perioperative period. Specific regimens should be selected based on individual patient risk

BOX 1: Risk factors for venous thromboembolism

Major VTE Risk Factors
Previous VTE
Cancer
Thrombophilia
Prolonged surgical procedure (>2 h)
Major general surgery
Major trauma
Fracture of hip or leg
Hip or knee replacement
Spinal cord injury
NYHA class III/IV heart failure
Respiratory failure requiring mechanical ventilation
Acute stroke with paresis (<3 mo)
Pregnancy/postpartum (up to 6 wk)

Minor VTE Risk Factors
Acute infection/sepsis
Bed rest
Immobility from prolonged sitting (e.g., travel)
Central venous catheter
Increasing age
Laparoscopic surgery
Estrogens/selective estrogen receptor modulators (e.g., tamoxifen)
Inflammatory bowel disease
Obesity
Pregnancy/antepartum
Varicose veins, arteriovenous malformations

NYHA, New York Heart Association; *VTE,* venous thromboembolism.

factors and the type of surgery being performed. Most protocols use subcutaneous injections of unfractionated heparin or low molecular-weight heparin (LMWH) after surgery. A preoperative dose 1 to 2 hours before surgery has shown some benefit and is used in many protocols. There is no definitive recommendation for which pharmacologic agent is used in most surgical patients, although the trauma and orthopedic literature suggest an advantage of LMWH over unfractionated heparin. The duration of prophylaxis is still a subject of debate, and it is routinely stopped at hospital discharge. However, excellent data in orthopedic surgery mandate extended, outpatient use, which is frequently prescribed. Similarly, data and guidelines suggest this extended prophylaxis be ordered for many patients undergoing major cancer or abdominal-pelvic surgery, although this is not routinely done.

An example schema of one published VTE prophylaxis algorithm for general surgery inpatients is shown in Figure 1. This algorithm places patients with major VTE risk factors and older patients (>60 years of age) with any risk factors into a "very high risk" category. Patients between the ages of 40 and 60 years, in the absence of major risk factors, are placed in the "high risk" category. The remainder of all other surgical patients is at "moderate risk." No surgical inpatients are truly at "low risk," although some patients undergoing short/minor, ambulatory, outpatient procedures warrant no specific recommendations for pharmacologic VTE prophylaxis.

Patients capable of ambulation should have their activity advanced as soon as feasible because this remains an effective adjunct (although it should not be routinely relied on as the sole VTE prevention measure). Additional mechanical prophylaxis approaches include graduated compression stockings, sequential compression devices, and intermittent pneumatic compression devices. Their efficacy is well proven, and they are often ordered as adjunctive measures in addition to pharmacologic prophylaxis. However, their effectiveness is hampered by poor compliance in routine practice (<50% of patients have working devices on in some studies) and contraindications in certain patients with lower extremity wounds, casts, immobilizers, or external fixation devices.

The use of inferior vena cava (IVC) filters for primary prophylaxis against PE (in the absence of documented DVT) is currently the object of some study and much controversy and debate and is discussed later in this chapter.

Despite evidence that VTE prophylaxis is effective, routine use of adequate prophylaxis is remarkably low. Published compliance rates hover around 50% to 60% in many studies of surgical patients across the United States and around the globe. Many approaches to improve this poor guideline adherence and improve quality of care have been attempted, often with little success.

Simple electronic reminders to use VTE prophylaxis in surgical patients have been shown to increase ordering of prophylaxis but had no change in VTE outcomes. A targeted electronic alert that tells ordering physicians that their patients are not being given prophylaxis has shown some improvement in adherence; however, this approach is reactive and does not instruct providers to use best practice VTE prevention from the beginning. The authors have recently published multiple papers that show significant benefits of a mandatory computerized clinical decision support (CDS) tool embedded within the hospital's computerized provider order entry (CPOE) system. This approach dramatically improves documentation of risk status, increases compliance with evidence-based guidelines for VTE prophylaxis, and decreases preventable harm from VTE events.

DIAGNOSIS

Diagnosis of VTE must always be considered and aggressively pursued when indicated in patients with clinical suspicion for DVT or PE. Historically, DVT has been confirmed with invasive contrast venography, but it now is diagnosed almost exclusively with duplex ultrasound scan. DVT can also be seen on contrast-enhanced computed tomographic (CT) scan or magnetic resonance imaging (MRI), although these tests are only rarely ordered for this indication specifically.

Similar changes in diagnostic testing for PE have occurred, and PE is now primarily diagnosed with contrast-enhanced CT angiogram of the chest. Improved techniques and capabilities of the current multidetector helical scanners allow for diagnosis of increasingly smaller PEs at the subsegmental level, the clinical significance of which is yet to be fully determined. Although CT scan is the current test of choice, other modalities must be considered in certain patient populations. Ventilation/perfusion (V/Q) scanning, a nuclear medicine test, can be used in patients who cannot receive contrast dye because of renal insufficiency or allergy, but this test must be interpreted in combination with the pretest probability of PE to be clinically useful. Critically ill patients in the ICU whose conditions are too unstable for transport to CT scan can be evaluated with transthoracic or transesophageal echocardiogram. Findings of right heart failure or pulmonary hypertension are highly suggestive of PE, and clot can sometimes be visualized directly with echocardiography. In combination with classic echocardiographic results suggestive of right heart strain, this is fairly specific for PE. Serum testing of D-dimer levels is quite helpful in the outpatient and emergency department settings to both rule in and rule out VTE. This laboratory test is less useful in perioperative surgical inpatients because D-dimer is often elevated in this patient population; however, it should still be routinely ordered because a normal test definitively rules out clinically important VTE. In patients in whom VTE is highly suspected and anticoagulation therapy is not contraindicated, empiric treatment should be rapidly initiated even before definitive diagnosis has been confirmed.

SCREENING OF ASYMPTOMATIC PATIENTS

Screening of asymptomatic patients for DVT remains controversial. Proponents of screening see benefit in performing a relatively inexpensive, noninvasive, nonradiation–based test (duplex ultrasound scan) to identify and treat DVT early, before progression to larger symptomatic DVT or conversion to PE. Opponents raise concerns about the direct financial costs of increased medical testing. In addition, identification of clots that never would have become clinically significant puts patients at risk by committing them to months of potentially dangerous anticoagulation therapy.

The largest body of literature on the topic of screening patients at high risk for DVT is in trauma surgery. Wide practice variation exists, primarily because studies have yet to show any definite improvement in patient outcomes with this strategy, particularly in patients who have been given adequate prophylaxis. Disagreement is found among guideline developers as well. The ACCP guidelines state that screening should not be performed, and the EAST guidelines suggest that it may benefit certain trauma patients at high risk.

Surveillance bias (the idea of "the more you look, the more you find") remains a primary concern, as studies have shown a direct correlation between increasing screening and increasing DVT rates. This issue is a timely and important problem because DVT rates have

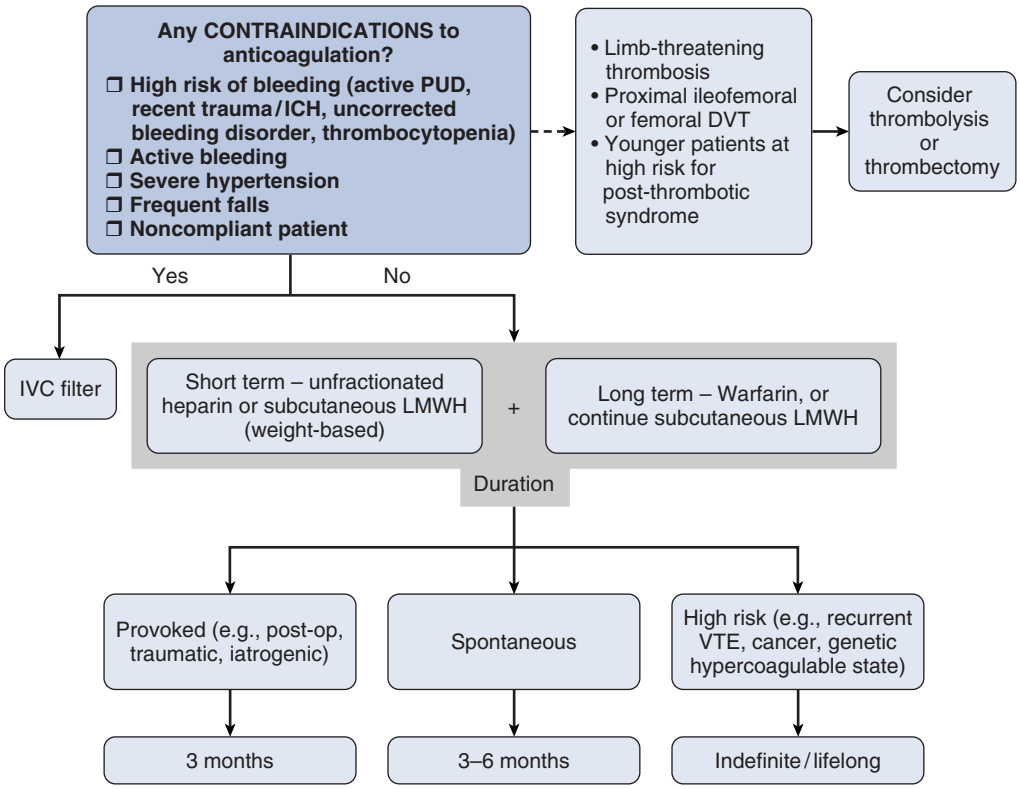

FIGURE 2 Deep vein thrombosis *(DVT)* treatment. *ICH,* Intracranial hemorrhage; *IVC,* inferior vena cava; *LMWH,* low-molecular-weight heparin; *PUD,* peptic ulcer disease; *VTE,* venous thromboembolism.

been proposed as a quality outcome measure and may be publicly reported in the near future. Comparison of a hospital (or trauma center) that screens many patients and identifies many DVT events with one that does many fewer duplex ultrasound scans gives biased information on quality of medical care. The increasing frequency of performing higher resolution CT scan may lead to similar problems. These CT scans are identifying increasing numbers of incidentally noted PEs, presenting a dilemma for how these patients should be treated and how these adverse event rates are used to study and report complications and outcomes and quality of care.

TREATMENT

Deep Venous Thrombosis

Treatment for DVT is largely medical and primarily based on anticoagulation therapy. Most protocols involve the rapid initiation of heparin, either weight-based intravenous unfractionated heparin or subcutaneous LMWH. One such protocol is shown in Figure 2. Long-term anticoagulation therapy can use either warfarin or ongoing weight-based LMWH. Duration of therapy is dependent on the particular circumstances surrounding the VTE event and individual patient characteristics. In general, recommendations suggest 3 months for provoked DVT (e.g., postoperative, trauma-related, or iatrogenic), 3 to 6 months for spontaneous DVT, and indefinite or lifelong therapy in patients at high risk (e.g., recurrent VTE, cancer diagnosis, inherited hypercoagulable states). Some clinicians routinely perform repeat duplex ultrasound scan to ensure the clot is gone and use these data to decide on how long therapy is needed.

Although the vast majority of patients with DVT are treated with anticoagulation therapy alone, other treatments for specific subpopulations exist. Some patients with isolated below-knee DVT who are at low risk of propagation (i.e., mobile outpatients without underlying predisposing factors) can be treated with compression stockings. In this case, repeat duplex scan (at approximately 2 weeks) is used to ensure the clot has resolved. Propagation above the knee should prompt a change to anticoagulation therapy. In patients with a contraindication to anticoagulation therapy, an IVC filter should be placed instead to prevent embolization of the DVT as it becomes a PE. Patients with limb-threatening thrombosis such as phlegmasia cerulea dolens or phlegmasia alba dolens may need open surgical or catheter-based thrombectomy in an attempt at limb salvage.

The role of thrombolysis in treatment of DVT has undergone much scrutiny. This therapy has been suggested for patients with proximal iliofemoral or femoral DVT, younger patients with long life expectancy and good physiologic reserve, and those with limb-threatening thrombosis. Early studies have shown a decreased incidence of postthrombotic syndrome, but this benefit was offset by higher rates of bleeding complications, primarily because systemic thrombolytics were used. Newer catheter-based techniques, involving catheter-directed mechanical or pharmacologic thrombolysis with much smaller doses of thrombolytics, have the potential to change the DVT treatment algorithm. An ongoing large, National Institutes of Health (NIH)–funded, multicenter, randomized, clinical trial named ATTRACT (Acute Venous Thrombosis: Thrombus Removal with Adjunctive Catheter-Directed Thrombolysis) is currently examining the role of this modality in a prospective fashion. This study is examining the safety, efficacy, cost effectiveness, and long-term outcomes (including postthrombotic syndrome and quality of life) when catheter-based therapy is compared with standard therapy alone.

Pulmonary Embolism

Treatment of PE depends first on the clinical cardiopulmonary stability of the patient. One potential algorithm is shown in Figure 3. In patients with hemodynamically stable conditions, the initial treatment algorithm is similar to that for DVT. Most protocols involve the

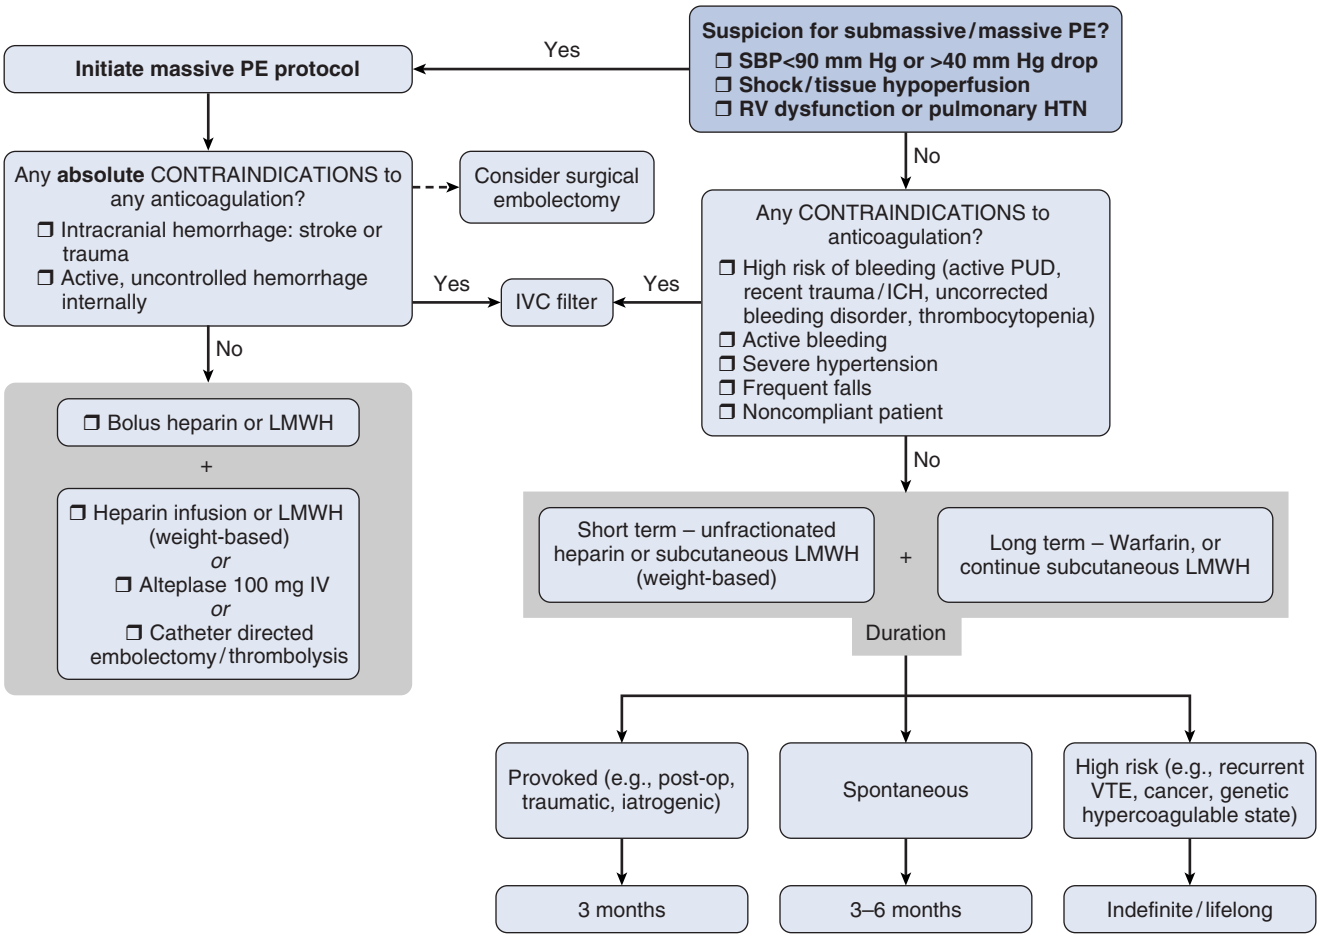

FIGURE 3 Pulmonary embolism *(PE)* treatment. *HTN,* Hypertension; *ICH,* intracranial hemorrhage; *IV,* intravenous; *IVC,* inferior vena cava; *LMWH,* low-molecular-weight heparin; *RV,* right ventricle; *SBP,* systolic blood pressure; *VTE,* venous thromboembolism.

initiation of heparin, either unfractionated or LMWH, with conversion to long-term anticoagulation therapy, with either warfarin or continuation of weight-based dosing of LMWH. Bilateral lower extremity duplex scan is suggested by some to assess for further risk of clot burden, although most of the time, this is negative once the PE is identified. Other clinicians do not perform this study as the presence or absence of DVT does not change therapy. In patients with a contraindication to anticoagulation therapy, an IVC filter should be placed to prevent embolization of more DVT into pulmonary emboli.

Patients with submassive or massive PE, defined as actual or impending cardiopulmonary collapse or progression to right heart failure and shock, should be treated more aggressively. A "Scientific Statement from the American Heart Association" (Jaff et. al.) gives excellent guidance on therapy in these patients (and others with certain subsets of VTE). Patients with massive PE should be treated with systemic fibrinolysis (i.e., alteplase 100 mg intravenously [IV]), assuming they have no definite contraindication and have acceptable bleeding risk. In patients unable to receive systemic fibrinolysis, surgical embolectomy (Trendelenburg's procedure) and catheter-based embolectomy or fragmentation are appropriate options, depending on locally available expertise and resources.

Inferior Vena Cava Filters

Although introduced decades ago, the use of IVC filters has recently been on a rapid upswing. The ease with which these devices can be placed and the technology of removable (also known as optional) IVC filters have likely driven this upward trend of their use. Filters are now routinely placed by many specialists, including interventional radiologists and invasive cardiologists, and trauma, general, and vascular surgeons in operating rooms, interventional suites, and intensive care units. This can be done with the familiar technique of fluoroscopic imaging, although this is no longer necessary as filters are now routinely inserted with intravascular ultrasound scan (IVUS) to guide placement.

Indications for IVC filter placement fall into three main groups. They include absolute and relative indications (both for proven VTE) and prophylactic indications (patients without VTE). In recent years, a consensus has been reached regarding this, and a multidisciplinary study involving representatives from interventional radiology, cardiology, hematology, general surgery, and vascular surgery outlined these indications in detail as seen in Box 2. Although the primary treatment for VTE is acknowledged to be pharmacologic, filters are indicated in certain specific patients. Consideration should be made from the outset as to whether the patient has a limited period of risk, such as in major surgery and trauma, or whether underlying mechanisms dictate a lifelong need for filter. In patients with a contraindication to anticoagulation in whom a filter is placed, anticoagulation therapy should be reconsidered and started as soon as feasible.

The advent of newer retrievable filters that can be removed once the period of highest PE risk has passed has driven the interest in prophylactic filters. However, issues of poor follow-up and nonremoval remain significant. No consensus exists in the literature regarding the prophylactic use of filters. The greatest push has been

BOX 2: Indications for inferior vena cava filter

Absolute Indications
Recurrent VTE on adequate anticoagulation therapy
Absolute contraindication to anticoagulation therapy
Complications from anticoagulation therapy
Pulmonary hypertension in setting of chronic PE
Immobile trauma patients with ICH

Relative Indications
Iliocaval DVT
After thrombolysis for iliocaval DVT
Large, free-floating thrombus
Difficulty reaching therapeutic levels of anticoagulation or poor compliance
VTE in patients with poor cardiopulmonary reserve
Propagating DVT in setting of adequate anticoagulation therapy
After surgical or mechanical pulmonary embolectomy
After catheter-directed thrombolysis for PE
After surgical or mechanical ileofemoral thrombectomy
Recurrent PE with filter in place
High risk of complications from anticoagulation therapy (e.g., ataxia, movement disorders, frequent falls)

Prophylactic Indications: Primary Prophylaxis Not Feasible
Multitrauma patients with long bone or pelvic fractures and contraindication to pharmacologic prophylaxis other than ICH (e.g., solid organ injury)
Patients with cancer undergoing extensive resection with high risk for VTE and for postoperative hemorrhage
Other surgical patients or those with medical conditions with high risk for VTE

DVT, Deep vein thrombosis; *ICH,* intracranial hemorrhage; *IVC,* inferior vena cava; *PE,* pulmonary embolism; *VTE,* venous thromboembolism.

in trauma patients at high risk, specifically those with contraindications to pharmacologic prophylaxis (i.e., head injury, solid organ injury). Other suggested uses for prophylactic IVC filters are in bariatric, oncologic, and spine reconstruction surgery.

CONCLUSION

VTE remains a common source of morbidity and mortality in surgical practice, despite increased awareness. Prevention of these events requires diligent prophylaxis, which must be considered for all surgical patients. Early recognition and treatment of VTE is crucial to prevent immediate mortality and long-term morbidity in surgical patients. New technology promises to improve the way in which this disease is prevented and treated; however, the basic premises of giving appropriate prophylaxis and monitoring closely for clinical events should remain a key component of surgical training and practice.

Deep Venous Thrombosis

Mun Jye Poi, MD, and Peter H. Lin, MD

Venous thromboembolism (VTE) consists of two related conditions including deep venous thrombosis (DVT) and pulmonary embolism. Clinical consequences associated with DVT remain a major clinical problem despite advances in the modern health care system. It is estimated that DVT affects more than 3 million people in the United States annually. Among them, more than 120,000 patients suffer fatal outcomes as a result of pulmonary embolism. The clinical presentation of DVT commonly involves extremity swelling and pain, which is easily recognized by most physicians. The primary treatment strategy for DVT involves systemic anticoagulation, which is to prevent both worsening of acute symptoms and VTE-associated sequelae, including pulmonary embolism, recurrent thromboembolism, and postthrombotic syndrome. Although surgical interventions are typically not considered a first-line treatment strategy for VTE, it is important for surgeons to be familiar with the

diagnostic process and therapeutic strategies of this condition because they can often affect patients undergoing surgery and influence surgical treatment outcomes.

RISK FACTORS

The basic mechanisms resulting in VTE were described by Virchow, which include vascular endothelial damage, stasis of blood flow, and blood hypercoagulability. The most frequent risk factors for DVT include major surgery, trauma, hip fracture, lower extremity paralysis, previous VTE, advanced age, cardiac or respiratory failure, prolonged immobility, presence of central catheters, and hypercoagulable conditions.

DVT occurring in the setting of a known risk factor is defined as secondary, whereas that occurring in the absence of a known risk factor is termed *primary* or *idiopathic.* Men have a higher risk of recurrent VTE than do women, with a relative risk of 3.6 after an initial episode of unprovoked VTE. The recurrence rate reported in Hispanic and black women was also significantly higher than that of white women (3.1% per year vs 1.8% per year). The incidence of DVT increases with age. The influence of age on the incidence of DVT is probably multifactorial. DVT in children is almost always associated with recognized thrombotic risk factors. DVT is more common among pediatric patients in the intensive care unit and those with spinal cord injury, orthopedic immobilization, infection, trauma, or congenital thrombophilia. The prevalence of lower extremity DVT is parallel with the duration of bed rest; the incidence is increased among patients with prolonged bed rest and patients with paralysis. Prolonged immobilization in trauma and surgical patients is known to increase the risk of DVT.

Approximately 20% of all first-time VTE events are associated with malignancy. In older patients with primary DVT, the occurrence may be the first manifestation of a hidden malignancy. The mechanisms contributing to venous thrombosis in patients with malignancy are the hypercoagulable state and venous compression secondary to tumor growth. The risk is further increased by chemotherapy and metastasis. The role of other molecular thrombophilia as a risk factor for recurrent DVT has also been recognized. Abnormalities of the inhibitors of coagulation (antithrombin, protein C, and protein S), gene polymorphisms (factor V Leiden and prothrombin 20210A), elevated levels of coagulation factors (factor VIII), elevated levels of homocysteine, and circulating antiphospholipid antibodies have all been indicated as risk factors for thrombosis. Pregnancy and estrogen have also been associated with increased risk of DVT. Obesity is another independent predictor of VTE recurrence.

DIAGNOSIS

Multiple strategies have been developed to diagnose DVT. These include combinations of clinical risk stratification, measurement of D-dimer levels, venous ultrasound imaging, and contrast medium–enhanced venography. Duplex ultrasonography is the diagnostic test of choice for DVT. The hallmark of acute DVT is noncompressibility with venous distension and a hypoechoic lumen. Duplex ultrasonography has a mean sensitivity and specificity of 97% and 94%, respectively, with mean positive and negative predictive values of 97% and 98%, respectively, for symptomatic proximal DVT. Other noninvasive imaging includes computed tomographic venography (CTV) and magnetic resonance venography (MRV). If iliofemoral thrombus is identified, contrast medium–enhanced venography should be performed in anticipation of intervention.

Fibrin D-dimer is the final product of the plasmin-mediated degradation of crosslinked fibrin. Its plasma concentration is dependent on fibrin generation and subsequent degradation by the endogenous fibrinolytic system. D-Dimer levels are typically elevated in patients with acute venous thrombosis. As the result, the sensitivity of an elevated D-dimer concentration for VTE is very high. On the other hand, D-dimer levels can be elevated in other clinical conditions that are associated with enhanced fibrin production, including malignancy, trauma, increased age, disseminated intravascular coagulation, inflammation, infection, sepsis, postoperative states, and preeclampsia. Consequently, the specificity of an elevated D-dimer level for acute thrombosis is rather poor. Thus the diagnostic strength of D-dimer tests lies in ruling out DVT or pulmonary embolism.

Venous duplex ultrasonography, which combines B-mode imaging and Doppler signal analysis, is the first-line imaging modality for patients with clinically suspected DVT. The femoral and popliteal veins are directly visualized and subsequently assessed for their compressibility. Noncompressible femoral or popliteal vein, or both, is diagnostic for a first episode of acute proximal DVT in patients suspected of having clinically manifested DVT. In general, venous duplex ultrasonography is a cost-effective, accurate, and noninvasive diagnostic tool and serves as a first choice of imaging modality in patients with clinically suspected DVT of the lower extremities.

Historically, contrast medium–enhanced venography has been the diagnostic modality for lower extremity DVT. The diagnosis of DVT is confirmed when a constant intraluminal filling defect is identified on at least two views angiographically after intravenous administration of contrast material. Contrast medium–enhanced venography is contraindicated in pregnant women to avoid exposure of the fetus to radiation. Administration requires an invasive approach and can often lead to allergic reaction. Consequently, this invasive and costly diagnostic modality is seldom used today.

Computed tomographic scan (CT) and magnetic resonance imaging (MRI) may serve as alternative or complementary imaging tools to duplex ultrasonography. However, in comparison with duplex ultrasonography, both modalities have not been as well evaluated. The majority of clinical studies of the diagnostic accuracy of CT were performed in patients with suspected pulmonary embolism without symptoms or signs of lower extremity venous thrombosis, for whom the CT scan was subsequently extended to the legs. MRV can be performed with or without intravenously administered gadolinium. Although numerous studies have demonstrated that the sensitivity and specificity of CTV and MRV are comparable with those of duplex ultrasonography, the safety of withholding anticoagulant treatment on the basis of normal findings on CTV or MRV has not been evaluated. Consequently, these imaging modalities cannot be recommended as first-line imaging approaches. CTV or MRV could be useful in patients with a suspected DVT in whom duplex ultrasonography cannot be performed or is less reliable, such as patients with morbid obesity or casts and patients with a suspected DVT in the iliac or inferior cava vein or suspected venous anomaly.

THERAPY

The latest guidelines of the American College of Chest Physicians recommend treatment with a full-dose of unfractionated heparin (UFH), low-molecular-weight heparin (LMWH), fondaparinux, vitamin K antagonist (VKA), or thrombolysis for most patients with objectively confirmed VTE. However, to prevent life-threatening pulmonary embolism (PE) in patients with VTE and contraindications to anticoagulant treatment, such as bleeding complications during antithrombotic treatment or VTE recurrences despite optimal anticoagulation, interruption of the inferior vena cava (IVC) with a filter should be considered. Likewise, catheter-guided thrombolysis and mechanical thrombectomy are interventional modalities that can be considered in selected patients. The efficacy and safety of these therapeutic approaches and the appropriate indications are discussed herein.

Anticoagulation

Patients with acute DVT should be treated with parenteral anticoagulant therapy, followed by VKA therapy, for 3 months. The duration depends on the risk of recurrence, as determined by the presence or absence of an inciting event and the presence of hypercoagulable states. Anticoagulation, however, only prevents clot propagation; the patient's own fibrinolytic system must open occluded segments to restore patency and preserve valvular function. The anatomic location of DVT can influence the risk of VTE recurrence. The more proximal the upper limit of the initial clot, the higher the risk of recurrence. In comparison with patients with femoral or popliteal DVT, patients with iliofemoral DVT have a significantly higher risk of recurrence. Isolated distal DVT could be safely treated with 6 weeks of anticoagulant therapy, especially when the event was triggered by a transient risk factor. In patients with acute isolated distal DVT of the leg and without severe symptoms or risk factors for extension, serial imaging of the deep veins for 2 weeks is an acceptable alternative to initial anticoagulation, especially in patients with high risk of bleeding. Anticoagulation should be started if the thrombus extends. Proximal DVT should be treated for 3 months. If the DVT is unprovoked, extended therapy is given if bleeding risk is low or moderate. When DVT is associated with active cancer, extended therapy with LMWH is recommended over VKA, and is given as long as the cancer remains active.

Surgical Thrombectomy

Enthusiasm for surgical thrombectomy for DVT in the United States was initially high and has fallen with subsequent reports of poor results. Serial reports of the European results have rekindled interest. In a series of reports, Plate described surgical therapy for acute iliofemoral DVT. These reports detailed the experience of patients randomly assigned to undergo anticoagulation versus surgical thrombectomy with creation of a temporary arteriovenous fistula who were monitored for 5 and then 10 years. The numbers of those completing follow-up were small, which reduced the ability to produce statistical significance. Radionuclide venous study showed patency of the iliac vein in 83% of patients with surgical treatment, in comparison with 41% of patients with anticoagulation; this difference was significant. Surgical thrombectomy can be considered if thrombolytic therapy is contraindicated. Surgical thrombectomy can be performed with a Fogarty balloon to remove thrombus through a groin incision for proximal and distal thrombus removal. A temporary arteriovenous fistula is sometimes created to reduce early rethrombosis.

Thrombolytic Therapy

In light of the morbidity of postthrombotic syndrome, more aggressive treatment regimens of DVTs have been proposed. The early reports of surgical thrombectomy and its effect on postthrombotic syndrome encouraged development of nonsurgical methods to remove clots and achieve the same goals with minimally invasive means. Thrombolysis of DVTs offers the potential to rapidly clear thrombus from the obstructed segments and reduce the chance of subsequent obstruction and reflux. There are various means of achieving thrombolysis of occluded venous segments. The basic options are pharmacological thrombolysis, administered directly into the thrombus via an infusion catheter; mechanical thrombectomy; and the combination of the two, termed *pharmacomechanical thrombolysis.* These various options of thrombolytic therapy are discussed as follows.

Catheter-Directed Thrombolytic Therapy

Routine use of systemic thrombolysis for acute DVT is discouraged because of the high rate of incomplete thrombolysis and bleeding complications. Because of inconsistent results, long treatment times, and high complication rates reported with systemic infusions, attention has turned to catheter-directed thrombolysis. Mewissen and colleagues (1999) published a multicenter registry experience of catheter-directed urokinase infusion that included a total of 287 patients who underwent catheter-directed thrombolysis for lower extremity DVT. In this series, complete lysis was noted in 31% of patients; in another 52%, more than 50% lysis was achieved. The degree of lysis was found to be correlated with patency at 1 year. The DVTs in the iliofemoral segment responded better, with 64% patency at 1 year, in comparison with 47% in the femoral popliteal segment. Major bleeding complications occurred in 11% of patients, the majority being puncture site hematomas. There was one intracranial hemorrhage, which was fatal, and one subdural hematoma, which was sustained after a fall. There were PEs in 2% of patients, which was within the expected incidence among patients with proximal DVTs.

Multiple authors have found that catheter-directed therapy is more effective than systemic infusion of thrombolytic agents for treatment of DVTs. Although the numbers are small and the trial was nonrandomized, the data reported by Laiho and colleagues provide a comparison between systemic and catheter-directed thrombolysis for iliofemoral DVTs. Using a hospital registry, they identified 32 patients with iliofemoral DVTs. Equal numbers of patients received catheter-directed and systemic thrombolysis. Catheter-directed thrombolysis proved superior, with a deep system competence of 56% in comparison with 19% in patients with systemic thrombolysis. Paralleling the incidence of deep system reflux was a significantly higher incidence of postthrombotic syndrome in the systemic therapy group. In a review, Baldwin documented the experience in the literature of more than 600 patients with catheter-directed thrombolysis and found decreased rates of postthrombotic syndrome, improved quality of life, and some evidence for reduced incidence of recurrent DVT. The pooled risk of intracranial hemorrhage was noted to be 0.2%.

Mechanical Thrombectomy

Although a detailed discussion of mechanical thrombectomy in DVT is beyond the main focus of this section, this therapeutic modality has become important in the management of thrombotic occlusion, particularly when a mechanical thrombectomy device can be used in conjunction with pharmacological thrombolysis. One of the percutaneous mechanical thrombectomy (PMT) systems that has been shown to be effective in the removal of acute DVT is the AngioJet (Medrad, Minneapolis, Minn.) system. The principle of this device is based on the Venturi effect, which creates rapidly flowing saline jets that are directed backward from the tip of the device to outflow channels in a coaxial manner. This generates a vacuum force that draws the thrombus into the catheter. One major advantage of this treatment modality is that the thrombectomy catheter can be delivered through a small-bore introducer sheath, which reduces access site trauma and avoids operative exposure required with conventional Fogarty thromboembolectomy. A clinical study in which researchers evaluated the efficacy of the AngioJet system demonstrated that such a mechanical thrombectomy system is effective in thrombus removal, venous patency restoration and maintenance, and symptom relief. The Angiojet rheolytic thrombectomy system is designed to produce an area of extremely low pressure at the catheter tip by controlled high-velocity saline jets. Through this mechanism, thrombus surrounding the catheter tip is macerated and rapidly evacuated via an effluent lumen into a collection chamber. In this study, only 4 (23.5%) patients achieved more than 90% thrombus clearance with PMT alone. Adjunctive thrombolytic agents were used in 9 of 17 patients, in whom a lesser amount of clot was extracted with the use of the PMT catheter. Often the thrombolytic catheter was left in place, and the average duration of lytic therapy was 20.2

hours. Clinical symptomatic improvement was seen in 82% over a follow-up time frame of 11 months.

Permanent Inferior Vena Cava Filters

Decousus and colleagues conducted a randomized study to evaluate the efficacy of permanent IVC filter in the prevention of PE. These authors randomly assigned 400 patients with proximal DVT and at risk for PE to receive an IVC filter (200 patients) or no IVC filter (200 patients), in addition to standard anticoagulant therapy. The authors noted that there were no significant differences in mortality or other outcomes at 24 months. The authors therefore concluded that in patients with proximal DVT at high risk, the initial beneficial effect of IVC filters for the prevention of PE was counterbalanced by an excess of recurrent DVT, without any difference in mortality. In a Cochrane review, researchers evaluated all existing published controlled clinical trials and randomized clinical trials in which investigators examined the efficacy of filters in preventing PE. The authors concluded that no recommendations could be made with regard to the use of permanent IVC filter in prevention of pulmonary embolism. Because of the lack of strong evidence in the literature, the most recent guidelines of the American College of Chest Physicians (ACCP) recommend against the routine use of an IVC filter in addition to anticoagulants in patients with DVT; the placement of an IVC filter is suggested only for patients with acute proximal DVT or PE and a contraindication to anticoagulation because of bleeding risk.

Retrievable Inferior Vena Cava Filters

Nonpermanent filters are classified as temporary or retrievable devices. Temporary filters remain attached to a wire or catheter that exits the skin; they are often difficult to manage and are accompanied by frequent complications such as thrombosis, infections, or migrations. They must be removed within a few days of placement, which is often not enough time to solve the clinical problem that had led to their placement. Retrievable filters are a new generation of IVC filters and may represent a more attractive option because they may be either left in place permanently or safely retrieved after a quite long period when they become unnecessary. This optimism must be tempered by important unresolved issues, including the appropriate maximum implantation time, the possibility of safely and efficaciously removing the filters without compromise by entrapped clots, and the use of anticoagulants during the implantation period and at the time of removal.

SPECIAL CONSIDERATIONS

Phlegmasia Alba Dolens and Phlegmasia Cerulea Dolens

Phlegmasia alba dolens, also known as *milk leg* or *white leg syndrome,* is part of a spectrum of clinical syndromes associated with extensive iliofemoral thrombosis. In phlegmasia alba dolens, the iliac vein is occluded, but the hypogastric and collateral veins remain patent. Affected patients have severe swelling and leg tenderness but no ischemia. Management is anticoagulation with or without catheter-directed thrombolysis. Phlegmasia cerulea dolens is characterized by massive swelling, cyanosis, and pain. Pedal pulses remain palpable in 50% of affected patients. Massive fluid sequestration may lead to hypovolemia and hypotension. Sixty percent of affected patients progress to venous gangrene. Anticoagulation alone is ineffective in the treatment of phlegmasia cerulea dolens. Catheter-directed pharmacomechanical thrombolysis is strongly recommended for impending venous gangrene in the presence of iliofemoral thrombosis.

External Compression of Deep Veins

Venous occlusion may result from external compression by retroperitoneal fibrosis, tumor, cyst, aneurysm, abnormal muscle insertion (popliteal vein entrapment), fibrous band of ligament (soleal arch syndrome and femoral vein compression by inguinal ligament), left iliac vein compression by right iliac artery (May-Thurner syndrome) and compression of the subclavian vein by cervical ribs, clavicular anomalies, and musculofascial bands ("effort thrombosis," thoracic outlet syndrome, or Paget-Schroetter disease). The treatment of DVT caused by external compression should include removal of the source of external compression if possible, such as first rib resection and scalenectomy for thoracic outlet syndrome. Percutaneous endovascular stent placement has emerged as the method of choice for treatment of May-Thurner syndrome. Open venous reconstruction is usually performed only in selected cases of failed stent procedures or occlusion of the stent.

Internal Jugular Vein/Axillosubclavian Vein Thrombosis

In the general population, the majority of DVTs occur in the lower extremity. Upper extremity DVTs constitute only 4% of all DVTs. Upper extremity DVT has become more common as a result of increased intravenous catheterization and transvenous pacer placement. Treatment of internal jugular and subclavian vein thrombosis consists of one of the following elements: rest, elevation, external compression, anticoagulation, catheter removal, thrombolytic therapy, surgical decompression of the thoracic outlet, or open or endovascular venous reconstruction. The treatment options depend on the location of the thrombosis; severity of symptoms; the patient's age, level of activity, and general medical condition; the presence of central venous catheter and whether it can be removed; and any contraindications to anticoagulation, thrombolysis, or surgical treatment. Patients with mild symptoms or who are debilitated with significant comorbid conditions tend to have acceptable results with anticoagulation alone. For those with catheter-associated central venous thrombosis, the catheter should be removed if possible. For patients with nonreversible risk factors, such as malignancy and the presence of catheters or pacemaker that cannot be removed, a longer course of anticoagulation (3 to 6 months) is indicated.

Catheter-directed thrombolysis should be considered in patients with axillosubclavian DVT who present with extensive swelling and functional impairment of the arm and who are at low risk for bleeding complications. Affected patients who are young and active with vigorous exercise often have persistent arm swelling and pain exacerbated by upper extremity exercise because the venous outflow from collateralized central venous occlusion often cannot keep up with the arterial inflow. Thrombolytic therapy is more likely to be successful for acute thrombus that has been present less than 1 week. Patients in whom provocative arm positioning elicits extrinsic compression should be considered for a thoracic outlet decompression procedure. Patients with intrinsic venous compromise caused by residual scar or thrombus can be treated with balloon angioplasty with or without stent placement or venous repair in conjunction with thoracic outlet surgery.

Superficial Vein Thrombosis

The majority of the superficial vein thromboses are associated with intravenous catheter placement or related to varicose veins and involve the great saphenous vein (GSV). Such thromboses are treated with rest and nonsteroidal antiinflammatory medication. When the GSV is involved, follow-up ultrasonography should be performed. If the thrombus propagates to the saphenofemoral junction,

anticoagulation should be started. Extensive superficial vein thrombosis should be treated with a prophylactic dose of fondaparinux or LMWH.

Vena Cava Filters

Christos S. Georgiades, MD, PhD, FSIR, and Todd Schlachter, MD

INTRODUCTION

The rationale for inferior vena cava (IVC) interruption by means of filter placement is prevention of clinically significant pulmonary embolism (PE) with trapping of venous emboli that originate in the deep veins of the pelvis or the lower extremities. Deep venous thrombosis (DVT) is a major cause of morbidity and mortality in the United States, with an annual incidence of approximately 2,000,000. The incidence of clinically significant PE in the United States is reportedly between 150,000 and 600,000, with 25% to 40% of patients presenting with sudden death. The remaining patients are treated with either systemic anticoagulation therapy or placement of IVC filter, and rarely with surgical or catheter-directed thrombectomy or thrombolysis. Venous thromboembolic disease (VTE) constitutes a clinical spectrum that includes both DVT and PE.

The history of IVC interruption for the prevention of PE was born from the work of Virchow, Trousseau, and Bottini in the mid to late 1800s. Mechanical prevention of pulmonary embolus has evolved from open surgical ligation of the IVC to the percutaneous endovascular filters used today. Since the advent of a percutaneous approach by Greenfield in 1983, the use of IVC filters has drastically increased. From 1980 to 2000, the number of filters placed increased from 2000 to about 50,000 per year. The first IVC filter was marketed in the late 1960s. Before that, surgical ligation of the IVC, first described by Armand Trousseau in 1865, was the only option for prevention of PE in patients at high risk. In 2007, almost 167,000 filters were implanted, with an estimated 259,000 IVC filters to be deployed in 2012. With the increasing market demand for filters came a diversity of filter designs and capabilities including, most notably, the ability for retrieval.

The standard treatment of acute DVT or PE is nearly always immediate, full pharmacologic anticoagulation therapy. IVC filters are indicated when a patient has VTE and contraindications to or complications from anticoagulation, or recurrent embolism while on adequate therapy. IVC filters may also be used as PE prophylaxis in patients deemed at high risk for clinically significant PE. Although filters are accepted as safe devices, there are still filter-associated risks. Therefore, the indications for filter placement and the choice of the appropriate filter must be carefully followed. Figure 1 shows the 10 filter types (13 different filters) available in the United States, and Table 1 showcases their features.

INDICATIONS AND CONTRAINDICATIONS FOR INFERIOR VENA CAVA FILTER PLACEMENT AND RETRIEVAL

Table 2 summarizes the indications for IVC filter placement. Most IVC filters are placed in patients with DVT who have a contraindication to anticoagulation (56%) or in patients at high risk for prophylaxis (27%) or in patients with recurrent PE despite anticoagulation therapy (15%). Patients may have a preexisting contraindication to anticoagulation because they are at high risk for bleeding complications. Such conditions include intracranial neoplasm, vascular neoplasm in critical locations, recent myocardial infarction (MI), and recent surgery or trauma. Other patients may "declare" themselves as high risk with a recent history of gastrointestinal (GI) hemorrhage, intracranial hemorrhage (ICH), or other hemorrhage. Combined, this group represents the majority of patients (56%) who receive an IVC filter.

Trauma-related severe multiorgan injury is a major risk factor for DVT and PE. When these patients have a PE, their mortality risk is much higher compared with patients with non-trauma–related PE. PE is thought to contribute to or be the direct cause of death in at least 85% of trauma patients with PE. Therefore, prevention is crucial for a positive outcome. In some patients with major trauma, the associated bleeding risk precludes effective anticoagulation therapy, leaving IVC filters as the only option to prevent PE from DVT.

Major surgery raises the risk for VTE for many reasons. Prolonged immobilization of the patient is common, especially after major abdominal, neurologic (especially), and orthopedic surgeries. The risk of VTE is increased, albeit less, even in minor surgeries. Transient dehydration is another factor that predisposes patients to the formation of clot, as is surgery-associated vascular injury or extrinsic compression. All patients undergoing surgery should receive some form of prophylaxis for VTE. In most cases, pneumatic compression stockings are adequate because recovery from surgery is relatively short. When recovery is prolonged and the risk of DVT is high, pharmacologic anticoagulation therapy has been shown to reduce the risk of VTE. However, many patients are not candidates for anticoagulation therapy after surgery. Until recently, placement of an IVC filter in these patients was avoided because of the transient nature of the risk for VTE. Since the advent of retrievable filters, however, their use in the perioperative period has increased because they can be removed after the risk normalizes. In particular, preoperative placement of an IVC filter reduces the risk of pulmonary embolus and perioperative mortality in patients undergoing open gastric bypass for morbid obesity with a body mass index (BMI) of more than 55 kg/m^2.

A smaller percentage of patients (15%) receive an IVC filter because of recurrent PE during anticoagulation therapy. An important note is that PE during anticoagulation therapy does not

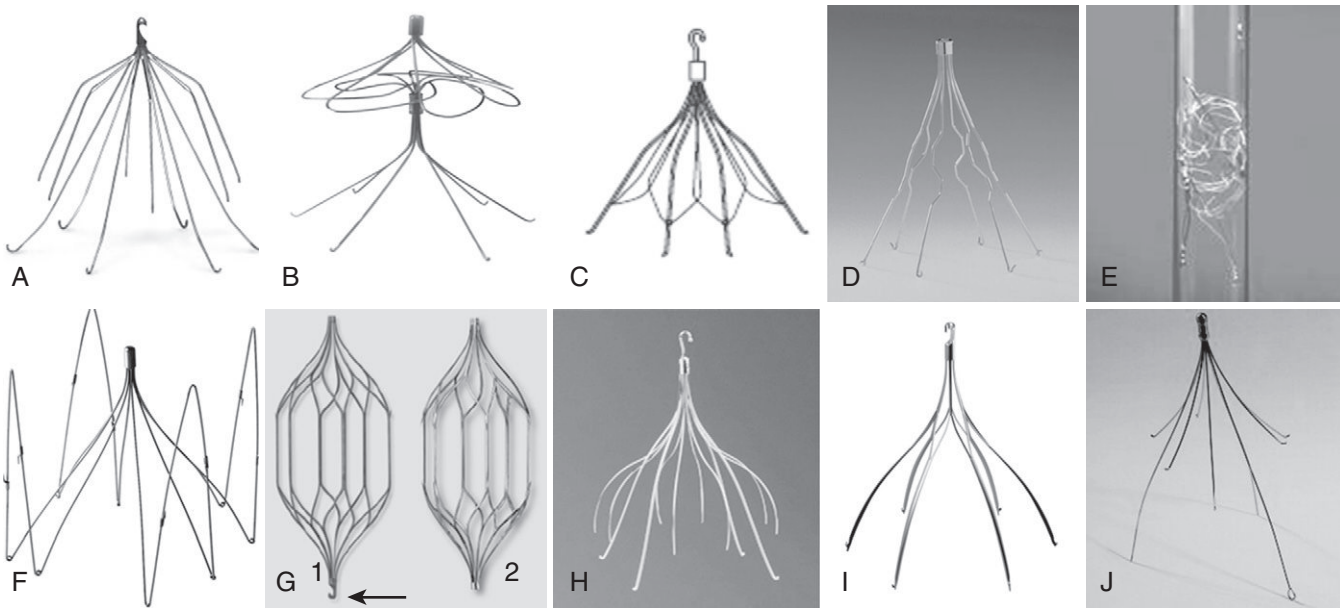

FIGURE 1 The filters available in the United States. **A,** The Bard family of filters that includes the original G2, the newest Meridien, and the (electropolished) Eclipse (Bard, Tempe, Ariz). **B,** Simon Nitinol (Bard, Tempe, Ariz). **C,** Gunther-Tulip (Cook Medical, Bloomington, Ind). **D,** Greenfield (Boston Scientific, Natick, Mass). **E,** Bird's Nest (Cook Medical, Bloominton, Ind). **F,** Vena-Tech (B-Braun Medical, Bethlehem, Penn). **G,** Optease *(1;* with retrievability hook in bottom) and Trapease *(2;* Cordis , Bridgewater, NJ). **H,** Celect (Cook Medical, Bloominton, Ind). **I,** Option (Argon/Rex Medical, Plano, Tex). **J,** ALN (ALN, Miami, Fla).

represent failure of anticoagulation. One must ensure that the measure of the efficacy of anticoagulation (international normalized ratio [INR] for warfarin; activated partial thromboplastin time ratio [aPTTr] for heparin) was within the therapeutic range when the PE occurred. If not, the dose should be adjusted so that the outcome measure is within therapeutic range. Only then should a filter be considered. The risk of PE recurrence for patients during therapeutic anticoagulation is 5% to 10%.

Free-floating clot in the IVC or iliofemoral veins is extremely rare. If clot is identified incidentally, then a prophylactic filter is indicated as is anticoagulation therapy. Free-floating clots are usually fresh clots and thus vulnerable to anticoagulation. If the patient does not need long-term prophylaxis with a filter, then a retrievable one is indicated; it is removed when the clot resolves. Chronic pulmonary hypertension with limited pulmonary reserve is a rare condition of unknown cause, although chronic thromboembolic events have been postulated to be the main culprit. Along with etiology, treatment is controversial. It does not present a serious medical problem from an epidemiologic standpoint because only 500 to 2500 new cases are reported each year. However, given the limited pulmonary reserve in these patients, prevention of further embolic events is crucial for survival. Although no prospective, randomized study exists to show any benefit from routine IVC filter placement in such patients, most centers that treat such patients recommend routine IVC filter placement for the prevention of new embolic events. Even without anticoagulation therapy, patients who receive an IVC filter alone show a significantly reduced PE-related mortality.

A smaller percentage of patients who receive a filter (19% to 27%) do so because they are considered at high risk for development of DVT and therefore sustaining a life-threatening PE. This category includes patients with multiple risk factors that when combined place them at significant risk for VTE.

Both acquired and congenital thrombotic risk factors are additive for each patient presentation. Acquired risk factors include the following: age, surgery or major trauma, cancer, human immunodeficiency virus (HIV), antiphospholipid syndrome, pregnancy/postpartum, immobility, oral contraceptives, smoking, travel, and infections. Patients may be immobilized because of major trauma, central nervous system (CNS) injury or deficit, or intensive care unit (ICU) level of care. Congenital hypercoagulable states include antithrombin III deficiency, protein C or S deficiency, factor V Leiden mutation, prothrombin 20210A, sickle cell disease, and hyperhomocysteinemia, most commonly.

These patients are very common in clinical practice and present a difficult therapeutic challenge. On one hand, the underlying disease predisposes the patient to DVT and thus an increased risk for PE; on the other hand, the filter itself may be the cause of focal clot formation and subsequent IVC thrombosis. Even in patients with contraindication to anticoagulation, filter placement should be considered carefully and only with input from the hematology service. Patients who despite their hypercoagulable state do not have a DVT or PE should in general not receive a filter. At the other end of the spectrum are patients with DVT and recurrent PE who cannot receive anticoagulation and should receive a filter. The gray zone in between is more common, and the decision to place a filter should be based on a careful multidisciplinary risk–benefit analysis. For example, asymptomatic DVTs have been reported in 60% to 80% of patients with permanent spinal cord injury, whereas symptomatic DVT is reported in less than 20%. Therefore, IVC filter placement in patients with paraplegia or tetraplegia should not be routine but reserved in patients with documented, symptomatic DVT or in those who cannot or will not receive lifelong systemic anticoagulation therapy.

FILTER SELECTION

No study exists that compares the efficacy and safety of the available filter types in a rigorous manner. Therefore, the choice of filter should depend on technical factors (i.e., size of IVC) and operator experience.

TABLE 1: Profiles of the 13 filters available in the United States

Filter (company)	Sheath size	Max IVC diameter	MRI compatibility	Retrievability	Notes
G2, Meridien, Eclipse (Bard, Tempe, Ariz)	10F	28 mm	Conditional (up to 3 T)	Yes	
Simon-Nitinol (Bard, Tempe, Ariz)	7F	28 mm	Safe	No	If general anesthesia within 2 wk, maximal IVC diameter is 24 mm
Gunther-Tulip (Cook Medical, Bloomington, Ind)	8.5F	30 mm	Conditional (up to 1.5 T)	Yes	
Greenfield Meditech, Boston Scientific Corp., Natick, Mass	12F	28 mm	Conditional	No	(Titanium Greenfield system, Steel not available)
Bird's Nest (Cook Medical, Bloomington, Ind)	11F	40 mm	Conditional (up to 1.5 T)	No	(7-cm footprint)
Vena-Tech (B-Braun Medical, Bethlehem, Penn)	9F	28 mm	Safe	No	
Optease (Cordis, Bridgewater, NJ)	6F	30 mm	Conditional (up to 3 T)	Yes (up to 23 d)	
Trapease (Cordis, Bridgewater, NJ)	6F	30 mm	Conditional (up to 3 T)	No	
Celect (Cook Medical, Bloomington, Ind)	8.5F	30 mm	Conditional (up to 3 T)	Yes	
Option (Argon/Rex Medical, Plano, Tex)	6.5F	30 mm	Conditional (up to 3 T)	Yes	
ALN (ALN, Miami, Fla)	7F	28 mm	Compatible (limited data)	Yes	

IVC, Inferior vena cava; *MRI,* magnetic resonance imaging.
(Three successive generations of Bard filters are included in first row). All current filters are MRI safe or conditional, meaning they are safe for immediate MRI use up to 1.5 to 3.0 T. For IVC diameters above 30 mm, only the Bird's Nest can be deployed. Retrievability is another major determinant of filter choice.

TABLE 2: Current indications for inferior vena cava filter placement

DVT with high risk for bleeding (i.e. recent major trauma, surgery including cardiopulmonary resuscitation)	56%
Hemorrhage on or failure of anticoagulation (i.e., recurrent PE, patient non-compliance)	15%
Extreme risk of morbidity/mortality from next PE (i.e., limited cardiopulmonary reserve, large/free floating thrombus, chronic PE with pulmonary HTN)	2%
High risk despite anticoagulation (i.e., severe trauma with prolonged immobilization, paraplegia, quadriplegia, multiple/severe bone fractures, surgery in patients with BMI >55 Kg/m^2	27%
Total	100%

BMI, Body mass index; *CNS,* central nervous system; *DVT,* deep vein thrombosis; *HTN,* hypertension; *PE,* pulmonary embolism.

Special Considerations: Suprarenal Inferior Vena Cava Filter

The ideal location of any IVC filter is properly centered (not skewed) in the IVC with its cephalad tip at or just below the lowermost renal vein. Placement of the filter too low may result in a higher rate of IVC thrombosis related to filter-induced turbulent flow. Placement of the filter above the renal veins may result in renal failure if the filter thromboses and the resulting clot obstructs the renal vein drainage, although this is an extremely rare complication. At times, placement of a filter in a suprarenal location is necessary despite this higher risk. Such indications include pregnancy, duplicated IVC, and thrombosis of the infrarenal IVC. Whatever the indication, if feasible, any suprarenal IVC filter should be removed as soon as the risk of PE returns to baseline. Therefore, retrievable filters are preferred in this location.

Special Considerations: Superior Vena Cava Filters

There is little indication that superior vena cava (SVC) filters offer any VTE protection. In addition, a higher risk of complications is found, especially of filter migration or embolization, and retrieval may be more challenging. Therefore, the insertion of an SVC filter should be reserved for well-selected cases of significant risk of life-threatening PE from the upper extremities.

Contraindications for Placement of Inferior Vena Cava Filter

Contraindications for IVC filter placement are both technical and clinical. Technical reasons include a thrombosed or occluded IVC, clot in the intrahepatic IVC, and no available venous access. Clinical contraindications include severe uncorrectable coagulopathy, severe prothrombotic state, and active bacteremia. Although active bacteremia is a contraindication to filter placement, the risk of seeding a filter is probably extremely low. If a filter is necessary in a patient with active bacteremia, then a retrievable one may be placed; it should be removed as soon as not needed or replaced as soon as bacteremia resolves. A prothrombotic state increases the risk for in situ filter clot formation. It should not prevent filter placement if protection against potentially lethal PE is necessary. Hematology input is important to screen these patients and have a plan of action related to type of filter used, duration of protection, retrieval, and possibly concurrent systemic anticoagulation therapy.

TECHNIQUE

Optimum performance requires catheter expertise, proper venous access selection, appropriate filter type, and proper location and orientation of the deployed filter. First, the clinical indication for IVC filter placement should be scrutinized and confirmed. Next, informed consent must be obtained from the patient. Then, review of imaging studies and physical examination of the patient dictate appropriate venous access selection.

The basic steps of filter insertion are:

1. Selection of appropriate venous access. Left common femoral vein access has the advantage of showing clearly the presence (or absence) of a duplicated or left-sided IVC. Of course, the location of DVT may confound site selection. Right common femoral, right jugular, and left jugular vein accesses are also available. If a long enough sheath or filter is available, antecubital of popliteal vein access is also possible.
2. IVC venogram. This necessary step is used to measure the diameter of the IVC, exclude clot in the IVC, and delineate any aberrant anatomy (i.e., retroaortic or duplicated renal veins).
3. Deployment of filter. Ideal location is with its cephalad tip being bathed by the renal vein inflow to mitigate the filter's thrombogenicity.
4. A post deployment venogram or plain view to ensure proper filter positioning.

For patients with a duplicated IVC, the filter may be placed in both inferior cavae, or a suprarenal filter may be considered when technically feasible. If the vena cava diameter is greater than 28 to 30 mm ("mega cava"), an appropriate filter must be selected. Currently, the only available filter for a mega cava is the Bird's Nest filter (Cook Medical, Bloomington, Ind). Up to 2% of patients have a mega cava. Although a Bird's Nest filter expands to 40 mm, it requires a 7-cm infrarenal footprint. Alternatively, bilateral common iliac vein filters may be deployed. Once all diagnostic imaging has been reviewed, final filter selection may occur. Figure 2 shows the critical aspects of IVC filter deployment.

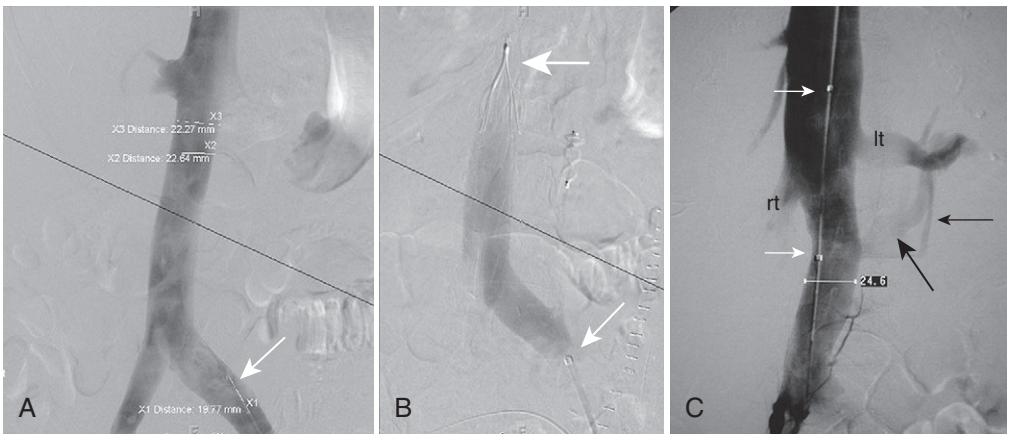

FIGURE 2 Steps during filter deployment. **A,** Inferior vena cava (IVC) venogram performed via a left common femoral vein access *(black arrow)* shows a single IVC, no obstructive clot, and no aberrant venous anatomy. The diameter of the IVC is measured at the level of the filter hook implantation at 23 mm. **B,** Postdeployment venogram in a different patient shows the filter properly centered and with its tip bathed by the renal vein inflow, the optimum location. **C,** Predeployment IVC venogram in a different patient uncovers a left retroaortic renal vein *(large black arrow)* next to a normal gonadal vein *(small black arrow)*. To prevent PE via the retroaortic renal vein, the filter must be deployed below that vein's origin.

FILTER RETRIEVAL

Any filter that can be retrieved and is no longer needed or effective should be removed as soon as possible. If the patient's underlying risk factors for PE are low or if the patient has become a candidate for anticoagulation therapy, the filter should be removed. If the filter itself is ineffective (migrated, kinked, fractured), it should be removed and, if necessary, replaced. In patients with active bacteremia when no other source is isolated, the possibly of an infected filter should be considered and the filter removed or replaced. Regarding retrievable filters, the U.S. Food and Drug Administration (FDA) issued the following statement: "implanting physicians and clinicians responsible for the ongoing care of patients with retrievable IVC filters consider removing the filter as soon as protection form PE is no longer needed."

Filter retrieval is more challenging and requires more extensive skills; however, in experienced hands, filter retrieval is successful greater than 90% on the time. Filter endothelialization is thought to start to occur around 3 weeks; therefore, the less time a filter has been in place, the higher the retrieval success rate. A venogram is required to exclude residual clot within the filter before removal. A filter with a large volume of clot cannot be removed for fear of causing PE during removal. Thus, many filters that are labeled as retrievable become permanent ones. If a small amount of clot is present, bringing the patient back in 6 weeks for reevaluation may show resolution of clot from endogenous lyses. Another contraindication to filter removal is persistent clot in the pelvic or lower extremity veins, unless the patient can now undergo anticoagulation therapy. Unless the risk for PE normalizes and if the patient is still not a candidate for anticoagulation therapy, the filter cannot be removed.

Proper access depends on the type of filter used. The Celect (Cook Medical, Bloomington, Ind), G2 (Bard, Tempe, Ariz), and Günther-Tulip filters (COOK Medical, Bloomington, Ind) are removed via a jugular approach, whereas the Optease (Cordis, Bridgewater, NJ) is removed via a femoral approach. Figure 3 shows the steps for filter removal for a G2 filter.

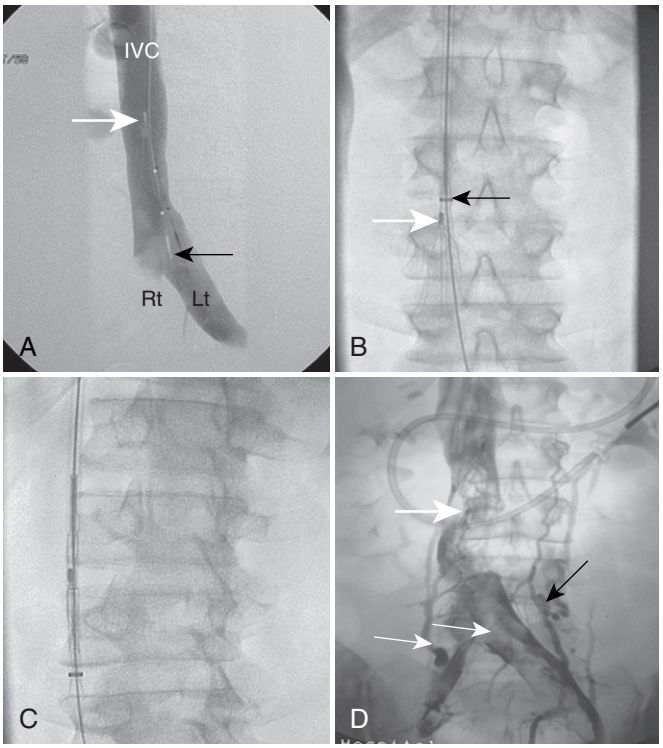

FIGURE 3 Retrieval of a G2 filter. **A,** A preretrieval venogram performed via the jugular-placed catheter *(black arrow)* excludes clot in the right, left common iliac veins, and inferior vena cava (IVC). Filter tip is indicated with *white arrow*. **B,** Then, the sheath is advanced over the conical retrieval system *(black arrow)* and grabs the cephalad tip of the filter *(white arrow)*. **C,** The filter is pulled into the sheath and is then removed en bloc. **D,** Preretrieval IVC venogram in a different patient shows a large burden of clot in filter *(large white arrow),* iliac vein *(white arrows),* and collateral drainage *(black arrow)* precluding filter removal.

COMPLICATIONS

Complications related to IVC filters are periprocedural or delayed. Periprocedural complications include filter malpositioning, migration, iatrogenic pulmonary embolism, groin hematoma, and infection. All of these complications can be avoided with experience and proper patient preparation. Meticulous technique and experience can prevent malpositioning, choice of appropriate filter can prevent migration, and proper technique and patient care can prevent hematoma and infection. The rates of these complications are listed in Table 3 and range between 0 and 6%. The most feared complication of IVC filters is filter thrombosis with subsequent IVC occlusion and possible PE. Long-term IVC thrombosis after filter placement is reportedly between 2% and 19%, and the risk increases with indwelling time.

DISCUSSION

The standard of treatment for VTE is systemic anticoagulation therapy. A major misconception is that systemic anticoagulation therapy with warfarin, heparin, low molecular-weights heparin (LMWH), or argatroban treats existing thrombus. The goal of systemic anticoagulation therapy is to prevent extension of existing clot and recurrence of DVT or PE. A 6-month systemic anticoagulation therapy reduces the 2-year risk of recurrent DVT or PE by 50%, from 18% to 9%. However, not all patients have the same risk for development of thromboembolic disease nor do all patients have the same pulmonary reserve. Therefore, treatment should be tailored according to individual risk and ability to sustain a thromboembolic event. Patients with first-time DVT or PE with idiopathic disease and normal pulmonary reserve should be treated with systemic anticoagulation therapy alone. This group represents the majority of patients. However, a large number of patients for a variety of reasons cannot receive anticoagulation and still others have comorbid conditions that increase their risk of recurrence, limit their tolerance to another event, or altogether prevent them from undergoing anticoagulation therapy. These are the patients that should be considered for an IVC filter.

An explosive increase in IVC filter utilization has been seen in the last decade with the advent of more versatile filters and increased incidence of VTE. IVC filters reduce the risk of PE without affecting all-cause mortality and have increased rates of rethrombosis at 8 years. Breakthrough pulmonary emboli are reported to occur in 1% to 6% of patients; however, recurrent fatal PE is less than 1%. Most worrisome is the possibility that IVC filters may confer a risk of postthrombotic syndrome. It is therefore prudent to properly select the patients and ensure placement of an IVC filter is truly indicated. The clinical scenario for each patient is different and affects the choice of filter, retrievability, location, duration, and associated risks. When unsure about the duration of required protection, a retrievable filter should be selected. Any filter that is no longer providing its intended benefit, whether because the underlying risk for PE has returned to baseline or the filter is ineffective, should be removed as soon as possible. The longer a filter remains in a patient, the more likely it will become permanent because of clot formation or

TABLE 3: List of periprocedural and long-term complications of filter deployment

Complication	Reported rates (%)
Death	0.1
Access site thrombosis	3-10
Deployment outside target area	1-9
Iatrogenic pulmonary embolism	1
Filter movement	0-18
Filter embolization	0.1
Filter fracture	2-10
IVC penetration	<1
IVC occlusion	2-30 (long-term)

IVC, Inferior vena cava.
The herein reported rates of access site thrombosis (up to 10%) and filter movement (up to 18%) are extremely high and should approach 0 with experience and proper technique.
Complications from IVC filter placement can be procedure related (groin hematoma, infection, or iatrogenic pulmonary embolism [PE]) or delayed (migration, IVC thrombosis). With the exception of in situ filter thrombosis, the associated risks are minimal (1% to 6%). However, IVC thrombosis can lead to considerable morbidity, including PE and symptoms of lower extremity venous stasis. Long-term follow-up of patients with filters is limited, and the true risk of IVC thrombosis is unknown. Removal of a filter that is no longer needed or is ineffective (kinked, fractured, source of PE upper extremities) is indicated to minimize this risk.

BOX 1: Take-home messages

1. IVC filters may reduce mortality from PE, but only in well-selected patients.
2. IVC filters reduce risk for symptomatic PE.
3. Permanent IVC filters increase risk of future DVT.
4. Err on side of retrievable filters.
5. Remove filter as soon as indicated.
6. Incidence of symptomatic PE in United States is 160,000 to 600,000.
7. 260,000 filters will be deployed in 2012.

DVT, Deep vein thrombosis; *IVC,* inferior vena cava; *PE,* pulmonary embolism.

endothelialization. The main take-home messages of this chapter are summarized in Box 1.

The Prevention of Venous Thromboembolism

Eric J. Turney, MD, and Sean P. Lyden, MD

EPIDEMIOLOGY

Venous thromboembolism (VTE) is defined as deep vein thrombosis (DVT), pulmonary embolism (PE), or both. Two thirds of the patients with VTE present with DVT, and the remaining one third present with PE. DVT can occur in the setting of an inciting event or be idiopathic. According to the Centers for Disease Control and Prevention, VTE affects 300,000 to 600,000 individuals in the United States each year and causes significant morbidity. Up to one third of patients with VTE have a recurrence within 10 years, and the mortality rate from pulmonary embolism can be as high as 30%. VTE may account for 100,000 deaths per year and is the leading cause of preventable hospital death. Unfortunately, fewer than 40,000 deaths associated with VTE are recorded each year in vital records. One half of lower extremity DVT patients have development of chronic venous insufficiency and postthrombotic syndrome.

Both hospitalized medical and surgical patients routinely have multiple risk factors for VTE, and pharmacologic methods to prevent VTE are safe, effective, and cost effective and advocated by authoritative guidelines. Despite the nearly universal risk of VTE among inpatients, large prospective studies continue to show that preventative measures are significantly underutilized. In the era of changing healthcare and pay for performance, the Centers for Medicare and Medicaid Services is considering the inclusion of hospital-acquired DVT and PE in its list of events for which hospitals will no longer be reimbursed. The need for understanding of risk factors, appropriate use of preventative measures, and use of algorithms to treat VTE has never been more important.

RISK FACTORS

Rudolph Virchow first proposed in 1884 that thrombosis was the result of at least one of the following etiologic factors: vascular endothelial damage, stasis of blood flow, and hypercoagulability of blood. In the last century, we have recognized that all VTE risk factors (Table 1) reflect these underlying processes, and convincing evidence shows that risk increases in proportion to the number of predisposing factors. Strong risk factors for VTE (odds ratio, >10) include hip or leg fracture, hip or knee replacement, major general surgery, major

TABLE 1: Identified risk factors for venous thromboembolism

Genetic	Acquired	Transient acquired
Family history	Advanced age	Pregnancy
Factor V Leiden	Antiphospholipid antibodies	Oral contraceptives/ hormone therapy
Prothrombin G20210A	Cancer	Central venous lines
Protein C deficiency	Chronic disease	Hospitalization
Protein S deficiency	Obesity	Surgery
Antithrombin deficiency	Congestive heart failure	Trauma
Sickle cell trait	Stroke	Immobilization

TABLE 2: Risk of deep vein thrombosis in hospitalized patients with no prophylaxis and routine objective screening

Patient group	DVT incidence rate (%)
Medical patients	10-26

DVT, Deep vein thrombosis.

TABLE 3: Contraindications and other conditions to consider with pharmacologic venous thromboembolism prophylaxis

Absolute	Relative	Other conditions
Active hemorrhage Severe trauma to head or spinal cord with hemorrhage in the last 4 wk	Intracranial hemorrhage within last year Craniotomy within 2 wk Intraocular surgery within 2 wk Gastrointestinal, genitourinary hemorrhage within last month Thrombocytopenia (<50K) or coagulopathy (prothrombin time, >18 s) End-stage liver disease Active intracranial lesions/neoplasms Hypertensive urgency/emergency Postoperative bleeding concerns	Immune-mediated heparin-induced thrombocytopenia Epidural analgesia with spinal catheter (current or planned)

trauma, and spinal cord injury. Moderate risk factors for VTE (odds ratio, 2 to 9) include arthroscopic knee surgery, central venous lines, chemotherapy, congestive heart failure, respiratory failure, hormone replacement therapy, malignancy disease, oral contraceptive therapy, paralytic stroke, postpartum pregnancy state, previous venous thromboembolism, and thrombophilia. Weak risk factors for VTE (odds ratio, <2) include bed rest for longer than 3 days, immobility from sitting (prolonged car or air travel), increasing age, laparoscopic surgery, obesity, antepartum pregnancy state, and varicose veins.

Without proper prophylactic measures, the risk of DVT can be quite high in surgical patients, with specific factors such as age, type of surgery, immobility, infection or inflammatory state, central venous access, and history of cancer or previous thrombosis playing an important role (Table 2). Major general surgery is a risk, and the term is generally used for patients undergoing abdominal or thoracic surgical operations that require general anesthesia lasting longer than 30 minutes. Advanced cancers, especially cancers of the breast, lung, brain, pelvis, rectum, pancreas, and gastrointestinal tract, are associated with a high risk of VTE. The administration of chemotherapy for cancer also increases VTE risk.

VENOUS THROMBOEMBOLISM PROPHYLAXIS

A VTE prophylaxis protocol is the best way to ensure all hospital patients are treated. An ideal VTE protocol should be well integrated into all admission, transfer, and postoperative orders. A properly constructed protocol should give the provider the option of using, or not using, the decision support elements. The protocol should define what appropriate prophylaxis is for patients of varied risk. A VTE prophylaxis tool should also offer decision support for contraindications to pharmacologic or heparin prophylaxis (Table 3). Ideally, the best protocols are easy to access and simple to use and fit into the normal workflow of orders as a default action. Multiple VTE risk assessment protocols exist, and no single VTE risk assessment has been prospectively validated as superior to others.

Primary VTE prophylaxis is accomplished by either mechanical or pharmacologic means, or with a combination of the two. Mechanical prophylaxis includes use of intermittent pneumatic compression

(IPC) or graduated compression stockings and early ambulation. Pneumatic compression works by both reduction in venous stasis and reduction of plasminogen activator inhibitor-1, which results in stimulation of intrinsic fibrinolytic processes. Mechanical prophylaxis is appropriate for surgical patients in the low-risk category and can also be valuable when bleeding risk prohibits pharmacologic methods. Barriers to successful mechanical prophylaxis include noncompliance and presence of extremity surgical procedures or fractures.

Pharmacologic prophylaxis has been shown to be the most effective method for VTE prevention, and multiple agents are available. Low-dose unfractionated heparin (UFH), 5000 units injected subcutaneously every 8 or 12 hours, has been shown to decrease the risk of fatal PE from 0.7% to 0.1%, with negligible risk of bleeding. It is easily administered and inexpensive, and no monitoring is required for the level of anticoagulation. There is a risk of heparin-induced thrombocytopenia (HIT), so platelet levels should be checked every 3 days.

Low molecular-weight heparin (LMWH; dalteparin, enoxaparin), administered subcutaneously once or twice daily, is an alternative that has been shown to be effective in preventing VTE. In the general surgery population, it has been shown to be noninferior to UFH, with a similar risk of bleeding and a slightly decreased risk of HIT. In the trauma and oncologic populations, LMWH has been found to be superior to unfractionated heparin with a similar risk profile.

Fondaparinux, a synthetic pentasaccharide factor Xa inhibitor, has mixed data when compared with LMWH. Several studies suggest it is superior to both dalteparin and enoxaparin, particularly in oncology patients, with similar bleeding profiles, and other studies with an alternative dose of LMWH did not reach the same conclusion.

New oral anticoagulants, rivaroxaban (factor Xa inhibitor) and dabigatran etexilate (factor IIa inhibitor), are two products currently under review in the United States for use in VTE prophylaxis. Pooled data from both phase III trials and randomized control trials suggest that both are more effective than enoxaparin with a similar bleeding risk.

Instances of clear superiority or inferiority do exist among prophylaxis options but only for just a few select patient groups. In medical patients, fondaparinux and the LMWHs enoxaparin and dalteparin have efficacy comparable with heparin given three times a day subcutaneously but offer lower complication rates. In certain higher risk patient groups (e.g., hip and knee replacement, trauma, and spinal cord injury), LMWH has shown superiority over subcutaneous heparin. In certain patient groups (e.g., hip replacement, surgery for cancer, and possibly medical patients with reduced mobility), extending prophylaxis with LMWH to approximately 5 weeks is more effective than providing it for 1 week. In certain patient groups, such as medical inpatients, the adequacy of heparin given twice a day subcutaneously has not been proven. High-quality randomized trials showing relative equivalence of LMWH to UFH all used a 5000-unit, three times a day dosing of UFH. In very high-risk patient groups, the addition of mechanical prophylaxis to a pharmacologic regimen may offer an added benefit. Certain patient groups should not receive certain pharmacologic agents or doses or should receive smaller doses (e.g., LMWH if creatinine clearance less than 30 mL/min, and UFH and LMWH if patient has HIT). Certain patient groups should receive pharmacologic doses in close coordination with other events (e.g., surgery or neuroaxial blockade).

For patients with contraindications to pharmacologic prophylaxis, an alternative approach to decrease the risk of clinically significant VTE is secondary prevention. This consists of screening ultrasound scans at a regular interval aimed at early detection of subclinical venous thrombi. Screening ultrasound scan often is used in conjunction with mechanical prophylaxis measures in the high-risk population.

VENOUS THROMBOEMBOLISM DIAGNOSIS

Any patient with new unilateral extremity swelling or unexplained pain should raise suspicion for DVT. Pain on passive dorsiflexion (Homans' sign) is not reliably present, and any clinical suspicion should prompt venous duplex imaging. For the ambulatory patient, a D-dimer assay is an exceptionally sensitive test (as high as 95%) when the goal is to rule out presence of venous thrombosis.

New-onset shortness of breath, hypoxia, anxiety, or congestive heart failure should prompt concerns for pulmonary embolism. Computed tomographic (CT) angiography of the chest with imaging timed to highlight the pulmonary veins has supplanted ventilation/perfusion scans in the diagnosis of PE. Clinically significant PE is detected with this method with nearly 100% sensitivity.

The gold standard for evaluation for presence of extremity deep venous thrombosis is venous duplex scan. Venous duplex examination is highly sensitive and specific, noninvasive, and poses no risk to the patient. In quality noninvasive vascular laboratories, the evaluation of the infrapopliteal veins is also easily accomplished, as are upper extremity/neck veins. With utilization of Doppler flow characteristics, thrombosis of veins within the abdomen and chest can also be detected, although not always visually confirmed. Duplex scan can determine whether DVT is acute or chronic. Acute clot is hypoechoic, with distended noncompressible veins. Respiratory phasic flow is lost, and flow does not augment with compression. Chronic clot is hyperechoic, and the vein is contracted or nondilated. With chronic clot, the vein remains noncompressible or partially compressible.

Other means of diagnosing DVT include contrast-enhanced venous phase CT scan, magnetic resonance venographic (MRV) imaging, and contrast venography. CT scan and MRV also evaluate surrounding structures and can identify potential sources of extrinsic compression or etiologies for venous obstruction.

VENOUS THROMBOEMBOLISM TREATMENT

Systemic anticoagulation therapy is the primary treatment modality in VTE as it both helps prevent pulmonary embolism and reduces local clot propagation and helps minimize risk or recurrence. Therapeutic levels of anticoagulation should be achieved as soon as possible, which reduces the risk of recurrence fourfold. This can be done with weight-based dosing of LMWH or intravenous unfractionated heparin. LMWH has the advantage that it does not require monitoring and has a lower risk of bleeding as a result of a more predictable anticoagulation level. Unfractionated heparin is titrated to an activated partial thromboplastin time (aPTT) of 2 to 2.5 times normal. Once adequate anticoagulation therapy is achieved, patients are typically bridged to oral therapy. Warfarin is most commonly used for long-term anticoagulation therapy. Overlap of heparin or LMWH therapy with warfarin is important because protein C and S are the first factors to be inhibited, leading to a transient hypercoagulable state.

Long-term anticoagulation therapy can also be done with LMWH. It has also been shown to be superior to warfarin for patients with malignancy disease. Fondaparinux can be used to bridge to warfarin and as an alternative long-term therapeutic option. Dabigatran etexilate is currently indicated for anticoagulation therapy for stroke prevention for patients with atrial fibrillation but has not yet been approved for VTE therapy in the United States.

Duration of anticoagulation therapy is highly variable, and specific patient factors must be taken into account. The initial occurrence of a femoral-popliteal DVT without other predisposing risk factors should be treated for at least 3 months with systemic

anticoagulation therapy, whereas an infrapopliteal DVT can be treated for 6 to 12 weeks. For those with calf vein thrombosis, either 3 months of anticoagulation therapy or ambulation and repeat weekly imaging to ensure no further propagation is reasonable.

Recurrent or unprovoked VTE necessitates prolonged anticoagulation therapy for 12 months or longer and consideration of evaluation for a hypercoagulable state and occult malignancy disease. Individuals with homozygous factor V Leiden, prothrombin 20210A mutation, protein C or protein S deficiency, antithrombin deficiency, antiphospholipid antibodies, and active malignancy disease should be considered for long-term anticoagulation therapy. In addition, patients with a substantial pulmonary embolism at initial presentation are also considered for prolonged anticoagulation therapy.

For patients undergoing surgical intervention within the period of required anticoagulation therapy after an acute VTE, bridging with UFH or LMWH can be performed perioperatively. For those individuals who are at high risk for PE, a removable inferior vena cava (IVC) filter should be considered.

Venous compression stocking therapy (30 to 40 mm Hg) is an important component of therapy for the treatment of patients with DVT that is commonly overlooked. Pain, swelling, and chronic venous insufficiency (CVI) lead to lifelong postphlebitic limb issues. Use of stockings has been shown to reduce the risk of chronic venous ulceration by 50%. There is no curative therapy for chronic venous insufficiency from chronic DVT. Compression stockings play a critical role in the management of CVI. Stockings reduce limb edema and ambulatory venous hypertension, thus reducing the risk of skin breakdown.

INFERIOR VENA CAVA FILTER

Inferior vena cava interruption with percutaneously placed filters is indicated for patients with a contraindication to anticoagulation or recurrent or propagated VTE despite therapeutic anticoagulation. Multiple approved devices are on the market, all with similar efficacy and risk profile. In individuals with an enlarged IVC (>28 mm), most permanent filters are too small to anchor in place, so either bilateral iliac vein filters or a Birds Nest filter (Cook Inc., Bloomington, Ind) can be used. Protection from PE (>95%) with IVC filters is equivalent to that of properly managed systemic anticoagulation therapy, with no increased benefit when both are used concurrently. For those patients with a limited period of time in which anticoagulation is contraindicated, removable filters are available. The importance of removal of temporary filters after the period of risk of hemorrhage has passed cannot be emphasized enough because IVC filters do pose some long-term risk of fracture, embolization, perforation, and caval thrombosis.

CATHETER-DIRECTED THROMBOLYTIC THERAPY

Extensive iliofemoral deep venous thrombosis predisposes the most significant risk of long-term sequelae from chronic venous insufficiency. Patients with limb-threatening venous outflow obstruction (phlegmasia cerulea dolens or venous gangrene) also benefit from rapid recanalization. In this population, active treatment with percutaneous pharmacomechanical thrombectomy or catheter-directed lysis can substantially reduce the thrombus burden and restore valvular function. When followed by systemic anticoagulation therapy, these percutaneous therapies have reduced long-term sequelae. Technical success is greater when intervention is performed with 14 days of thrombotic event, and long-term success correlates with the amount of thrombus clearance.

SYSTEMIC THROMBOLYSIS

Patients with a large pulmonary embolism and hemodynamic compromise are candidates for systemic thrombolytic therapy, if it is initiated within 48 hours of onset. Right ventricular strain and dysfunction on echocardiography can be seen as the sequelae of massive PE. Ultrasound scan–enhanced catheter-directed pharmacologic thrombolysis of PE has also shown to be beneficial for patients with hemodynamic compromise. In the short term, hemodynamic improvement is more rapid with lytic therapy, but long-term outcomes are not necessarily superior to anticoagulation-based therapy alone. In patients with failed lytic therapy and ongoing hemodynamic instability, surgical embolectomy remains an option.

COMPLICATIONS

Major bleeding is the most common complication of long-term anticoagulation therapy, occurring between 2% and 6% per year in those with an international normalized ratio (INR) of 2 to 3. Major bleeding is defined as intracranial hemorrhage, significant gastrointestinal bleeding, or deep tissue bleeding, such as retroperitoneal. Reversal of anticoagulation, protamine for unfractionated heparin and vitamin K/fresh frozen plasma for warfarin, should be performed immediately, and a vena cava filter should be placed as indicated. An unfortunate consequence of LMWH and some of the novel anticoagulants is that there is no reversal available, so supportive management and transfusion as necessary are all that can be done.

A second complication specific to heparinoids is heparin-induced thrombocytopenia. This can occur both with prophylactic and therapeutic dose unfractionated and low molecular-weight heparin. Immune-mediated thrombocytopenia most often occurs within 3 to 5 days after exposure, and the incidence increases with serial exposures. HIT should be suspected with an acute drop in platelet count by 50% or to below 100,000. A platelet factor-4 enzyme-linked immunosorbent assay (ELISA) is the initial test performed; it may be confirmed with a serotonin release assay. The morbidity of HIT comes from the small vessel thrombosis that occurs, so cessation of heparin exposure is followed by anticoagulation therapy with direct thrombin inhibitors.

Inferior vena cava filter complications can be categorized as those that involve the implantation and long-term complications. Short-term complications include access site (hematoma, arteriovenous fistula, hemorrhage, access site thrombosis), treatment site (improper position, tilt, vessel perforation), and systemic (dye allergy, contrast-induced nephropathy) issues. Most conical filters retain protection from PE even with tilt angles of up to 30 degrees.

Long-term complications of filter placement include PE around the filter, filter fracture, and migration. Inferior vena cava thrombosis can lead to impaired venous return, hemodynamic compromise, and massive lower extremity edema. Filter strut perforation (intact or fractured) into adjacent structures such as the aorta or small bowel can lead to substantial morbidity and mortality.

SUMMARY

Venous thromboembolic disease is a major source of preventable morbidity and mortality in both medical and surgical patients. With accurate assessment of risk factors and proper application of prophylactic measures, this risk can be reduced significantly. Diagnosis is best made with duplex ultrasound scan. Furthermore, timely diagnosis before clinical consequences and prompt initiation of anticoagulation therapy is important for improved outcomes. Therapeutic anticoagulation therapy for 3 months for uncomplicated situations is the minimum, but longer duration treatment may be necessary. Long-term anticoagulation is achieved with LMWH or warfarin and

with novel agents. Use of 30-mm Hg to 40-mm Hg elastic compression stockings is important in reducing the risk of late chronic venous ulceration. In cases of iliofemoral thrombosis, pharmacomechanical thrombolysis should be considered. When anticoagulation therapy is contraindicated, vena cava interruption is an alternative to protect against PE but not the sequelae of DVT.

Lymphedema

Natalia O. Glebova, MD, PhD, and Jennifer Heller, MD

Lymphedema is a condition characterized by the interstitial accumulation of protein-rich fluid as a result of impaired lymphatic drainage. Whereas the venous capillary system is responsible for 90% of the return of interstitial fluid into circulation, the lymphatic system handles the return of the largest macromolecules and their associated fluid. Reduced lymphatic uptake capacity causes a net increase in the amount of interstitial proteins and fluid.

As the condition progresses, increasing dilation of the remaining functional lymphatics causes valvular incompetence and reversal of flow. Lymphatic walls then undergo fibrosis, and fibrinoid thrombi ultimately obliterate the remaining patent channels. Stasis of interstitial proteins leads to an inflammatory response, with macrophages and fibroblasts replacing supple, elastic interstitium with fibrosclerotic, thickened, congested tissues. Soft, pitting edema gives way to induration, hypertrophy of adipose deposits, acanthosis, hyperkeratosis, and skin breakdown. Infectious complications often ensue, with recurrent bouts of cellulitis and lymphangitis. Rarely, chronic lymphedema degenerates into a highly aggressive lymphangiosarcoma, known as *Stewart-Treves syndrome*. A consensus on the staging of lymphedema has been published by the International Society of Lymphology (Box 1).

Lymphedema may be either primary or secondary. *Primary lymphedema* is the result of a developmental abnormality, although often with delayed manifestations. *Secondary lymphedema* is acquired and results from disease, trauma, or iatrogenic causes.

Primary lymphedema is further subclassified on the basis of inheritance (familial versus sporadic) and time of onset (congenital, praecox, or tarda). Women are predominantly affected by all forms of primary lymphedema. *Congenital lymphedema,* or Milroy's disease, includes all forms that present within the first 2 years of life, representing 10% to 25% of all primary cases. It typically involves bilateral lower extremities, is not progressive, and may improve spontaneously with age. *Lymphedema praecox,* or Meige's disease, typically presents at puberty (by definition before age 35 years) and represents 65% to 85% of primary lymphedema cases. Unilateral lower extremity involvement is usual. *Lymphedema tarda* presents spontaneously after the age of 35 years and is the rarest form of primary lymphedema. Table 1 describes demographics and typical presentations of the three forms of primary lymphedema.

Secondary lymphedema represents an acquired dysfunction of normally developed lymphatics. Worldwide, the most common cause is infection by the nematode *Wuchereria bancrofti,* spread by mosquitoes. Adult filarial worms reside in and obstruct lymphatic channels, causing irreversible scarring and fibrosis and often massive edema. In the United States and other developed nations, nearly all causes of secondary lymphedema are related to malignancies and their therapies. Mainstays of cancer treatment, such as tumor resection, radiation therapy, and lymphadenectomy, are related to higher rates of lymphedema. Lymphadenectomies are often performed to stage and treat malignant disease, including superficial and deep inguinal lymph node dissections for extremity melanoma and other tumors and axillary dissections commonly done during breast cancer treatment. Other risk factors including trauma, infection, and obesity are considered to contribute to secondary lymphedema (Figure 1).

DIAGNOSIS

The workup for lymphedema starts with a thorough history and physical examination. Other causes for edema must be ruled out, including cardiac, venous, renal, and hepatic etiologies and

BOX 1: Lymphedema staging

Stage 0: Latent
- Impaired lymphatic function
- No evident edema; subclinical
- May last months or years before progression

Stage I: Spontaneously Reversible
- Early accumulation of protein-rich fluid
- Pitting edema
- Subsides with elevation

Stage II: Spontaneously Irreversible
- Accumulation of protein-rich fluid
- Pitting edema progresses to fibrosis
- Does not resolve with elevation alone

Stage III: Lymphostatic Elephantiasis
- Nonpitting
- Significant fibrosis
- Trophic skin changes

From International Society of Lymphology: The diagnosis and treatment of peripheral edema: 2009 consensus document of the International Society of Lymphology, Lymphology *42(2):51-60, 2009.*

TABLE 1: Primary lymphedema classifications

Classification	Age of onset	Gender predilection	Presentation	Genetics
Congenital (Milroy's disease)	Birth to 2 y	Female : male = 2 : 1	Predominantly lower extremity involvement, usually bilateral May involve gastrointesinal tract, intestinal lymphangiectasias, cholestasis Anaplastic lymphatic trunks	Autosomal dominant inheritance *FLT4,* tyrosine receptor kinase signaling pathway in lymphatics
Praecox (Meige's disease)	15 to 35 y	Female : male = 4 : 1	Predominantly lower extremity involvement, usually unilateral Associated anomalies may include vertebral defects, cerebrovascular malformations, distichiasis, yellow nails, sensorineural hearing loss, cleft palate Hypoplastic peripheral lymphatics	Autosomal-dominant inheritance *FOXC2,* involved in adipocyte metabolism *FLT4*
Tarda	>35 y	Female > male	Spontaneous onset Typically lower extremity involvement Hyperplastic histologic pattern, large tortuous lymphatics with absent or incompetent valves	*FOXC2*

FIGURE 1 Bilateral lower extremity edema in the setting of morbid obesity.

TABLE 2: Differential diagnosis of peripheral edema

Etiology	Characteristics
Lymphedema	Asymmetric, painless, dorsum of foot involvement, Kaposi-Stemmer sign, hyperkeratosis
Cardiac	Symmetric, heart failure signs (jugular venous distention, lung crackles)
Hepatic	Symmetric, presence of ascites
Venous insufficiency	Asymmetric, pitting, aching, presence of varicosities, brawny hemosiderin deposits
Postthrombotic syndrome	Asymmetric, pitting, aching

compressive or occlusive vascular syndromes (Table 2). Physical examination characteristics include pitting edema that decreases with limb elevation, thickened skin, hyperkeratosis, and dermatitis. Lymphangioscintigraphy is currently the imaging gold standard for patients in whom these secondary etiologies are not suspected. This technique uses radioactively labeled macromolecules that are too large to enter systemic capillaries, such as Technetium-labeled human serum albumin. After a subcutaneous or intradermal injection into the interstitium (usually into a web space of hand or foot), the path of the tracer is visualized with a gamma camera. Quantitation can be achieved after correction for the decay of the tracer. This technique is somewhat limited by resolution and can be nondiagnostic with suboptimal injection but is low risk. Magnetic resonance imaging and computed tomographic scan are also useful in lymphatic visualization and may help to rule out associated malignant disease. Contrast magnetic resonance lymphangiography with gadobenate dimeglumine is a fast, less invasive diagnostic test for evaluation of lymphedema. Although imaging studies may be of some value, most patients can be diagnosed without additional confirmatory testing.

TREATMENT

Nonoperative Management

Nonoperative management is the mainstay of treatment for lymphedema. Public health measures to reduce vector transmission of *W. bancrofti* with diethylcarbamazine plus ivermectin can have significant effects on secondary lymphedema caused by the parasite.

The goal of nonoperative therapy is reduction of proteinaceous interstitial fluid, with the hope of stemming the cycle of edema, inflammation, and fibrosis. Modalities include hygiene management, compression and elevation, physical therapy, and long-term compliance. Treatments are often time intensive and inconvenient, and patient compliance is a necessary component of any regimen.

Basic lifestyle modifications are essential in managing the sequelae of lymphedema. Skin hygiene is important to reduce skin breakdown and resulting infection. Patients should be encouraged to lose weight if obese, to address minor skin traumas and breakdown appropriately, and to avoid constrictive clothing.

Compression therapies range widely and include graduated compression garments, multilayered inelastic bandaging, and controlled compression therapy. Compression garments are refitted as swelling decreases. These methods reduce the volume of excess edema by approximately 30% to 45%. External sequential compressive devices have also been used with variable success. Compression therapies are typically combined with elevation of the affected extremity whenever feasible.

Physical therapy, specifically decongestive lymphatic therapy, is a more time-intensive treatment strategy. This modality emphasizes manual lymphatic drainage via massage, compressive garments, and exercise. Numerous protocols exist for such therapies, which operate on the belief that these methods reduce edema by augmenting lymphatic contractility and increasing lymphatic flow. Studies vary as to whether lymphatic massage therapy leads to improved outcomes as compared with compression garments or bandaging alone.

The success of nonoperative strategies varies widely, in part because of differences among patient populations and individual patients. However, patient compliance plays a significant role; discomfort or embarrassment associated with compression garments or the inconvenience of physical therapy may limit outcomes.

Pharmacologically, antibiotics are used to treat recurrent infections that range from superficial infections to more serious cases of cellulitis or lymphangitis. Beyond antibiotics, however, pharmacologic therapies play a limited role in the management of lymphedema. Benzopyrenes are thought to increase lymphatic uptake of peptides through proteolysis of interstitial proteins, facilitating absorption into the bloodstream. Literature shows conflicting results with respect to benzopyrene usage, and documented hepatotoxicity limits long-term therapy (published trials are no longer than 3 to 6 months in duration). Diuretics have been used historically, but with only limited benefit, and they may actually lead to increased interstitial protein accumulation and fibrosis. Studies that examine the use of nutritional supplements, such as sodium selenite or vitamin E with pentoxifylline, have not shown any significant benefit in patients with lymphedema.

Operative Treatment

Surgery is an adjunct to primary conservative therapy in refractory cases, but the surgical indications for lymphedema are not absolute. Surgery is usually reserved for moderate to severe lymphedema, and its goal is long-term remission and improvement in quality of life. A number of variables are taken into account during assessment. Relative indications include size and weight of the patient, extent of lymphedema, recurrent lymphangitis, lymphorrhagia, abscess, fistula, diminished quality of life, worsening comorbidities, and most importantly, failure of nonoperative management.

The two general categories of surgical therapy are *debulking* and *physiologic procedures.* Nonoperative therapies such as lifestyle modifications, proper hygiene, and compressive therapies should be continued immediately after any surgical procedures because these surgical procedures are adjuncts to the previously mentioned therapies.

Debulking Procedures

The Charles procedure (1912), a radical excision technique, removes all skin and subcutaneous tissue down to the muscle fascia. Excised skin is used for grafting on the fascia (Box 2). The Van der Walt modification allows for negative-pressure dressing with grafting done in a delayed fashion. The operation is indicated for severe cases and carries a high risk of complications, including but not limited to infection, ulceration, hyperpigmentation, dermatitis, and a severe altered aesthetic outcome (Figure 2).

The Sistrunk procedure (1918) is a planned, staged excision of affected subcutaneous tissues. This technique has been modified over the last 80 years and incorporates burying of dermal flaps within the skin flaps (Box 3). Long-term results can achieve a reduction of at least half of the affected tissue in 75% of patients. It is safe, reliable, and predictable. Complications include nerve damage in the affected area, epidermolysis from poor blood supply, wound dehiscence, and infection.

Liposuction was first used for brachial lymphedema in 1987 and was refined in 1993; it is now a useful adjunct for treatment (Box 4). Liposuction is safe, quick, and allows for an immediate decrease in

BOX 2: Charles procedure

1. Mark the lymphedematous area proximally and distally.
2. Make an incision medially and laterally down to the muscle fascia.
3. Excise all the tissue superficial to this plane.
4. Remove the skin of the affected area with a dermatome for a split-thickness graft or with a knife for a full-thickness graft. If a full-thickness graft is used, be sure to remove all the fat from the skin.
5. Use this graft to cover the exposed area.
6. Apply petroleum gauze or other nonadherent dressing over the graft.
7. Apply a pressure dressing via a vacuum-assisted device, bolster, or cotton.
8. Splint the extremity in the proper anatomic position.
9. Remove dressing after 3 to 5 days for a split-thickness graft or after 7 to 12 days for a full-thickness graft.

FIGURE 2 Lower extremity after Charles procedure.

BOX 3: Sistrunk procedure

1. Mark out the affected area.
2. Plan to excise and debulk sufficient tissue, leaving dermal flaps to bury beneath the skin in the closure. A variation of this is carried out in the Thompson procedure, in which dermal flaps are buried beneath the muscle.
3. Close the incision over drains.
4. Allow 12 weeks to heal before the next serial excision.

BOX 4: Liposuction

1. Mark out affected area and 2 cm beyond.
2. Choose port sites to effectively reach all areas, both proximally and distally.
3. Inject tumescent solution (1 L Ringer's lactate mixed with 1 mL ampule of epinephrine 1:1000 and 30 mL of 1% lidocaine) until blanching is achieved and a moderate amount of turgor is seen.
4. Wait 30 to 45 minutes.
5. Suction with a 4-mm to 6-mm cannula in a deep plane in all areas, followed by a 2-mm to 3-mm cannula in a more superficial plane for a smoother contour.
6. Close port sites with absorbable suture.
7. Apply sterile dressings and a pressure garment.
8. Advise the patient not to shower or remove the pressure garment for 72 hours, and encourage the patient to walk at least 3 times a day.
9. After 3 days, the patient can shower daily and may begin massaging the affected areas.
10. The pressure garment should be worn for 6 to 10 weeks.

volume and pressure of the lymph fluid, promoting better lymphatic flow. Brorson of Sweden reports a complete reduction with no recurrence in his 15-year experience. Risks include lidocaine toxicity, thrombotic and fat emboli, hematoma, seroma, and contour irregularities. It has been used alone and in addition to other debulking procedures.

Physiologic Procedures

The main aim of physiologic procedures is to improve lymphatic flow and drainage. Omental flaps, enteromesenteric bridging, dermal flaps, and lymphangioplasty have all been attempted with minimal to no success. More recently, operations have been devised to construct connections between the lymphatic system and the venous system in the periphery. Lymphatic vessel and small veins have been used as grafts to reestablish lymphatic flow (prosthetic grafts have been investigated and determined to have abysmal patency). Microvascular lymphovenous shunts and nodal transplantation are new therapies that are showing promising results.

Microvascular lymphovenous shunts were first introduced in 1953 by Sherman and colleagues. Over the decades, microsurgery has evolved and is now used more to relieve postobstructive lymphedema (Box 5). A more recent study describes Campisi's experience in treating more than 800 patients with failed previous nonoperative therapies, with an average follow-up of 7 years. More than 80% of patients undergoing microsurgical lymphovenous shunting experienced significant reduction of excess volume (67% on average), with an even greater reduction in the incidence of cellulitis. Results were stable with both volumetric assessment and lymphoscintigraphy.

BOX 5: Microsurgical lymphovenous shunt

1. Begin with lymphatic and venous scintigraphy.
2. Inject lymphazurin into the web space in the distal extremity.
3. Take postobstruction dissection down to venous and lymphatic channels.
4. Use microsurgical connection to reestablish lymph flow directly or use a vein graft.
5. Insert a Penrose nonsuction drain.
6. Evaluate postoperative flow and imaging studies.

BOX 6: Vascularized nodal transplantation

1. Palpate femoral pulse and design skin paddle lateral to pulse, inferior and parallel to the inguinal ligament.
2. Take dissection of the flap from distal to proximal, harvesting the superficial fibronodal tissue with the superficial circumflex iliac vessels.
3. Make a transverse incision on the wrist, and perform microvascular anastomosis to the radial artery and vein.
4. Use a skin paddle for monitoring.

Vascular nodal transplantation has had several successful animal studies, those in rats by Shesol in 1979 and again by Chen in 1990. This technique harvests vascularized fat and nodal tissue from the groin and transplants it to the distal upper extremity via microvascular anastomoses to the radial artery and vein (Box 6). This technique shows improvements that include decreased size, increased skin elasticity, decreased infection, increased lymphatic flow, increased lymphatic pathways toward the flap site, and most importantly, discontinued use of physiotherapy.

SUMMARY

Lymphedema remains a challenging clinical problem with significant morbidities. Treatment includes early implementation of long-term nonoperative measures along with surgical procedures for more difficult cases. Patient commitment and lifestyle modifications are central to the success of any therapeutic regimen.

Trauma and Emergency Care

Initial Assessment and Resuscitation of the Trauma Patient

Gregory Peck, DO, and Timothy G. Buchman, PhD, MD, FACS, FCCP, MCCM

INITIAL ASSESSMENT AND RESUSCITATION OF THE TRAUMA PATIENT

The purpose of this chapter is to provide the practicing surgeon with a framework for assessment and resuscitation of the acutely injured patient. The principles and their implementation reflect the experience of the worldwide trauma community and the clinical practice of the authors. Effective surgical care depends on collaborative practice with prehospital providers, emergency and critical care physicians, radiology and operating room teams, and consultant specialty surgeons. A "shared mental model" of care fosters close collaboration, effective integration, and ultimately better outcomes for patients. The authors therefore recommend this chapter be shared among those providers, discussed, and then modified as needed to best suit local needs and established care patterns. The existence of a standard practice is more important than any specific component.

Stop the Harm and Do No (Further) Harm

The Hippocratic Oath includes a promise "to abstain from doing harm." The acutely injured patient has already been harmed, and therefore, the immediate goal of the surgeon must be to stop the result of the initial harm and take action to minimize the possibility of well-intended interventions to cause additional harm. The general approach requires that a team of providers agree on and practice a structured system of care that simultaneously identifies and addresses immediate life-threatening injury, initiates general resuscitative measures, inventories all injuries, and then prioritizes the treatment of injuries towards a patient-specific, comprehensive plan of care.

One framework for that general approach is contained within the Advanced Trauma Life Support (ATLS) Program of the American College of Surgeons that is currently taught in more than 60 countries and can therefore be considered a global standard. This chapter reflects that framework.

Preparation of the Team and Resuscitation Area

Successful assessment and resuscitation require that all team members know their role and can fulfill that role within the resuscitation area. Prior planning and mock resuscitations help to ensure that team members are cross-trained in the various roles and are familiar with the location and operation of essential equipment (such as physiologic monitors, oxygen sources, and airway adjuncts).

When a trauma patient is announced (either by information from prehospital providers or through the unexpected appearance of the patient), the team leader should assign tasks as described subsequently and, whenever possible, supervise and coordinate others in those roles. Often, one team member may have to assume more than one task, but all tasks must be fulfilled. The team leader is always responsible for ensuring completion of all tasks. The team leader is also responsible for the safety of the team and therefore must ensure that standard precautions, including appropriate personal protective equipment (gowns, gloves, and masks), are maintained throughout the resuscitation.

PRIMARY SURVEY

To stop the harm, the team must identify the immediate threats to life and address them in the order they are identified. The urgency of the tasks is self evident. Thus, the primary survey seeks to support three core physiologic functions (namely, ventilation, oxygenation, and perfusion) while verifying the integrity of neurologic, pulmonary, and cardiovascular systems. To simplify and coordinate these tasks, an alphabet sequence is recommended: A, B, C, D, E, and F, which represent Airway, Breathing, Circulation, Disability, Exposure, and FAST (Focused Assessment with Sonography for Trauma).

Airway (With Cervical Spine Control)

Looking and listening often verify that the patient has a patent airway. Observation of a speaking, screaming, or crying patient is sufficient to establish the airway at least temporarily patent. Conversely, patients who struggle to sit up, especially those with facial or cervical trauma, often do so because of imminent loss of the (natural) airway. Hoarseness and stridor are audible signs of impending airway loss. Although suction can clear secretions and a jaw thrust can displace the tongue to open the pharynx, trauma patients with a compromised airway nearly always need an artificial airway. Most often this involves endotracheal intubation with a translaryngeal tube with a sedative-amnestic (such as etomidate) and a short-acting neuromuscular blocking drug (such as succinylcholine). In every case, the team must ensure that all airway manipulations are performed with the cervical spine kept neutrally positioned until a cervical spine injury can be reasonably excluded. In every case, the surgeon must be prepared to

provide a surgical airway via cricothyrotomy in the event that a translaryngeal tube cannot be safely and expeditiously inserted. Assessment and verification of the airway should always be followed by supply of 100% oxygen.

Breathing

Looking and listening is important for verification of normal ventilation. The trachea should be midline; deviation to one side suggests either ipsilateral atelectasis or contralateral tension pneumothorax. The chest should expand symmetrically. During the primary survey, with the patient typically supine, auscultation through the chest wall of the axilla is the most reliable way to verify ventilation of peripheral lung. Auscultation at this location minimizes both intervening tissue and the chance that tracheobronchial air movement is confused with peripheral ventilation. Any abnormality of tracheal position, chest expansion, or breath sounds (asymmetry or absence) must immediately be followed by three steps: reassess presence of an adequate airway; palpation of the chest to detect crepitus, fracture, or a flail segment; and percussion of the chest to identify a potential pneumothorax. Clinical suspicion of a tension pneumothorax is sufficient justification to decompress the hemithorax before chest radiography; whether a needle is used before tube thoracostomy is less important than securing adequate drainage, typically via the fourth intercostal space in the anterior-midaxillary line connecting the tube to –20-cm water suction to accelerate decompression.

Circulation (With Hemorrhage Control)

Obvious bleeding should be controlled with direct pressure. If the blood is from an extremity where a blood pressure cuff can be applied proximally, inflation of that cuff in excess of systolic pressure is sufficient to temporarily control that blood loss. Otherwise, the assessment of circulation relies on the palpation of carotid, femoral, and radial pulses along with compression and release of a nail bed for qualitative assessment. The carotid pulse is the last to be lost, disappearing when the systolic pressure falls below 60 mm Hg. Initial support typically consists of infusion of 30 mL/kg balanced salt solution (normal saline solution or lactated Ringer's solution) via two peripheral intravenous cannulas, size 16-gauge or larger. Palpable pulse asymmetry speaks either to underlying vascular disease (common in the older trauma victim) or focal acute injury. Absent pulses at every point of palpation speaks either to a systolic blood pressure below 60 mm Hg or absence of mechanical cardiac function, both of which demand immediate action.

At this point in the care of the patient, the team leader should *explicitly assess and announce* that oxygenation, ventilation, and perfusion are adequate, recovering, or unresponsive. The two key assessment tools are pulse oximetry (which provides evidence of perfusion and oxygenation) and capnometry (which provides evidence of perfusion and ventilation, especially in patients on mechanical ventilation). Electrocardiographic (ECG) tracing confirms electrical activity of the heart, but this can be uncoupled from perfusion by cardiac tamponade, tension pneumothorax, or exsanguinations and should not be taken as independent evidence of perfusion.

Defects in oxygenation are the result of defective delivery to the lungs, defective diffusion across the lung tissue, or defective perfusion. Check that the oxygen source is connected to and flowing into whatever device is supplying the patient, including the fractional concentration of oxygen in inspired gas (FiO_2) setting on the ventilator. If delivery to the lungs is adequate, a significant lung injury or a perfusion compromise is likely.

Defects in ventilation are typically mechanical: the patient cannot self ventilate or something is interfering with mechanical ventilation. Disconnecting the patient from mechanical ventilation and "hand-bagging" the patient with a bag-valve device (AMBU bag) quickly establishes whether gas flows easily into and out of the lungs. If ventilation is easy, falling or absent end-tidal CO_2 is often evidence of a serious perfusion problem.

Defects in perfusion are common. The most common cause of underperfusion is hypovolemia as a result of hemorrhage. Although the initial balanced salt solution is infusing, perfusion failure from arrhythmia, cardiac tamponade, or tension hemopneumothorax should be reconsidered, especially in the absence of an obvious bleeding point or cavity. The quickest way to exclude these three as cause of the perfusion defect may be ultrasound scan, which can display mechanical cardiac function, visualize pericardial fluid, and confirm that neither fluid nor gas lie between the chest wall and the lung parenchyma (extended FAST examination). If bleeding is the suspected or is the obvious cause of severe hypoperfusion, transfusion with the constituents of whole blood (red blood cells, fresh frozen plasma, and platelets transfused at a ratio of 1 : 1 : 1) is necessary. The hemorrhage, depending on the severity and location, is expeditiously halted with operative intervention. Vasopressor and inotrope treatment may be appropriate for some causes of perfusion compromise but should be recognized as adjuncts to volume return and search with reversal of the cause is underway. Vasopressor and inotropes are not the treatment for hemorrhagic shock but are instead indicated in perfusion compromise from neurogenic or cardiogenic shock.

Disability (Neurologic Assessment)

This evaluation is meant to be brief and aims to determine level of consciousness and any lateralizing signs. Operationally, this means a determination of the Glasgow coma score, an inspection of the pupils, and a command to "wiggle" fingers and toes. The responsive patient who has sustained a fall, direct blow to the neck or head, rapid deceleration, torque, or an axial load should also be asked about transient loss of consciousness and transient hemiplegia or quadriplegia. Positive responses dictate advanced imaging, particularly computed tomographic (CT) angioplasty or magnetic resonance imaging (MRI), to seek evidence of vascular dissection or cord impingement, respectively. The unresponsive patient with a Glasgow coma score of less than 9 should have the airway secured with an endotracheal tube before a CT scan or MRI. Unresponsive patients with asymmetric pupils constitute a neurosurgical emergency; immediate neurosurgical consultation and intervention is necessary, treatment with osmotic diuretics or hypertonic saline solution should be initiated, and plans should be made for immediate CT scan to define the lesion.

Exposure (With Environmental Control)

The patient must be completely undressed, and all surfaces are inspected. "Logrolling" with attention to maintaining spine neutrality is important to assess focal level of spine pain or deformity, all dependent on the level of a patient's consciousness. The posterior skin and the perineum and axillae should be inspected for lacerations, punctures, and hematomas. If penetrating injuries are found, clinical impressions should be formed as to likely trajectories, particularly if there is a likely violation of key anatomic zones (such as the central chest or abdominal vascular). Obvious traverse of the thoracic cavity and abdomen accompanied by hypotension suggests a life-threatening thoracic or intra-abdominal injury that necessitates immediate transfer to the operating room for exploration.

Palpation should assess for masses, fluid collections, crepitus, and obvious fracture, including the spine and pelvis. Constrictions (rings, bracelets, and circumferential eschar in burn cases) should be relieved if circulation or ventilation is threatened.

The importance of environmental control cannot be overstated. Injured patients often have defects in thermoregulation that are amplified in the setting of hemorrhage or directly by wet clothes or

bed sheets. Patients with spinal cord injuries have no vasoconstriction in response to cooling and become poikilothermic. The resuscitation bay should therefore be kept uncomfortably (with respect to the gowned resuscitation team) warm. Environmental control also requires attention to mitigation of pressure points, especially in the unconscious patient.

Focused Assessment With Sonography for Trauma

Ultrasound scan is now a standard tool for initial assessment of the injured patient. Four conditions dictate its immediate use during the primary survey: hypotension, abdominal trauma, impaired consciousness, and pulseless electrical activity. Four views are obtained, including the pericardium and heart, the perihepatic spaces, the perisplenic space, and the pelvis. If no cardiac motion is seen, then the patient is clinically dead and the team can determine whether sufficient reason exists to attempt resuscitative thoracotomy. Otherwise, the purpose of the FAST examination is to detect fluid that would compromise perfusion, either tamponade around the heart or frank blood loss into the abdomen leading to hypovolemia. Furthermore, lateral thoracic and parasternal views to assess for hemothorax or pneumothorax, respectively, are used routinely depending on user experience.

RESUSCITATION AND MONITORING

The next phase of care is resuscitative. The team leader should revisit the components of the primary survey and reverify that the patient is oxygenated and ventilated and that fluids are infusing if indicated. Four key decisions follow. First, is additional fluid necessary? Second, if additional fluid is necessary, is colloid indicated? Third, is a medication or procedure immediately necessary to resuscitate the patient? Finally, does the procedure need to be performed in the resuscitation area? Here, some judgment is needed to tailor the resuscitation.

The resuscitation target is often a systolic pressure of 90 mm Hg and definitive control of any site of hemorrhage. If fluids beyond 2 L are necessary, blood products are required and plans should be made to promptly control the bleeding either via the interventional radiology route or operatively. Newer concepts are damage control resuscitation, introducing the concept of frontloading resuscitative efforts with permissive hypotension, minimization of crystalloids, use of hypertonic saline solution, and early transfusion of packed red blood cells or whole blood, fresh frozen plasma, and specific coagulation cascade factors if massive hemorrhage is present. Hypotension is never neurologic in origin, with one notable exception: patients with cervical spinal cord transection can require both a vasoconstrictor and a cardiac accelerator to overcome the traumatic sympathectomy and thereby augment blood pressure (dopamine or low-dose epinephrine conveniently combines both effects).

Thoracotomy performed in the resuscitation area (resuscitative thoracotomy) is successful only in a very narrowly selected patient population. The strongest indication is penetrating thoracic trauma leading to loss of signs of life either in front of the team or within 5 minutes of arrival to the trauma center. Reported success rates are more favorable in penetrating injury than in blunt, and in knife wounds better than in gunshot.

Monitoring of the patient should already be underway with pulse oximetry, capnometry (if mechanical ventilation is being used), and display of the ECG. Blood sampling should be performed by protocol and include (at a minimum) type and screen, a hemogram, a basic metabolic panel, and base deficit with lactate determination. Coagulation studies are often useful as a baseline determination because it is a comprehensive metabolic panel if there is a chance of major intra-abdominal injury. Patients who are ventilated and those with burn with potential inhalation injury (including CO poisoning) require arterial blood gas analysis. In all but the most minor trauma, a bladder catheter should be inserted after the absence of blood at the urethral meatus is verified. The urine should be inspected for gross blood or microscopic hematuria to exclude genitourinary injury. The Foley system should have an urimeter to record subsequent urine output.

Adequately resuscitated patients should make 0.5 to 1 mL/kg/h of urine and have lactate levels that trend to below 2.5 mmol/L. Persisting oliguria or metabolic acidosis should prompt a search for a perfusion defect.

If an oxygenation, ventilation, or perfusion defect persists at this point, a chest radiograph must be performed to exclude an undetected thoracic injury or a hemodynamically compromising pelvic fracture. Otherwise, imaging strategies depend on local custom. The time-honored recommendation that every patient undergo plain radiography of the cervical spine (three views), chest (anteroposterior view), and pelvis remains valid and appropriate for smaller hospitals where CT scan equipment is often located some distance from the emergency department or not available 24 hours a day. Many major trauma centers have installed close-by scanners and have operationally shifted to the rapid use of comprehensive CT scan that includes the brain and cervical spine, followed by infusion of intravenous contrast with the scan continued caudally through the chest, abdomen, and pelvis. Such a sequence can be performed with current generation scanners in less than 10 minutes and yield far more comprehensive information than conventional plain films. Again, assessment and clinical suspicion determine the indication for each anatomic area to be surveyed.

SECONDARY SURVEY

The secondary survey, which must be completed before the patient leaves the trauma resuscitation area for additional imaging, is simply a head-to-toe physical examination that includes a finger or tube in every natural orifice in patients who are unconscious and therefore cannot describe their symptoms. (In such cases, the stomach should be drained with a nasal or oral gastric tube. The rectum should be checked for injury. The vagina should be inspected for injury, and any foreign body [tampon] should be removed.) The purpose of the secondary survey is to complete an inventory of the evident injuries and direct additional imaging as necessary (e.g., a skeletal radiograph at the site of a deformity, pain, or extremity hematoma). The secondary survey is also the time to at least temporarily stabilize obvious fractures with splints, traction apparatus, and pelvic compression for unstable pelvic fractures.

NEXT STEPS

Details of further care depend on the injury pattern. Experience suggests a few points that can help the surgeon avoid common pitfalls.

1. Some member of the team should be assigned to document the resuscitation. This might be a nurse or nonphysician provider. Whoever it is should not have any other responsibilities, except to take a brief focused history from the patient or personal representative. The key elements include allergies, medications, significant history, time of the last oral intake, and the events leading up to the trauma. (The mnemonic here is AMPLE.)
2. Patients with unstable conditions belong in a treatment area, such as the operating room or the interventional radiology suite. The trauma bay in the emergency department is a place to initiate resuscitation while defining a treatment plan. It is not a place to execute a treatment plan.
3. A head CT scan is tempting to obtain in patients with unstable conditions with multiple injuries. Experience suggests that

patients with serious isolated head injuries are rarely hemodynamically unstable. The question arises in the patient who has multiple injuries, including a head injury, and is poorly responsive to the initial resuscitation—to scan or to explore? If the source of bleeding is known, it should be controlled and the blood pressure normalized. This is by far the best treatment for the injured brain, which can be scanned as soon as temporary control of the hemorrhage is obtained or simultaneously addressed in the operating room by neurosurgery. The situation is harder when FAST and plain films fail to show a bleeding source or explanation for the instability. In such cases, a CT scan can be considered as one of a collection of bad options, if mechanism suggests a devastating head injury.

4. Pouring blood into a patient who is bleeding is most helpful after bleeding is controlled surgically. Attempting to resuscitate a patient to normal hemodynamics before the offending vessels are clamped wastes time and blood, both of which are costly to the patient.
5. After initial treatment (operative, interventional, or merely supportive) and the patient's return to the intensive care unit or to the ward, someone must conduct a tertiary survey. It is best performed when the patient can communicate but should always be done within the first postinjury day. The tertiary trauma survey is a comprehensive review of the medical record with emphasis on the mechanism of injury and pertinent comorbid factors, such as age. It includes the repetition of the primary and secondary surveys, a review of all laboratory data, and a review of images and their official interpretation. New physical findings are quite common and require further studies to exclude missed injuries.

Airway Management in the Trauma Patient

Samuel M. Galvagno, Jr., DO, PhD, and Thomas M. Scalea, MD

Airway management is the first step in the management of the trauma patient to prevent hypoxia and cellular hypoperfusion. Cervical spine instability, brain injury, hemodynamic instability, lack of patient cooperation, risk of aspiration, time pressure, and facial injuries can make this more challenging. Techniques for rapid establishment and maintenance of a patent airway, with emphasis on the importance of adequate oxygenation and ventilation throughout all phases of airway management, are described.

INITIAL AIRWAY ASSESSMENT AND THERAPY

A patient who is alert, oriented, and speaking normally without injuries to the head or neck has an adequate airway. Any change in voice, report of a sore throat, dyspnea, tachypnea, use of accessory muscles, noisy breathing (snoring or stridor), or unexplained agitation may be a sign of imminent airway compromise.

A systematic approach to airway assessment should predict a potentially difficult airway. This should follow the line of sight of the provider from the upper incisors to the vocal cords, with a focus on the inside of the mouth and pharynx, and conclude with examination of the mandibular space, neck, and chest. Figure 1 and Boxes 1 and 2 describe clinical tests that can be used to determine whether one is likely to have a poor view of the vocal cords during direct laryngoscopy.

Oxygen therapy helps maintain pulse oximetry (SpO_2) above 92%. A nonrebreathing mask provides a fractional concentration of oxygen in inspired gas (FiO_2) of more than 90% and should be the initial choice. Oxygen therapy can be modified later to a simple face mask (FiO_2, 35% to 55%), a Venturi mask (FiO_2, 24% to 60%), or a nasal cannula (FiO_2, 24% to 44%).

If the airway is compromised and the patient is not ventilating and oxygenating adequately, noninvasive interventions can maintain oxygenation during preparation for definitive airway. Bag-valve mask ventilation with 15 L/min of oxygen should be initiated (FiO_2, 90% to 100%). Independent risk factors that predict an inability to perform bag-mask ventilation include male gender, a history of sleep apnea, Mallampati 3 or 4 status, and the presence of a beard. The spinal cord must be protected until spinal cord injury has been excluded.

Oropharyngeal or nasopharyngeal airways alleviate airway obstruction by the tongue. Oral airway size can be gauged with measurement of the airway from the corner of the patient's mouth to the external auditory canal. Nasopharyngeal airways should not be used if the patient has a suspected craniofacial injury for fear of inserting the devices through an injured cribriform plate into the brain. The chin-lift method gently lifts the mandible without hyperextension of the neck and may open the airway. The jaw-thrust maneuver can help by displacing the mandible forward while applying pressure to both angles of the mandible. Either can be performed during in-line cervical stabilization.

RAPID SEQUENCE INDUCTION AND INTUBATION

In most trauma patients, rapid sequence induction and intubation (RSII) is used to establish a definitive airway. RSII is a highly organized sequence of events that starts with preoxygenation for at least 3 minutes. The "6 Ps" of RSII describe the recommended sequence (Table 1). During the preparatory stage, a suction catheter is prepared

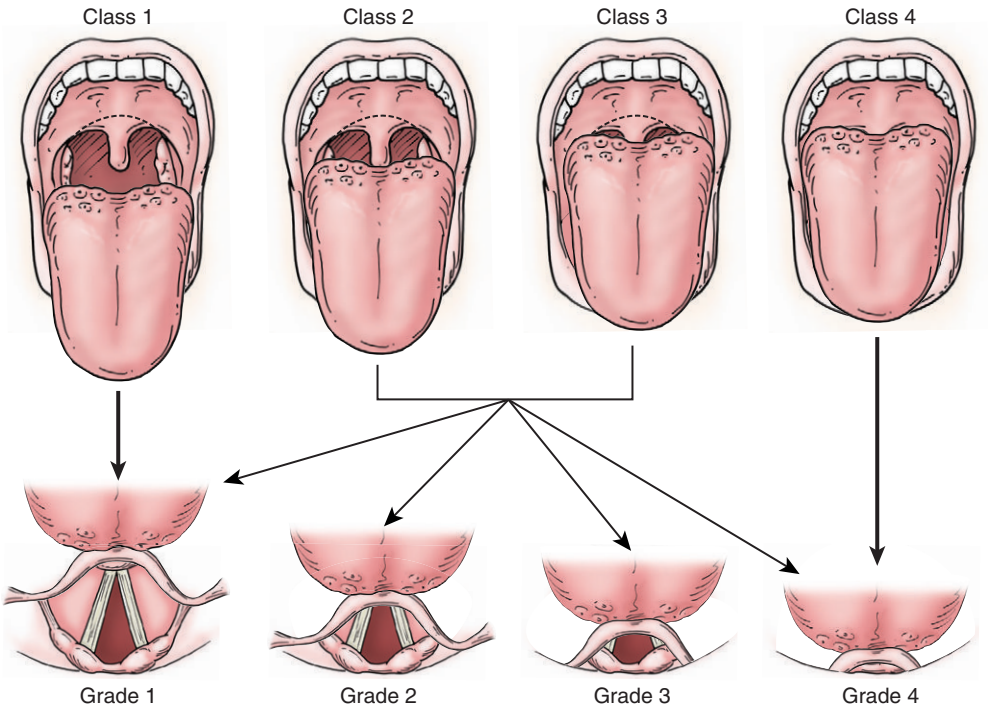

FIGURE 1 The Mallampati classification. The higher the class, the worse the Cormack-Lehane view of the vocal cords during direct laryngoscopy. *(From Lalwani AK, ed:* Current diagnosis and treatment in otolaryngology: head and neck surgery, *ed 2,* http://accessmedicine.com, *Accessed July 28, 2013.)*

BOX 1: Mandibular protrusion test

Class A
Lower incisors can be protruded anterior to the upper incisors.

Class B
The lower incisors can be brought edge to edge with upper incisors.

Class C
The lower incisors cannot be brought edge to edge with upper incisors.

The test assesses jaw mobility. Class A portends better vocal cord visualization during direct laryngoscopy than class B or C.

BOX 2: Indications of potentially difficult airway

Prominent incisors or abnormal dentition
Mandibular protrusion (see Box 1)
Mouth opening (>3 fingerbreadths or 5-6 cm is normal)
Mallampati classification (see Figure 1)
Thyromental distance (>3 fingerbreadths or 6 cm is normal)
Cervical range of motion (should *not* be tested in any patient with a suspected C-spine injury)
Anatomic abnormalities (masses, swelling)
Thickness of neck
Length of neck (shorter neck associated with difficult intubation)

TABLE 1: Sequence of steps for rapid sequence induction and intubation

RSII step	Time interval	Pharmacologic agents
Preoxygenation	0-3 min	Oxygen
Premedication	3 min	Induction agent ± fentanyl, lidocaine, atropine, defasciculation agents (vecuronium, rocuronium; usually 1/10 the induction dose)
Paralysis	3.5-5.5 min	Midazolam, ketamine, etomidate, propofol, or other induction agents *followed by* succinylcholine or rocuronium
Placement	6-6.5 min	Oxygen
Performance	7-7.5 min	Oxygen
Postintubation management	7.5 + min	Oxygen, sedatives, analgesics, etc.

RSII, Rapid sequence induction and intubation.

and tested, a source of oxygen is readied for connection, a pulse oximeter is attached to the patient, pharmacologic agents are prepared, and airway equipment is organized. RSII ideally requires at least four providers: one to apply cricoid pressure, one to maintain in-line cervical stabilization, one to ventilate with a bag-valve mask (BVM) and intubate, and one to administer drugs and assist with airway devices (Figure 2).

Many practitioners find that gentle mask ventilation (inspiratory pressure, <20 cm H_2O) is acceptable during the induction sequence and may help prevent hypoxemia in obese, pregnant, pediatric, and critically ill patients. This also tests for the adequacy of mask ventilation in the event that intubation attempts fail.

Before paralytics are given, an induction agent is administered (Table 2). Paralytics are recommended as part of RSII because omission of neuromuscular blockade results in suboptimal intubation conditions. Either succinylcholine (1 to 1.5 mg/kg) or rocuronium (0.8 to 1.2 mg/kg) is administered for paralysis. Succinylcholine can be administered intramuscularly if an intravenous line is not established, but an increased dose of 3 to 4 mg/kg is recommended for this route. Both succinylcholine and rocuronium provide optimal intubation conditions when dosed appropriately.

FIGURE 2 Four providers are recommended for securing the airway. Providers are assigned to: (1) ventilate with the bag-valve mask and intubate; (2) maintain in-line cervical stabilization; (3) administer cricoid pressure; and (4) push drugs and assist with airway devices.

Priming doses of nondepolarizing agents are usually not used in trauma patients because these agents must be administered at least 3 minutes before the loading dose of muscle relaxant. In elderly or debilitated patients, pretreatment with a small dose of muscle relaxant may predispose to aspiration. Succinylcholine is contraindicated in patients with burns, open globe injuries, neuromuscular disorders, hyperkalemia, pseudocholinesterase deficiency, severe crush injuries, and chronic paralysis. Rocuronium, a nondepolarizing agent, is an alternative, but this agent cannot be administered intramuscularly and the duration of action is much longer (typically up to 45 minutes) than in succinylcholine (6 to 10 minutes).

Use of opioids may be considered during RSII. Fentanyl (2 μg/kg), alfentanil (20 to 30 μg/kg), or remifentanil (1 μg/kg) may help attenuate hemodynamic responses to intubation in unpremedicated cases. Opioids alone do not provide adequate amnesia and thus are usually not used as sole induction agents for RSII. Midazolam, a short-acting benzodiazepine with excellent amnestic properties, is often used. After preoxygenation, lidocaine may be given to attenuate increases in intracranial pressure, although a paucity of data exists to support this.

ENDOTRACHEAL INTUBATION

Endotracheal intubation remains the first-line standard intervention for securing the airway in trauma patients. Cricoid pressure (backward and upward application of pressure to the cricoid cartilage) occludes the esophagus and prevents regurgitation. However, the technique is often incorrectly applied and may worsen laryngoscopic views. If the laryngoscopic view worsens with the technique, pressure can simply be released or adjusted as necessary.

Cervical immobilization is critical in any patients at risk for cervical spine injury. Manual in-line stabilization has been shown to be

TABLE 2: Properties of induction agents commonly used during airway management in trauma patients

Induction agent	Dose for RSII	Onset	Duration of action	Comment
Propofol	1-3 mg/kg	10-30 s	8-10 min	Dose usually reduced, sometimes by as much as 1/10 the recommended induction dose; causes decreased systemic vascular resistance and hypotension
Ketamine	1-2 mg/kg IV 2-4 mg/kg IM	30-60 s	5-20 min	Acceptable for use in patients with increased ICP; direct myocardial depressant but has indirect stimulatory effects (best avoided in patients with coronary artery disease)
Etomidate	0.2-0.3 mg/kg	30-45 s	10-20 min	A single dose causes adrenocortical suppression; recent evidence supports safety in septic shock
Remifentanil	1 μg/kg	30-60 s	<10 min	250 times more potent than morphine; may cause hypotension; not a reliable amnestic; does not accumulate; broken down by nonspecific esterases
Midazolam	0.3-0.6 mg/kg	2-3 min	20-30 min	When combined with opioids, can cause marked hypotension and respiratory depression

ICP, Intracranial pressure; *IM,* intramuscularly; IV, intravenously; *RSII,* rapid sequence induction and intubation.

superior for prevention of inadvertent movement of the cervical spine during intubation as compared with a cervical collar alone. During intubation, one provider is dedicated to maintain manual in-line stabilization.

A laryngoscope with a MacIntosh or McGill blade should be held in the left hand and inserted into the right side of the patient's mouth, displacing the tongue to the left. The airway structures are lifted into view, avoiding use of the blade as a fulcrum on the teeth. The epiglottis and vocal cords are visualized. The endotracheal tube should be gently inserted with the cuff past the vocal cords and inflated with enough air to provide a good seal (<30 cm H_2O). In general, intubation attempts should not take more than 30 seconds. Verification of tube placement is accomplished with auscultation of bilateral lung sounds, observation of chest rise, absence of epigastric/gastric gurgling or distension, and presence of end-tidal carbon dioxide with either a colorimetric device or continuous capnography. If a colorimetric device is used, the color indicator should change from purple to yellow, and at least six ventilations with an appropriate color change should be observed to avoid potential false-positive results. A chest radiograph confirms tube position.

In patients with a poor visualization of cords, a gum elastic bougie may used. The bougie is a flexible 60-cm 15F introducer with a Coude tip angled at 40 degrees, 3.5 cm from the distal end.

The bougie is lubricated and inserted with the Coude tip directed anteriorly and advanced until at the level of the tracheal rings. The endotracheal tube is then advanced over the bougie into the trachea. Videolaryngoscopy (VL) has evolved as a technology that allows direct visualization of the airway by all airway team members. VL can be used at all stages of intubation, including initial laryngoscopy.

SUPRAGLOTTIC AIRWAY DEVICES

A variety of supraglottic devices exist for use when attempts at endotracheal intubation or BVM ventilation fail. The laryngeal mask airway, multilumen esophageal airway (Combitube, Kendall-Sheridan Corporation, Argyle, NY).), and the laryngeal tube airway are three devices that can be placed without direct visualization of the glottis. Although these devices enable ventilation, either by providing a seal around the laryngeal inlet or occluding the esophagus, none of these devices represent a definitive airway. Each of these devices requires additional training, and all must eventually be replaced with a definitive airway.

AWAKE FIBEROPTIC INTUBATION

When patients are suspected of having cervical spinal cord injuries but do not need *emergent* intubation, awake fiberoptic intubation (AFOI) may be used to secure the airway. This method minimizes cervical spine movements, preventing neurologic impairment. Careful titration of sedation is mandatory for AFOI because spontaneous ventilation is needed with this technique. Oxygen is delivered via a nasal cannula. Patients are premedicated with glycopyrrolate (0.2 to 0.4 mg) to reduce secretions.

Sedation with opioids or benzodiazepines can be helpful. Opioids can cause synergistic respiratory depression when used with benzodiazepines. Opioids may be used instead of benzodiazepines, keeping in mind that opioids do not provide reliable amnesia. Lidocaine ointment is applied to the posterior tongue via a tongue depressor to anesthetize the glossopharyngeal nerve. Cotton balls (with strings attached to ensure easy retrieval from the airway) are soaked in 4% lidocaine. With either a Magill forceps or right angle tonsil holder, the cotton balls are gently introduced deep into the piriforms and held in place for 60 to 90 seconds on each side, effectively anesthetizing both branches of the superior laryngeal nerve. Finally, an oral airway is inserted (to prevent biting of the fiberoptic scope), and the fiberoptic scope is introduced.

Once the vocal cords are visualized, 1 to 2 mL of 1% or 2% lidocaine is sprayed through the fiberoptic scope directly on the vocal cords, anesthetizing the recurrent laryngeal nerve. Once all three nerves are anesthetized, the endotracheal tube can safely be inserted with either a videolaryngoscope (i.e., "awake" video laryngoscopy) or over a fiberoptic bronchoscope. Careful attention must be paid to the amounts of lidocaine used because a dose greater than 5 mg/kg may result in anesthetic toxicity. The technique can be modified accordingly for nasotracheal intubation with use of topical vasoconstrictors and anesthetics to anesthetize and mitigate bleeding in the nasal passages.

AIRWAY MANAGEMENT DECISION MAKING

Figure 3 provides a decision algorithm for patients in need of an immediate airway. Initial priorities always include adequate preoxygenation and in-line cervical immobilization. In trauma patients, the option to wake the patient, as one would do for an elective surgical procedure, is not feasible. After a third failed attempt at intubation, an laryngeal mask airway (LMA) can be inserted to facilitate the transition to a definitive airway via fiberoptic intubation or intubation through the LMA. However, if the airway cannot be expeditiously secured after the third laryngoscopy attempt, a surgical airway is necessary. The rate of conversion to a surgical airway has been reported to range from 0.2% to 2%.

SURGICAL AIRWAY

Cricothyroidotomy is usually the surgical technique of choice (Figure 4). The patient is placed in the supine position with the neck in a neutral position. After the neck is prepped and draped, the thyroid notch, thyroid cartilage, cricothyroid membrane, cricoid cartilage, and trachea are identified with palpation. With the thyroid cartilage stabilized with one hand, a 2.0-cm to 2.5-cm vertical incision is made over the cricothyroid membrane with a #10 or #11 surgical blade. A hemostat or tracheal spreader is introduced into the incision and rotated 90 degrees to open the airway. Either a cuffed endotracheal tube (5.0 or 6.0 size) or tracheostomy tube is inserted through the cricothyroid membrane incision. The cuff is inflated, and placement of the tube is confirmed with the usual methods.

In the event of insufficient time to complete the dissection for a full cricothyroidotomy, a needle cricothyroidotomy can be performed. The anatomic landmarks are identified, and a 12-gauge or 14-gauge needle attached to a 5-mL to 10-mL syringe is used to puncture the skin in the midline directly over the cricothyroid membrane. A small incision with a #11 blade may enable passage of the needle through the skin. Once the needle has passed through the skin, the needle is angled 45 degrees caudally for insertion through the lower half of the cricothyroid membrane. Aspiration of air should be noted once the needle is in the airway, and the syringe is removed. The needle is then connected to a jet ventilation device. Alternatively, a 3-mL syringe can be connected to the needle and attached to a plastic endotracheal tube connector. This allows for connection to a BVM device. Ventilation via a needle cricothyroidotomy only maintains oxygenation for approximately 30 to 45 minutes; hypercarbia may quickly develop. For both needle and surgical cricothyroidotomies, the airway is typically converted to a formal tracheostomy by 24 to 48 hours.

When and Where to Intubate? Field Versus Emergency Department or Trauma Unit Endotracheal Intubation

Several reports over the past decade have described the potential risks associated with endotracheal intubation, and these data must be considered carefully before endotracheal intubation is used to secure the airway in the prehospital environment. Rates of successful endotracheal intubation by emergency medical services (EMS) providers vary widely by jurisdiction and have been reported to be less than 70% in some studies. One patient population that has been shown to benefit from early rapid sequence intubation is patients with traumatic brain injury (TBI); at least one randomized controlled trial has shown improved functional outcomes in adults with severe TBI. Nonetheless, in other studies, patients intubated in the field have been shown to have delays to definitive neurosurgical procedures, increased risk of pneumonia, worse functional outcomes, and higher mortality.

The American College of Emergency Physicians (ACEP), the American College of Surgeons Committee on Trauma (ACS-COT), and the National Association of EMS Physicians (NAEMSP) endorse the use of drug-assisted endotracheal intubation by nonphysician EMS providers, but only for providers who have adequate training and regular practice. EMS providers who perform drug-assisted endotracheal intubation must possess training, knowledge, and experience in the techniques and drugs used to perform endotracheal intubation. Robust medical direction, proper patient selection, ongoing airway management training, standardized intubation protocols, and quality assurance are essential components for any prehospital program that chooses to use drug-assisted intubation for trauma patients in the prehospital arena. Drug-assisted intubation should not be considered mandatory for all trauma patients, and each EMS system must evaluate whether there is a specific need for the procedure and adequate resources to develop and maintain a safe protocol. In systems where endotracheal intubation is not feasible and safe in the prehospital environment, the airway should be managed with airway adjuncts, supraglottic devices, and properly performed bag-valve mask ventilation until the patient arrives in the emergency department or trauma resuscitation unit.

The Surgeon's Use of Ultrasound in Thoracoabdominal Trauma

Christopher J. Dente, MD, and
Grace S. Rozycki, MD, MBA

For nearly 15 years, surgeons in American trauma centers have successfully performed, interpreted, and taught ultrasound examinations of patients who are injured or critically ill. Real-time imaging allows the surgeon to receive instantaneous information about the clinical condition of the patient and, therefore, helps to expedite the patient's management. In many trauma centers, ultrasound machines are owned by surgeons and are part of the standard equipment in the trauma resuscitation room. While diagnostic peritoneal lavage and computed tomographic (CT) scanning are still valuable diagnostic tests for the detection of intraabdominal injury in patients, ultrasound is faster, noninvasive, and painless. As such, it is an examination that is well tolerated not only by adults but also by children. Moreover, the portability of the ultrasound machine makes it useful not only in the hospital setting but also in more austere settings.

As an extension of the physical examination, surgeons routinely use ultrasound in the acute setting to determine the presence or absence of fluid in the peritoneal cavity, the pericardium, and the pleural cavities. Additional uses of this modality include the detection of pneumothoraces and sternal fractures. What follows is a discussion of the use of ultrasound in blunt and penetrating thoracoabdominal trauma, with an additional discussion of the use of ultrasound in forward settings and in space exploration.

FOCUSED ASSESSMENT FOR THE SONOGRAPHIC EVALUATION OF THE TRAUMA PATIENT

The *F*ocused *A*ssessment for the *S*onographic evaluation of the *T*rauma (FAST) patient is a rapid diagnostic examination to assess patients with potential injuries to the thorax or abdomen. The test sequentially surveys for the presence or absence of fluid in the pericardial sac and in the dependent abdominal regions, including the Morison's pouch region of the right upper quadrant (RUQ), the left upper quadrant (LUQ) behind the spleen and between the spleen and kidney, and the pelvis including the area posterior to the bladder.

The FAST is performed in a specific sequence; the pericardial area is visualized first so that blood within the heart can be used as a standard to set the gain. Most modern ultrasound machines have presets so the gain does not need to be reset each time the machine is turned on. Occasionally, if multiple types of examinations are performed with different transducers, the gain should be checked to ensure that intracardiac blood appears anechoic. This maneuver ensures that hemoperitoneum will also appear anechoic and will be readily detected on the ultrasound image. The abdominal part of the FAST should begin with a survey of the RUQ, which is the location within the peritoneal cavity where blood most often accumulates and is most readily detected with the FAST. In a multicenter trial of 275 blunt and penetrating trauma patients, investigators found that regardless of the injured organ (with the exception of those patients who had an isolated perforated viscus), blood was most often identified on the RUQ image of the FAST. This can be a time-saving measure because when hemoperitoneum in the RUQ view is identified on the FAST examination of a hemodynamically unstable patient, then that image alone, in combination with the patient's clinical picture, is sufficient to justify an immediate abdominal operation. However in the hemodynamically stable patient, the examination of the RUQ is followed by the LUQ and pelvis as discussed later.

Technique

Ultrasound transmission gel is applied on four areas of the thoracoabdomen, and the examination is conducted in the following sequence: the pericardial area, RUQ, LUQ, and the pelvis (Figure 1). Abdominal structures are best imaged with a lower frequency transducer, which allows for deeper penetration into tissues (sacrificing some resolution). Most ultrasound probes are now capable of imaging in multiple frequencies, which allows achievement of the best balance of resolution (higher frequency) and tissue penetration (lower frequency) based on a patient's individual body habitus.

To begin the examination, a 3.5-MHz convex transducer is oriented for sagittal or longitudinal views and positioned in the subxiphoid region to identify the heart and to examine for blood in the pericardial sac. The normal and abnormal views of the pericardial area are shown in Figure 2. The subxiphoid image is usually not difficult to obtain, but a severe injury to the chest wall, a very narrow subcostal area, subcutaneous emphysema, or morbid obesity can prevent a satisfactory examination. Both of the latter conditions are

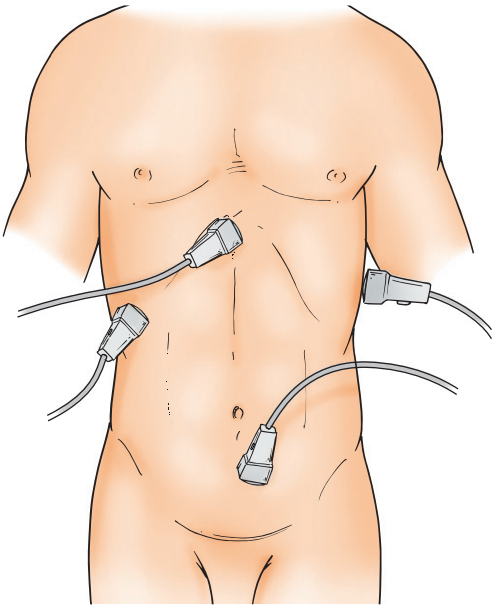

FIGURE 1 Transducer positions for FAST: pericardial, right upper quadrant, left upper quadrant, and pelvis.

associated with poor imaging because air and fat reflect the sound wave too strongly and prevent penetration into the target organ. If the subcostal pericardial image cannot be obtained or is suboptimal, a parasternal ultrasound view of the heart should be performed.

Next, the transducer is placed in the right anterior or midaxillary line between the 11th and 12th ribs to identify a sagittal section of the liver, kidney, and diaphragm (Figure 3). The presence or absence of blood is sought in Morison's pouch and in the right subphrenic space. Next, attention is turned to the LUQ and with the transducer positioned in the left posterior axillary line between the 10th and 11th ribs. The spleen and kidney are visualized and blood is sought in between the two organs and in the left subphrenic space (Figure 4). The splenic window is often the most difficult window, and the transducer should be placed more posterior (posterior axillary line) and superior (i.e., one to two rib spaces higher) than with the RUQ window.

Finally, the transducer is directed for a transverse view and placed about 4 cm superior to the symphysis pubis. It is swept inferiorly to obtain a coronal view of the full bladder and the pelvis, examining for the presence or absence of blood (Figure 5).

Accuracy of the FAST

Improper technique, inexperience of the examiner, and inappropriate use of ultrasound have long been known to adversely impact

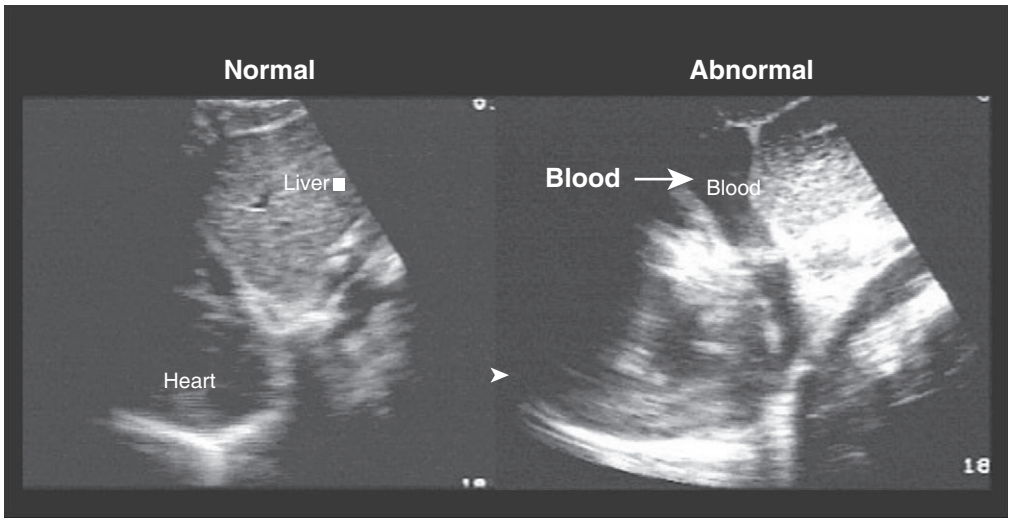

FIGURE 2 Normal sagittal view of pericardial area showing pericardium as single echogenic line *(left)*. Sagittal view of pericardial area showing separation of visceral and parietal areas of pericardium with blood *(arrow)* that appears anechoic *(right)*.

ultrasound imaging. The etiology of injury, the presence of hypotension on admission, and select associated injuries have also been shown to influence the accuracy of this modality. Failure to consider these factors has led to inaccurate assessments of the accuracy of the FAST by inappropriately comparing it to a CT scan and not recognizing its role in the evaluation of patients with penetrating torso trauma. Both false positive and negative pericardial ultrasound examinations have been reported to occur in the presence of a massive hemothorax or mediastinal blood. Repeating the FAST after the insertion of a tube thoracostomy improves the visualization of the pericardial area and decreases the number of false positive and false negative studies. Notwithstanding these circumstances in which false studies may occur, a rapid focused ultrasound survey of the subcostal pericardial area is a very accurate method to detect hemopericardium in most patients with penetrating wounds in the "cardiac box." In a large study of patients who sustained either blunt or penetrating injuries, the FAST was 100% sensitive and 99.3% specific for detecting hemopericardium in patients with precordial or transthoracic wounds. Furthermore, the use of pericardial ultrasound has been shown to be especially helpful in the evaluation of patients who have no overt signs of pericardial tamponade. This was highlighted in a study in which 10 of 22 patients with precordial wounds and hemopericardium on the ultrasound examinations had admission systolic blood pressures over 110 mm Hg and were relatively asymptomatic. Based on these signs and the lack of symptoms, it is unlikely that the presence of cardiac wounds would have been strongly suspected in these patients, and therefore this rapid ultrasound examination provided an early diagnosis of hemopericardium before the patients underwent physiologic deterioration.

The FAST is a focused examination for the detection of fluid in dependent areas of the abdomen and designed to answer the simple question of "fluid or no fluid." Therefore, its results should not be compared to those of a CT scan because the FAST does not readily identify intraparenchymal or retroperitoneal injuries. Select patients considered to be at high risk for occult intraabdominal injury should undergo a CT scan of the abdomen regardless of the results of the FAST examination. These patients include those with fractures of the pelvis or thoracolumbar spine, major thoracic trauma especially pulmonary contusion and lower rib fractures, and hematuria.

Recent Advances and Organ Specificity

As surgeons have become more facile with ultrasound examinations and as technology has improved, extensions of the FAST examination have been described. Again, it is noted that the standard FAST examination is designed to accurately answer two simple questions: Is there fluid in the peritoneal cavity, and is their fluid in the pericardial sac?

The use of ultrasound for more complex diagnostic interventions is described below, but these areas are less well studied and beyond the purview of the traditional FAST examination.

A prospective, multicenter trial conducted by members of the Western Trauma Association reported on the use of ultrasound to serially evaluate patients with documented solid organ injuries (SOI) after trauma. The so-called "BOAST" examination, or the *B*edside *O*rgan *A*ssessment with *S*onography after *T*rauma, was performed by a limited number of experienced surgeon-sonographers in 126 patients with 135 SOI in 4 American trauma centers. This study, performed over nearly 2 years, was designed to be a more thorough abdominal ultrasound examination, with multiple views obtained of each solid organ (kidneys, liver, and spleen). Criteria for enrollment included normal hemodynamics, absence of peritonitis or other need for urgent laparotomy, and lack of excessive blood transfusion in the attending physician's judgment. All patients were victims of blunt trauma, with a mean injury severity score (ISS) of nearly 15.

Overall, only 34% of injuries to solid organs were seen with BOAST, yielding an error rate of 66%. None of the 34 Grade I injuries were identified, and only 13 (31%) of the Grade II injuries were identified. Sensitivities for Grades III and IV injuries ranged from 25% to 75%, and only one Grade V injury (to the liver) was examined and positively identified. It is noted, however, that 11 patients developed 16 intraabdominal complications (8 pseudoaneurysms, 4 bilomas, 3 abscesses, and 1 necrotic organ), and 13 (81%) were identified by the sonographers. This study emphasizes that ultrasound, in most surgeons' hands, should not be considered a reliable modality for diagnosis and grading of SOI, although it may be acceptably accurate in the diagnosis of posttraumatic abdominal complications in patients who undergo nonoperative management for solid organ injury.

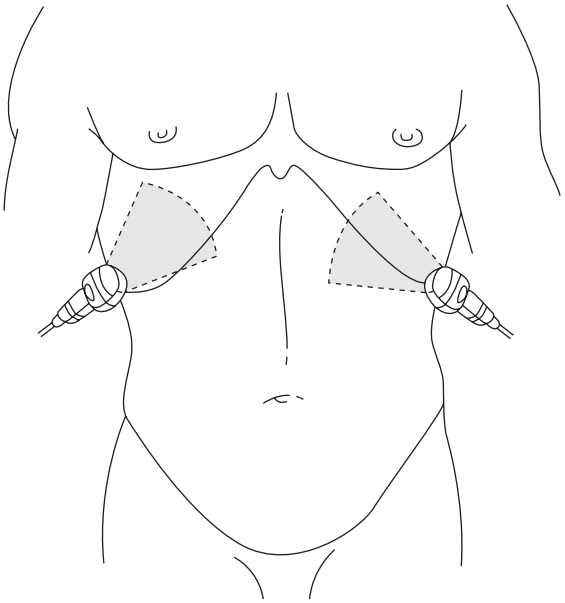
In Europe, preliminary work using Power Doppler to identify specific organ injuries has been published in recent years. Many of these examinations include the use of a sonographic contrast agent injected peripherally during the scan. In one study, the authors were able to document contrast extravasation in 20 of 153 patients (13%). Extravasation was seen not only from the spleen, liver, and kidney after trauma but also in postoperative patients (aortic aneurysm repair, postsplenectomy) and in a patient with a ruptured aortic aneurysm. In 9 of 20 patients, CT scan was performed, and all 9 confirmed contrast extravasation. In the 133 patients without extravasation, the absence of active bleeding was inferred by a subsequent CT scan in 82 patients, surgical data in 13 patients, and clinical follow-up in 38 cases, with no cases of active bleeding missed by ultrasound. Thus, the addition of ultrasonic contrast agent and Power Doppler may be of some benefit in the diagnosis of specific injuries. It should be emphasized, that the FAST examination in most American trauma centers is used simply as a screening tool to identify the presence or absence of hemoperitoneum or hemopericardium in a trauma patient.

TRAUMATIC HEMOTHORAX

A focused thoracic ultrasound examination was developed by surgeons to rapidly detect the presence or absence of a traumatic hemothorax in patients during the American College of Surgeons Advanced Trauma Life Support (ATLS) secondary survey. This examination is worthwhile because it dramatically shortens the interval from the diagnosis of a hemothorax to the insertion of a thoracostomy tube.

Technique

The technique for this examination is similar to that used to interrogate the upper quadrants of the abdomen in the FAST and also uses the same type and frequency of transducer. It is performed one to two rib spaces higher than the RUQ and LUQ FAST views. Ultrasound transmission gel is applied to the right and left lower thoracic areas in the mid to posterior axillary lines between the 9th and 10th intercostal spaces (Figure 6). The transducer is slowly advanced cephalad to identify the hyperechoic diaphragm and to interrogate the supradiaphragmatic space for the presence or absence of fluid (Figure 7) that appears anechoic. In the positive thoracic ultrasound



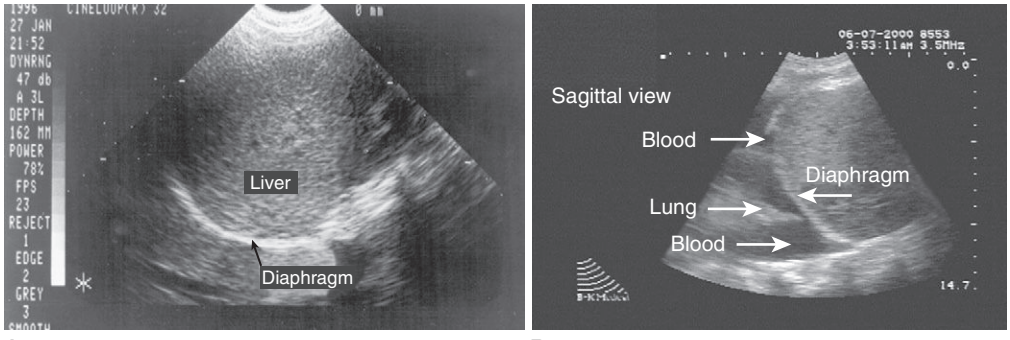


FIGURE 6 Transducer positions for thoracic ultrasound examination (detection of hemothorax).

A B

FIGURE 7 **A,** Sagittal view of liver, kidney, and diaphragm. Note supradiaphragmatic (lung) area but absence of pleural effusion. **B,** Sagittal view of right supradiaphragmatic space. The right hemothorax contains fluid (blood) that appears anechoic.

examination, the hypoechoic lung can be seen "floating" amidst the fluid. The same technique can be used to evaluate a critically ill patient for a pleural effusion.

Accuracy

Surgeons at Grady Memorial Hospital have examined the accuracy of this examination in 360 patients with blunt and penetrating torso injuries. They compared the time and accuracy of ultrasound with that of the supine portable chest x-ray and found both to be very similar: 97.4% sensitivity and 99.7% specificity observed for thoracic ultrasound versus 92.5% sensitivity and 99.7% specificity for the portable chest x-ray. Performance times, however, for the thoracic ultrasound examinations were statistically much faster (P <0.0001) than those for the portable chest x-ray. Although it is not recommended that the thoracic ultrasound examination replace the chest x-ray, its use can expedite treatment in many patients and decrease the number of chest radiographs obtained.

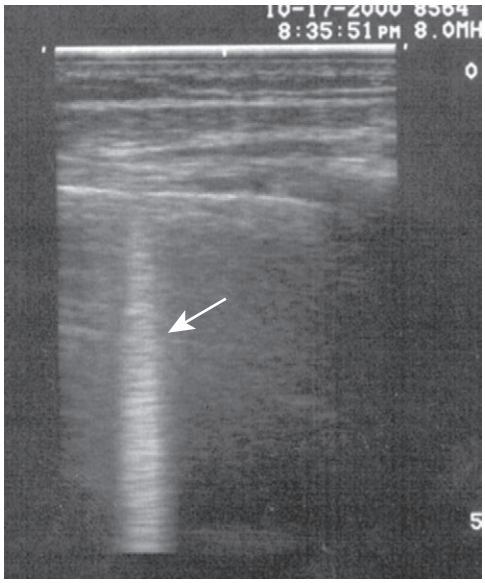

FIGURE 8 Comet tail artifact *(arrow)*.

PNEUMOTHORAX

Ultrasound examination is useful to the surgeon to evaluate a patient for a potential pneumothorax if (1) radiology equipment is not readily available; (2) inordinate delays for obtaining a chest x-ray are anticipated; or (3) numerous injured patients must be rapidly assessed and triaged. Although useful in the trauma resuscitation area, surgeons may also find this examination helpful to detect a pneumothorax in a critically ill patient after a thoracentesis procedure, or after discontinuing the suction on an underwater seal device.

Technique

A 5.0-MHz to 7.5-MHz linear array transducer is used to evaluate a patient for the presence of a pneumothorax. This higher frequency transducer allows for better resolution of superficial structures and the examination may be performed while the patient is in the erect or the supine position. Ultrasound transmission gel is applied to the right and left upper thoracic areas at about the 3rd to 4th intercostal space in the midclavicular line, and the presumed unaffected thoracic cavity is examined first. The transducer is oriented for longitudinal imaging, placed perpendicular to the ribs, and is slowly advanced medially toward the sternum and then laterally toward the anterior axillary line. The normal examination of the thoracic cavity identifies the rib (seen as black on the ultrasound image because it is a refraction artifact), pleural sliding, and a comet tail artifact. "Sliding" is the identification of the visceral and parietal layers of the pleura seen as hyperechoic superimposed pleural lines moving upon each other with respiration. When a pneumothorax is present, air becomes trapped between the visceral and parietal pleura and does not allow for the transmission of the ultrasound waves. Therefore, the visceral pleura is not imaged, and pleural sliding is not observed. The comet tail artifact is generated because of the interaction of two highly reflective opposing interfaces: air and pleura (Figure 8). When air separates the visceral and parietal pleura, the comet tail artifact is not visualized. If desired, the examination may be repeated with the transducer oriented for transverse views, and images obtained with the transducer parallel to the ribs.

Accuracy

Several studies have documented the sensitivity and specificity of ultrasound for the detection of a pneumothorax. Dulchavsky and colleagues from Detroit Receiving Hospital showed that ultrasound can be successfully used by surgeons to detect a pneumothorax in injured patients. Of the 364 patients (362 trauma; 18 spontaneous) evaluated with ultrasound, 39 had pneumothoraces, and ultrasound successfully detected 37 of them, yielding a 95% sensitivity. Pneumothoraces in two patients could not be detected because of the presence of significant subcutaneous emphysema. The authors recommended that when a portable chest x-ray cannot be readily obtained, the use of this bedside ultrasound examination for the identification of a pneumothorax can expedite the patient's management. In this authors' experiences, ultrasound is very sensitive for the detection of pneumothorax, and we have detected many that were seen only on subsequent thoracic CT scan. Thus, this test may be useful not only to rapidly diagnose a pneumothorax in a hemodynamically unstable patient but also to avoid an unnecessary chest tube in a patient who becomes hypotensive for unclear reasons.

STERNAL FRACTURE

Fractures of the sternum are visualized on a lateral x-ray view of the chest, but this film may be difficult to obtain in a multisystem injured patient. For this reason, an ultrasound examination of the sternum can rapidly detect a fracture while the patient is still in the supine position and, therefore, avoid the need to obtain an x-ray.

Technique

The ultrasound examination of the sternum is performed using a high-frequency linear array transducer that is oriented for sagittal or longitudinal views. Ultrasound transmission gel is applied over the sternal area while the patient is in the supine position. Beginning at the suprasternal notch, the transducer is slowly advanced in a caudad direction to interrogate the bone for a fracture, and then the examination is repeated with the transducer oriented for transverse views. The examination of the intact sternum is shown in Figure 9. A sternal fracture is identified on the ultrasound examination as a disruption of the cortical reflex (Figure 10). Investigators have found that the use of ultrasound for this diagnosis is as accurate as a lateral x-ray view of the chest.

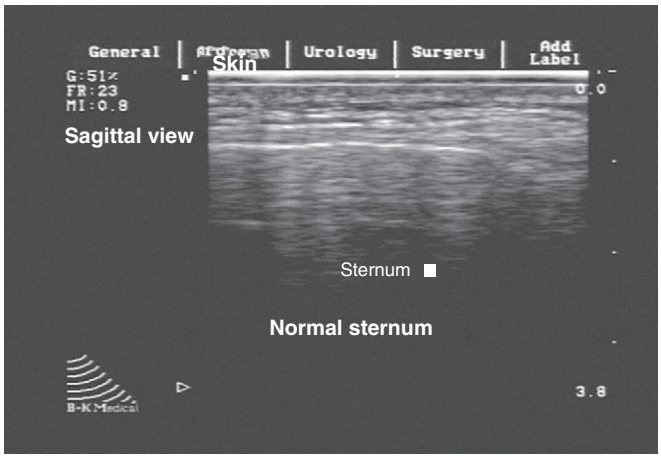

FIGURE 9 Sagittal view of sternum. Normal findings.

SPECIAL SITUATIONS

Ultrasound in the Pregnant Trauma Patient

Ultrasound would seem to be an ideal method of evaluating a pregnant patient with suspected blunt abdominal trauma because it is portable, noninvasive, and free of ionizing radiation. The American College of Surgeons ATLS course teaches that unrecognized abdominal trauma is one of the leading causes of death in the pregnant trauma patient. Concerns over changes in abdominal anatomy leading to difficulty in obtaining ultrasound images of the pregnant patient have not borne out in objective evaluation. Goodwin and colleagues reported on their 8-year experience with the FAST examination used to evaluate 127 injured pregnant patients. Five of 6 patients with hemoperitoneum were found to have fluid on FAST examination, yielding a sensitivity of 83%. Of the 120 patients without abdominal injury, 117 had true negative results (specificity 98%) and there were 3 false positive examinations due to serous intraperitoneal fluid. Furthermore, Brown and colleagues reported their experience with a more extensive ultrasound examination in 101 hemodynamically stable, pregnant patients with suspected blunt abdominal trauma. The median gestational age was just over 24 weeks. Patients underwent a standard abdominal ultrasound examination as well as an examination of the fetus and placenta by a registered ultrasound technician. The sensitivity of the examination was 80% and untrasound identified injuries to the placenta, spleen, liver, and kidney. None of the 96 patients with a negative ultrasound examination had injuries discovered later in their hospital course (specificity 100%). Thus, it would seem that ultrasound remains a good screening tool for the pregnant patient with blunt abdominal trauma.

Ultrasound in Penetrating Trauma

Ultrasound as used to evaluate patients with penetrating trauma has been studied much less extensively than its use for blunt trauma. Several of the larger, well-known series have included patients with penetrating trauma, and, as stated previously, the ultrasound of the pericardium has been shown to be accurate for diagnosis of injury in patients with penetrating injury to the "cardiac box." In a study of 32 patients with penetrating anterior chest trauma, ultrasound was used to diagnose 8 pericardial effusions with a reported 100% accuracy (8 true positive and 24 true negative examinations). Eight other patients were noted to have intraperitoneal fluid and underwent therapeutic exploration, including repair of the diaphragm, liver, spleen, stomach, small bowel, and adrenal gland. No false positive or fast negative examinations of the abdomen were reported. Other studies have shown that the accuracy of FAST after penetrating trauma is somewhat less, with one study reporting sensitivity for the detection of abdominal injury after penetrating trauma as low as 67%.

A report by Murphy and colleagues looked at the utility of ultrasound to diagnose fascial penetration after anterior abdominal stab wounds. In this study, 35 patients underwent ultrasound evaluation of their anterior abdominal fascia with an 8.0-MHz linear array transducer followed by a local wound exploration. While ultrasound had only a 59% sensitivity (13 out of 22 patients), it did have a 100% specificity with no false positive studies. Thus, if fascial penetration is noted on ultrasound, a more invasive wound exploration is probably not needed; however, a negative ultrasound evaluation is less helpful and does not preclude peritoneal penetration.

Use of Ultrasound in Austere Settings

Ultrasound on Deployment

The portability of ultrasound makes it ideal for use in forward settings. In fact, training courses are in place to teach military surgeons the use of the FAST examination, and handheld ultrasound is now routinely deployed within the British Defence Medical Services. In a survey of surgeons reviewing potential preventable casualties in Vietnam, ultrasound was the fourth most commonly mentioned advancement in technology (behind modern ventilators, CT scanners, and modern antibiotics) that may have assisted in better patient salvage.

Although up to 90% of war wounds are penetrating, ultrasound may allow quicker, more accurate triage decisions because patients with penetrating abdominal trauma with no or minimal hemoperitoneum may be transferred to the next echelon of care, where the study may be repeated or additional diagnostic tests undertaken. In a study from the Croatian conflict in 1999, FAST was shown to have a sensitivity of 86%, a specificity of 100%, and an accuracy of 97% when applied to 94 casualties evaluated over a 72-hour period. This was comparable to the accuracy achieved by the authors in their civilian experience with FAST in more than 1000 patients over the 3 years prior to the conflict. In a small series, FAST was used with excellent results in a British military hospital in Iraq. Fifteen casualties were evaluated with serial FAST examinations, and 14 of them had negative examinations on admission and again at 6 hours. One patient underwent laparotomy based on missle trajectory alone and two small perforations were discovered in the cecum. The other

13 patients recovered without sequelae. One examination was positive and led to immediate laparotomy in a patient with a Grade V liver injury after a motor vehicle collision.

Because ultrasound is portable enough to use in active combat situations, research is ongoing to evaluate the best method to teletransmit images obtained in the field. Several different satellite transmission systems have been evaluated, and high-quality images were able to be obtained in the majority of cases, although the balance between the weight of the system and the minimum image quality has still not been completely achieved. It is noted, that images can be transmitted from up to 1500 feet from the antennae without significant degradation. As technology advances, one would expect imaging systems to continue to become smaller and lighter with improved image quality, making ultrasound even more appealing as a modality for use in the forward setting.

Ultrasound in Space

Many of the same qualities that make ultrasound appealing for use in combat make it equally appealing as a diagnostic modality in space, where an injury might require abortion of a multimillion-dollar mission. Indeed, ultrasound is one of the only feasible diagnostic modalities on space missions, given size and weight restrictions. Also, ultrasound examinations are easily taught, and images can be relayed with minimal delay to physicians on the ground. ATLS procedures are also feasible in space, and lifesaving procedures could be performed based on ultrasound findings.

Ultrasound has been used in space for several decades. It has been ultrasound technology that has taught us much about the physiologic effects of microgravity, especially the fluid shifts associated with space travel. As early as 1982, cardiac ultrasound was used to evaluate left ventricular systolic function and cardiac chamber size in cosmonauts. The first American ultrasound system in space was the American flight echograph from Advanced Technology Laboratories (Bothel, Wash) that first flew in 1984 and eventually was capable of three-dimensional images using a tilt frame device. Currently, the Human Research Facility aboard the International Space Station (ISS) is equipped with a state-of-the-art Philips HDI 5000 (Philips Medical, Bothel Wash).

Because surface tension and capillary action are the principal physical forces in space, scientists questioned whether images obtained on the standard FAST examination would be useful in microgravity. There are now several published studies of ultrasound examinations performed on parabolic flights onboard the NASA Microgravity Research Facility, a KC-135 aircraft. This aircraft can generate 25 to 30 intervals of weightlessness using serial parabolic trajectories. A porcine model of intraabdominal hemorrhage was created on the ground and studied during parabolic flights. Over 2000 ultrasound segments were recorded, with 80% of these considered feasible for diagnosis of the presence or absence of abdominal fluid. The sonographers determined the examination was no more difficult than one done on the ground as long as the sonographer and patient were adequately restrained. For the intraperitoneal portion of the examination, a fourth view (the midline "abdominal sweep") was added, and with this addition, the FAST examination was able to reliably detect even relatively small amounts of intraperitoneal fluid. The Morison's pouch view remained the most sensitive window for fluid detection. Further study using a similar model revealed that ultrasound can also reliably detect both hemothorax and pneumothorax in microgravity.

Recently, astronauts aboard the ISS performed FAST examinations that were transmitted with a 2-second satellite delay to directors on the ground, who provided instructions for transducer position and system adjustments. Examinations were able to be completed in roughly 5 minutes, with adequate images obtained in all views. Astronauts have also been able to perform comprehensive ocular ultrasound examinations aboard the ISS with similar feedback.

In summary, ultrasound fulfills all the necessary criteria for a diagnostic modality in space. It is sufficiently portable, teletransmittable, teachable, and accurate. It will likely continue to be the only feasible technology to evaluate patients on space missions in the near future.

USING ULTRASOUND TO ASSESS INTRAVASCULAR VOLUME STATUS AND CARDIAC FUNCTION

For several years, ultrasound has been used by specialists to assess a patient's intravascular volume status at the bedside. This focused examination is performed with the same transducer as that used for the FAST examination. The longitudinal view of the vena cava is identified in the subxiphoid view and then assessed for compressibility. A vena cava that is easily compressible indicates that the patient is hypovolemic, whereas a vena cava that is noncompressible or has a diameter greater than 2 cm indicates that the patient is euvolemic or hypervolemic. A study by Ferrada and colleagues showed that the focused examination was 100% sensitive relative to a change in the vena cava diameter with a fluid challenge. A multicenter prospective study is being conducted to confirm the accuracy of the examination to guide the patient's initial resuscitation and that during the intensive care stay.

The Focused Rapid Echocardiographic Examination, or FREE, is a transthoracic examination that was developed to assess the critically ill patient's volume and cardiac status. This point of care examination uses hemodynamic information from the ultrasound examination with the patient's clinical parameters to determine whether the patient needs volume, inotropes, or pressors. Surgeons have shown that its accuracy is high and that it can be performed accurately by trauma team members who have been trained in the basic principles of ultrasound.

SUMMARY

As the role of the general surgeon continues to evolve, the surgeon's use of ultrasound will surely influence practice patterns, particularly for the evaluation of patients in the acute setting. With the use of real-time imaging, the surgeon receives "instantaneous" information to augment the physical examination, narrow the differential diagnosis, or initiate an intervention. Algorithms for the suggested use of ultrasound in penetrating trauma and blunt abdominal trauma are included as Figure 11.

The advantages of ultrasound are easily seen in each of the following clinical scenarios. As a noninvasive, nonionizing radiation modality, ultrasound can be used to evaluate the injured pregnant patient and simultaneously identify the fetal heart so that its rate can be recorded. For the patient with multiple fractures who is in traction, the portable machine is wheeled to the patient's bedside, and the FAST is performed without having to move the patient. If hypotension or an unexpected decrease in hematocrit occurs, an ultrasound examination can be easily repeated to exclude hemoperitoneum as the source of hypotension. When several patients with penetrating thoracoabdominal injuries present simultaneously to the emergency department, a rapid FAST examination with thoracic views can assess for pericardial effusion, massive hemothorax, or hemoperitoneum within seconds. This information helps the surgeon to prioritize resources and triage patients. Finally, this painless, noninvasive modality is well accepted, even by children, because it is performed at the bedside and is not intimidating. As surgeons become more facile with ultrasound, it is anticipated that other uses will develop to further enhance its value for the assessment of patients in the acute setting.

NEW HORIZONS IN POINT OF CARE ULTRASOUND

Current reliance on computed tomographic scanning for the assessment of surgical patients, especially those who are injured, is a major source of radiation exposure. This is particularly concerning because long-term, cumulative doses of radiation have been shown to have potential adverse effects on the patient's physiology. In an effort to address this concern, the American Institute of Ultrasound in Medicine is launching *Ultrasound First*, an initiative designed to call attention to the safe, effective, and affordable advantages of ultrasound as an alternative to other imaging modalities that are more costly and/or emit radiation. Unfortunately, despite its many advantages, ultrasound as a first-line diagnostic test is underutilized in the assessment of surgical patients. *Ultrasound First* will focus on educating health care workers and stakeholders on the benefits of ultrasound in medical care. Further, to bolster its validity as a "first-line modality," the *Journal of Ultrasound in Medicine* has launched a special feature, the Sound Judgment Series, consisting of invited articles highlighting the clinical value of using ultrasound as the first test in select patients and diagnoses where it has shown to be at least comparable to other diagnostic modalities. The integration of ultrasound into medical education is an equally critical component for realizing the benefits of ultrasound in patient care. With these efforts and the growing body of physicians using bedside ultrasound, it is anticipated that the use of evidenced-based guidelines for this modality will continue to grow and become a critical part of medical education.

Emergency Department Thoracotomy

Matthew V. Benns, MD, and
J. David Richardson, MD

OVERVIEW

Emergency department thoracotomy (EDT) following trauma has been used for a variety of indications since its introduction in the 1960s. Initial enthusiasm for the procedure was tempered by the reality of very poor overall meaningful survival. Results reported in the literature vary depending on the definition of EDT and the condition of the patients being treated. If the EDT is performed as a "resuscitative thoracotomy" on patients with a measurable arterial pressure, the results will likely be better than results following procedures performed on patients with signs of life only. The focus over the past several decades has been to better define the indications for effective use of EDT. Controversy still exists, however, with critics citing futility of care and potential dangers of exposure to healthcare workers. Nevertheless, EDT represents an immediate lifesaving intervention for a select group of patients. An understanding of the indications, pathophysiology, and techniques of EDT allows practitioners the best chance at achieving favorable outcomes.

INDICATIONS

EDT is a technique that can be employed rapidly to address a few basic injury patterns and assist with resuscitation. Specifically, EDT is performed for release of pericardial tamponade, control of cardiac or intrathoracic hemorrhage, correction of bronchovenous air embolism, open cardiac massage, or temporary occlusion of the descending thoracic aorta. It is ideally suited to address simple injuries within the thoracic cavity that are causing serious physiologic insult and impending death (Box 1). Unfortunately, the specific nature and severity of injuries are usually unknown until the EDT has been performed. Therefore, criteria have been developed to try to identify patients in whom EDT has the best chance of being beneficial. These criteria are broadly based on the patient's physiologic status, the mechanism of injury, and the timing of events prior to the patient's arrival to the emergency department.

Appropriate candidates for EDT uniformly present in *extremis*, but physiologic status is often discussed in terms of the presence of *vital signs* or *signs of life*. Vital signs include a measureable blood pressure, a palpable pulse, and spontaneous respiratory activity. Signs of life (SOL) include pupillary response, spontaneous respiratory effort, extremity movement, and cardiac electrical activity. The presence of SOL in the emergency department or within a known and short interval prior to arrival is a firm requirement for appropriate EDT. As a practical matter, judging if SOL were present prehospital and the length of time these have been absent is extremely difficult.

Defining absolute criteria for EDT is difficult, as aggressiveness must be balanced by real concerns regarding futility of care and the appropriate use of healthcare resources. In addition, there will always be an occasional outlier who survives EDT who is well beyond any established criteria for appropriate use of EDT. Box 2 lists the main indications and contraindications for EDT. It has been used successfully for patients with blunt and/or penetrating mechanisms of trauma, but outcomes are significantly better for penetrating thoracic injuries as the chances are greater of identifying a localized area of injury. Victims of blunt trauma who lose SOL often have significant associated multisystem injuries. Even if a blunt thoracic injury is discovered with EDT, the character of these injuries is often not amenable to simple and rapid control. Although there are many survivors reported in the literature, blunt mechanism remains controversial and should prompt a more rigid adherence to established guidelines.

Figure 1 shows a decision-making algorithm for EDT based on injury mechanism, SOL, and timing. Use of EDT is ultimately at the discretion of the clinician and will be heavily influenced by previous experience and clinical judgment.

PROCEDURAL TECHNIQUES

Initial Exposure

EDT is performed in the supine position. The patient's left arm is abducted to provide access to the left chest. A splash prep is performed, and an incision is made from the sternum and extending laterally to the mid-axillary line. The incision is located just inferior to the nipple in men and in the inframammary fold in women, which generally places it in the fourth or fifth intercostal space. The incision should curve gently along with the underlying ribs (Figure 2). The underlying soft tissue and intercostal musculature are rapidly divided with a scalpel or scissors, running along the top of the selected rib interspace to avoid the neurovascular bundle. The pleura is sharply incised to enter the chest and a Finochietto retractor is placed in the rib interspace. The handle of the retractor should be placed laterally (within the axilla) to facilitate extension of the EDT incision into a "clamshell" thoracotomy if needed. A clamshell thoracotomy involves dividing the sternum with a Lebsche knife or heavy shears and creating a matching thoracotomy incision on the patient's right side (Figure 3). The internal mammary arteries will be divided and must be controlled if circulation is restored. This type of incision provides unparalleled access to both thoracic cavities and the mediastinum.

Pericardotomy and Control of Cardiac Injuries

Pericardotomy is performed for release of pericardial tamponade and to evaluate any underlying myocardial injuries. Pericardial tamponade cannot be completely excluded based on visual inspection alone; thus, pericardotomy should always be performed during EDT. The pericardium is incised longitudinally from the aortic root to the apex. The incision should be made well anterior to the phrenic nerve to avoid inadvertent injury (Figure 4). Ideally, the pericardium should be grasped and pulled away from the heart when it is incised. In some situations of pericardial tamponade, the pericardium will be bulging and may prove difficult to grasp adequately. In these situations, a knife or single tine of scissors can be used to make an initial "stab" pericardotomy that is then extended. Extreme care must be undertaken to avoid injury to the underlying heart, but there will usually be a space buffer of underlying blood in these situations. Once the pericardium has been opened, all underlying blood and clot are evacuated and the myocardium is inspected. Injuries should be controlled rapidly with digital pressure or sutures. A skin stapler may also be used to quickly obtain temporary control of long myocardial lacerations. Any intervention performed in the emergency department should be simple and rapid to allow for restoration of vital signs and expeditious transport to the operating room for definitive repair.

Control of Intrathoracic Hemorrhage

Pulmonary or thoracic great vessel lacerations can lead to rapid exsanguination due to the lack of adjacent tissue tamponade within

BOX 1: Therapeutic maneuvers in emergency department thoracotomy

- Release of pericardial tamponade
- Control of intrathoracic or cardiac hemorrhage
- Performance of open cardiac massage
- Temporary occlusion of descending aorta
- Evacuation of bronchovenous air

BOX 2: Indications and contraindications for emergency department thoracotomy

Indications

- Penetrating injury with loss of vital signs in the ED, or with less than 15 minutes of prehospital CPR
- Blunt injury with loss of vital signs in the ED, or with less than 5 minutes of prehospital CPR

Contraindications

- No field SOL with penetrating or blunt injury
- Penetrating injury with greater than 15 minutes of prehospital CPR
- Blunt injury with greater than 5 minutes of prehospital CPR

CPR, Cardiopulmonary resuscitation; *ED,* emergency department; *SOL,* signs of life.

the chest. Injuries to smaller vessels such as the intercostals can also cause exsanguination if there is a delay in presentation. These injuries may be addressed with EDT. Digital pressure may be successful on a temporary basis for great vessel injuries if isolated. Straight or side-biting vascular clamps can also be used. Suture control in the emergency department may be appropriate for some injuries, but, in most cases, temporary control with formal repair in the operating room is the preferred approach. For major pulmonary vascular injuries, the pulmonary hilum can be clamped to provide temporary control. If an appropriate clamp is not available, the hilum can be twisted 180 degrees after release of the inferior pulmonary ligament. This maneuver generally will occlude hilar bleeding.

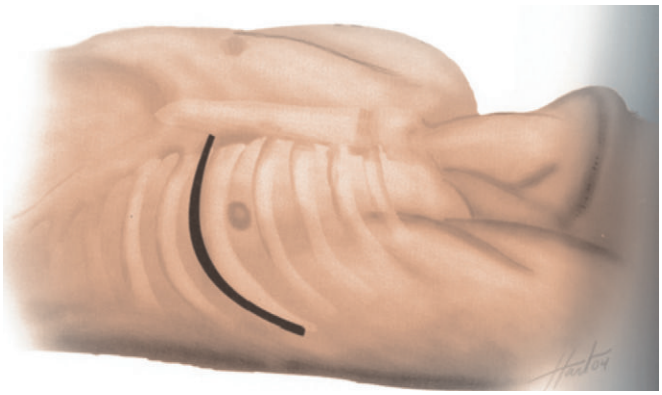

FIGURE 2 Incision for emergency department thoracotomy in the fourth or fifth intercostal space. The left arm is abducted and the incision is made just below the nipple in males or at the inframammary fold in females. The incision should follow the curvature of the ribs and be carried down to at least the mid-axillary line.

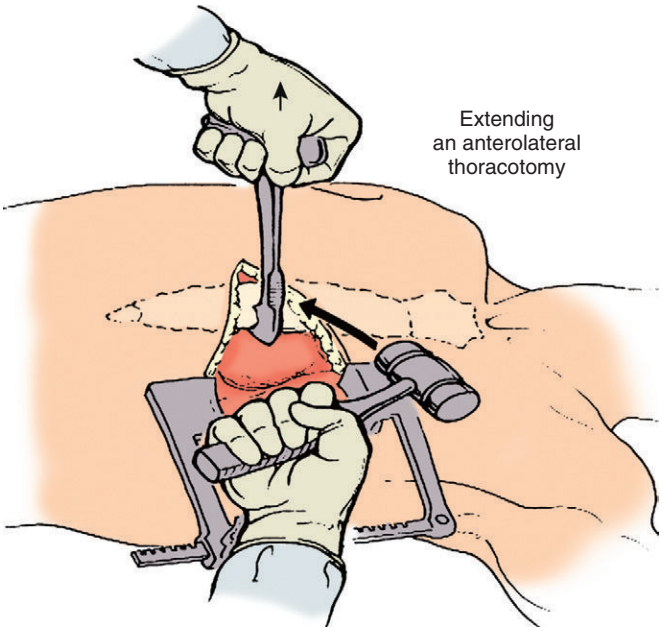

FIGURE 3 A left anterolateral thoracotomy can be extended easily into the right thoracic cavity to create a "clamshell" thoracotomy. A Lebsche knife and mallet or durable bandage scissors can be used to divide the sternum. The internal mammary vessels will be divided with this procedure and should be ligated. A clamshell thoracotomy provides wide exposure to both pleural cavities and the mediastinum.

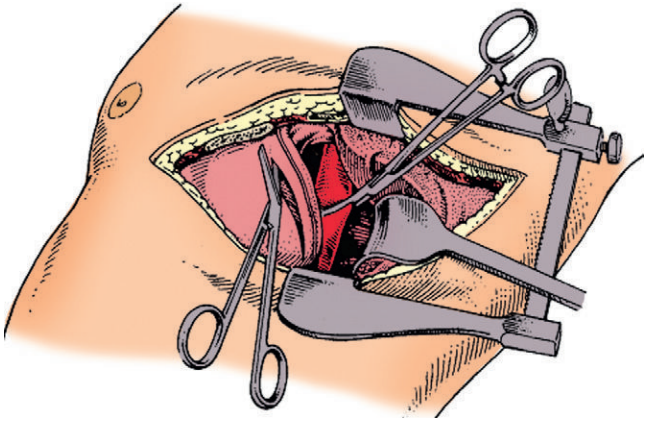

FIGURE 4 Pericardotomy and thoracic aortic cross clamping. The pericardium should be opened longitudinally and anterior to the phrenic nerve.

Occlusion of the Descending Aorta

The primary rationale for aortic occlusion during EDT is that it redistributes the patient's limited blood volume to the heart and brain. In addition, patients with intraabdominal injuries (the extent of which are often unknown at the time of EDT) will experience less subdiaphragmatic blood loss. Visibility is generally poor during EDT, and this maneuver is often performed using tactile senses rather than visual ones (i.e., "done by feel"). The lung is retracted medially, and a hand is slid along the left lateral thoracic wall. The aorta is located as a tubular structure on the anterolateral portion of the vertebral body. It is usually readily palpable even in the absence of pulsations. Digital compression can be achieved quickly by pressure against the vertebral column. More effective control can be obtained using a vascular clamp, but this requires dissection of the overlying pleura off the aorta. This dissection can proceed either bluntly or sharply starting in the groove between the aorta and vertebral column. Failure to adequately expose the aorta can lead to ineffective cross clamping or complete slippage of the clamp. Care should be taken to avoid injury to the esophagus or intercostal arteries during this maneuver. Cross-clamp time should be carefully monitored and should not exceed 30 minutes if possible, as there is a substantial metabolic burden with prolonged ischemia. Additionally, there is a risk of spinal cord ischemia and subsequent paraplegia with prolonged clamp times. We believe caution should be used in employing a thoracotomy to clamp the aorta for known intraabdominal injuries. Control of the hiatus can be achieved with a celiotomy and is our preferred method of aortic control. Although the transthoracic route may afford control slightly more quickly, it opens a second cavity, promotes more heat loss, and may potentiate coagulopathy.

Open Cardiac Massage

Patients who do not recover vital signs following initial EDT maneuvers require open cardiac massage. This maneuver provides better cardiac output than closed chest massage. It can be accomplished using a one- or two-handed (preferred) technique. In the one-handed technique, the heart is lifted and compressed against the underside of the sternum. In the two-handed technique, the heart is cupped between two hands opposed at the wrist. A gentle "clapping" motion is used to compress the heart from the apex toward the aortic root (Figure 5). In either technique, excessive fingertip pressure should be avoided to prevent injury to the heart. Internal cardiac defibrillation with 15 to 30 J of energy may also be utilized if clinically indicated.

Bronchovenous Air Embolism

Traumatic alveolovenous communications may produce air emboli that migrate and cause coronary artery or ventricular outflow obstruction. The typical scenario is that of a patient sustaining chest injury who develops profound hypotension or cardiac arrest following endotracheal intubation and positive-pressure ventilation. The combination of low intrinsic pulmonary venous pressure secondary to blood loss and high alveolar pressure from assisted positive-pressure ventilation increases the gradient for air emboli formation. Air embolism can be addressed by EDT by first isolating the injured lung and clamping the pulmonary hilum to prevent further

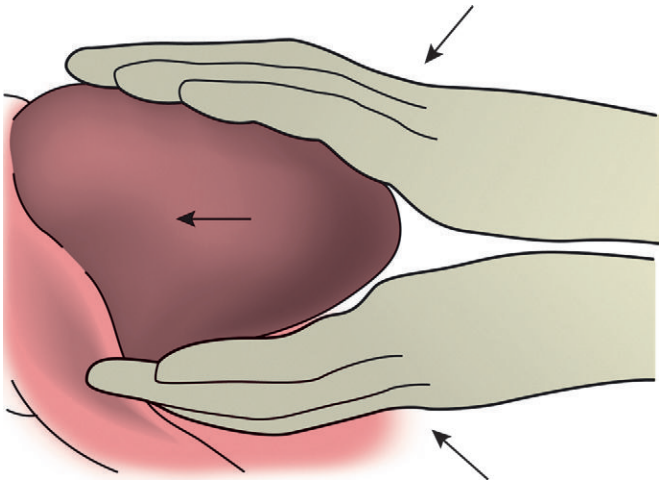

FIGURE 5 Bimanual cardiac massage. The two-handed technique provides better cardiac output and is the preferred method. The palmar surfaces of the fingers act in a clapping motion to compress the heart from the apex toward the aortic root. Fingertip pressure should be avoided at all times.

propagation of air. The inferior pulmonary ligament will usually need to be taken down to facilitate hilar isolation. Vigorous cardiac massage may promote dissolution of air present within the coronary arteries. The patient should then be placed in Trendelenburg position to trap air within the apex of the ventricle. Needle aspiration of the ventricle, atrium, or aortic root can then be performed as needed. If cardiac activity is achieved, the lung injury can be oversewn or stapled to prevent continued emboli formation.

OUTCOMES

Outcomes after EDT vary significantly depending on the mechanism, underlying injuries, and physiologic state at presentation. The highest overall survival rate is seen among patients with isolated cardiac injuries (3% to 35%), followed by victims of penetrating trauma (1% to 14%) and victims of blunt trauma (0% to 2%). A critical appraisal of EDT outcomes should consider "meaningful" survival, however. Many patients included in published series of EDT survivors have significant neurologic impairments as a result of prolonged hypotension and hypoxia.

The Management of Traumatic Brain Injury

Jon David Weingart, MD

The management of head injuries involves rapid evaluation of the extent of injury, followed by rapid intervention to halt ongoing injury and to prevent additional secondary injury. The overall goal of treatment is to maintain intracranial pressure (ICP) at a normal level. Elevated ICP results in decreased blood flow to the brain and subsequently leads to irreversible brain injury. Treatment includes surgical interventions to remove space-occupying mass lesions, primarily hematomas, and nonsurgical treatments to reduce brain tissue volume.

EVALUATION

The evaluation of a patient with a head injury is multidisciplinary. All patients must undergo a complete trauma evaluation because patients with severe head injuries secondary to nonpenetrating trauma are likely to have injuries to other systems. Assurance of cervical spine stability is an important aspect of the initial evaluation. The neck should be immobilized with a cervical collar until the stability of the cervical spine has been verified. A lateral cervical plain radiograph and an odontoid view plain radiograph are used to evaluate the cervical spine. The C7-T1 disk space must be visualized on the lateral image to verify stability of the cervical spine. If the C7-T1 disk space is not visualized, a computed tomographic (CT) scan through the C7-T1 disk space is obtained.

Ideally, the extent of the head injury is assessed before the patient is given any medications that will alter function of the central nervous system (CNS). When this is not possible because of cardiovascular instability or other unstable injuries, short-acting muscle relaxants should be used. The initial evaluation of the patient's CNS function is aimed at assessing for global brain dysfunction (i.e., level of consciousness) and for focal brain dysfunction (i.e., unilateral signs such as hemiparesis). The Glasgow Coma Scale (GCS) is an excellent, rapid way to evaluate for global or focal brain dysfunction. The GCS involves three parameters: eye opening, verbalization, and motor responses (Table 1). The GCS score is also reproducible and can be used to monitor a patient's neurologic status over time. Other aspects of the neurologic examination are papillary responses, corneal responses, and gag responses. These reflexes are used to evaluate brainstem function in an unresponsive patient with severe head injuries.

After the initial stabilization and evaluation are complete, the patient is taken as quickly as possible for a noncontrast brain CT scan. In the patient with a severe head injury, the brain CT scan should be obtained as quickly as possible because it helps determine whether a mass lesion, which necessitates surgical evacuation, is present. The CT scan should be evaluated for (1) presence of extra-axial or intraaxial blood, (2) mass effect or effacement of the lateral ventricle, (3) midline shift, and (4) presence or absence of cerebrospinal fluid in the basal cisterns. A patient with a mass lesion and a GCS score of 8 or less should undergo rapid surgical decompression.

SURGICAL TREATMENT

Acute Subdural Hematoma

Any patient with severe head injury (GCS score of 3 to 8) should be initially approached as if an acute subdural hematoma is causing increased ICP. The patient should be intubated and hyperventilated to achieve a partial pressure of carbon dioxide (Pco_2) of 28 to 30 mm Hg before the head CT scan is obtained. Mannitol, 1 g/kg, should be given intravenously over 15 minutes. Throughout this phase of the evaluation, intravascular volume should be maintained. Hypotension causes a decrease in cerebral perfusion and therefore should be treated if it occurs.

Early evacuation of acute subdural hematomas (within 4 hours of injury) has been shown to reduce the mortality rate. Patients with more than 1 cm of subdural blood in association with shift of the midline structures should be taken to the operating room immediately for evacuation. Patients with thin subdural hematomas (5 mm) and mild neurologic symptoms can be observed and treated medically because small subdural hematomas can resolve on their own. Such patients should be monitored with serial CT scans until the hematoma has resolved.

Patients with large subdural hematomas are taken directly from the CT scanner to the operating room. While the anesthesiologist is preparing the patient, the surgeon is positioning the patient's head. The head can be positioned on a donut or horseshoe cushion, but the author prefers to stabilize the head with head pins and the Mayfield skull clamp (SchaererMayfield USA, Cincinnati, Ohio). The entire half of the head is shaved. The location of the incision depends on the size of the subdural hematoma. The incision must be large enough to allow for the entire subdural space to be included in the craniotomy. For a subdural hematoma that is primarily frontal and temporal, a standard frontotemporal incision may be adequate. For a more posteriorly located subdural hematoma, a linear incision may be adequate. For a large subdural hematoma involving the frontal, temporal, and parietal areas, a large trauma or hemicraniotomy incision. The incision begins anteriorly in the midline and extends posteriorly to the lambdoidal suture, where it is curved forward to above the ear and around to the root of the zygoma.

After the area is prepared and draped, the incision is made quickly through the galea, with Raney clips placed on the skin edge to control bleeding. The temporalis muscle is incised with the cautery pen in line with the scalp incision. Cautery and periosteal elevators are used to dissect the pericranium off the skull with the skin flap. The skin and temporalis muscle are held back with towel clips or suture and a rubber band. The power perforator is used to quickly place burr holes in the temporal fossa at the root of the zygoma. If the dura seen through the burr hold appears blue, the dura should be opened at this point to allow for partial decompression. Several additional burr holes are placed frontally, along the midline, and posteriorly. The dura is stripped off the inner table, and a power craniotome is used to evaluate the craniotomy flap. At this point, several holes are placed in the flap and on the intact skull, through which size 0 Tevdek sutures (Deknatel, Mansfield, Mass) are passed. The Tevdek sutures are readied in case the bone flap must be replaced quickly, as in the case of malignant brain swelling. At this point, the dura is opened in a cruciate manner, allowing the hematoma to be extruded. Normal saline irrigation is used to wash the clot off the brain. At the edge of the dural opening, cotton strips are placed, and handheld brain spatulas are used to gently depress the brain. With use of irrigation again, the residual clot is washed off the cortex and evacuated. This is particularly important in the anterior frontal and temporal areas. Along the midline, the surgeon should be cautious when removing small clots, which may be causing tamponade in a torn bridging vein. While the hematoma is being washed out, any source of bleeding—from veins or arteries—is controlled with bipolar coagulation.

After evacuation of the convexity hematoma, the herniation in the medial temporal lobe and the uncal herniation over the tentorium should be relieved. This is accomplished by retracting and lifting the anterior temporal lobe off the floor of the middle fossa. If the anterior temporal lobe is contused and hemorrhagic, it can be resected, which will improve visualization. The brain spatula elevating the temporal lobe is advanced until the edge of the tentorium is identified. An attempt is made to lift the herniated medical temporal lobe back into the supratentorial space if the tissue looks viable. If the surgeon is unable to reduce the herniation or if the medial temporal lobe appears contused and nonviable, a subpial resection of the tissue should be carried out with suction and bipolar coagulation. Arachnoid attachments from the ambient cistern to the temporal lobe should be cut. A gush of cerebrospinal fluid is often seen when the temporal lobe has been reduced and the brainstem decompressed.

After the medial temporal lobe has been decompressed, the operative field is irrigated to check for any additional bleeding. The dura is closed in a primary manner if possible. If the closure appears to strangulate the brain because of brain swelling, a pericranial graft is used to cover the brain. Gelfoam (Pfizer, New York, NY) is placed in the epidural space, and the bone flap is attached with sutures or titanium plates.

At the end of the procedure, an ICP monitor should be placed on the opposite side. The ICP measurement is crucial for managing a patient with poor neurologic findings. Medical management is directed toward maintaining the ICP in a normal range. This ensures adequate blood flow to the brain and minimizes secondary injury. If

ICP increases rapidly while being monitored, head CT scanning should be repeated to look for development of a new hemorrhagic mass lesion.

All patients with acute subdural hematomas should have a follow-up head CT scan immediately after surgery and again 24 hours after surgery. It is not unusual for small remnants of the hematoma to remain or for a small amount of blood to reaccumulate. This baseline head CT scan is invaluable for interpreting follow-up head CT scans 2 to 5 days after surgery.

Two scenarios that can occur in the setting of a subdural hematoma are (1) the presence of a large intraparenchymal hematoma and (2) malignant brain edema. If a large intraparenchymal hematoma is present and is contributing to the mass effect in the brain, it should be decompressed. The hematomas usually come to the surface, and it is not difficult to enter them and to evacuate the blood clot. The goal is to decompress the brain and not to remove every small piece of hematoma. Intraparenchymal hematomas should be removed with irrigation and gentle suction. Aggressive removal of the clot in the wall of the hematoma cavity can produce bleeding that is difficult to stop. If this occurs, different hemostatic agents can be used to achieve hemostasis because bipolar cauterization is often ineffective. Hemostatic agents include cotton balls soaked in thrombin; thrombin-soaked Gelfoam; Avitene (fibrillar collagen; Davol, Cranston, RI); and, as a last resort, cotton balls soaked in half-strength hydrogen peroxide.

The second scenario to be aware of is the development of malignant brain edema and swelling, which occurs after the dura is open. When this occurs, the brain begins to swell out of the dural opening. This is a poor prognostic sign and probably reflects a severe diffuse brain injury. When met with this situation, the surgeon should quickly close. The dura can be reapproximated or left open. Similarly, the bone flap can be left off or replaced.

Epidural Hematoma

Epidural hematomas occur in the potential space between the dura and the inner table of the skull. Because the dura is strongly adherent to the cranial sutures, epidural hematomas typically do not cross the sutures. On a head CT scan, an epidural hematoma has a convex shape. Epidural hematomas usually occur in the setting of blunt trauma to the head and, in most cases, are associated with a skull fracture. The classic history of a patient with an epidural hematoma is a transient loss of consciousness after a head injury, followed by a lucid phase and then neurologic deterioration. Five different clinical courses have been described in patients with epidural hematomas: (1) unconscious-conscious-unconscious, (2) unconscious throughout, (3) conscious-unconscious, (4) unconscious-conscious, and (5) conscious throughout. On occasion, in a patient with an initial normal head CT scan, an epidural hematoma will develop, after some delay. Regardless of how the patient presents, the key issue for patients with epidural hematomas is that prompt treatment before loss of consciousness results in excellent outcomes. Because of the excellent prognosis with rapid treatment, all patients with impairment in consciousness after head trauma should have a head CT scan to rule out the presence of an epidural hematoma.

For an epidural hematoma that is causing alteration either in consciousness or in the patient's neurologic function, the treatment is evacuation of the hematoma. Patients can deteriorate quickly, so they should have surgery immediately. The general surgical approach involves adequate exposure of the hematoma and obliteration of the epidural space with dural tack-up sutures.

Patients can be positioned with the head on a horseshoe pad or in a three-point fixation head-holding device. The craniotomy should be large enough to completely expose the hematoma. Because epidural hematomas are commonly in the temporal area, a standard frontotemporal incision with or without posterior extension of the incision behind the ear is often used. As the burr holes are placed, the epidural hematoma is encountered immediately beneath the burr hole, and a partial evacuation can be carried out quickly. After the bone flap is elevated, the hematoma is evacuated and the source of the bleeding, if found, is controlled. Middle meningeal and other dural branches are the most common cause of epidural hematomas. The dura around the craniotomy edge is tacked up to the skull. Similarly, multiple tack-up sutures serve to obliterate the epidural space and reduce or eliminate the risk of recurrence. If the head CT scan indicates the presence of a concomitant subdural hematoma, the subdural space is explored before the bone flap is replaced. Ultrasonography can also be used to assess for a subdural hematoma before the intradural compartment is explored. If the intradural space is to be explored, a linear dural incision is adequate. If a subdural hematoma is encountered, the dura can be opened widely to drain the hematoma. In patients with GCS scores of 8 or lower, an ICP monitor is placed at the end of the hematoma evacuation. Postoperative management of increased ICP is the same as in patients with an acute subdural hematoma.

Epidural hematomas near the midline or in the posterior fossa should be approached with a plan to control a hole or tear in a venous sinus. A skull fracture crossing the sinus is typically seen. As long as there is no concern for the patency of the venous sinus, the bone flap should extend up to the sinus but not across it. Any sinus bleeding can be controlled with tack-up sutures located along the sinus. Gelfoam and Avitene can be useful in controlling sinus bleeding.

Epidural hematomas that are small and exert no mass effect can be managed conservatively. These are often located in the high parietal area, where the risk of herniation is lower because of the falx tentorial junction, which offers some protection against herniation. If an epidural hematoma is to be monitored conservatively, then serial CT scans are obtained until it resolves.

Penetrating Injuries and Gunshot Wounds

Gunshot wounds to the head are evaluated and treated in the emergency department in the same way as blunt head trauma. The entrance site and, if present, an exit site should be identified on the scalp. Once stabilized, patients immediately undergo head CT scanning to evaluate the trajectory and the areas of brain affected by the missile. The two major issues in management of these types of injuries are (1) the presence of a hematoma, extraaxial or intraaxial, that causes mass effect and increased ICP and (2) the risk of infection because of the bone fragments and other debris carried into the brain by the force of the bullet. Hematomas that cause mass effect and neurologic compromise are unusual and should be surgically removed.

The standard treatment of gunshot wounds to the head remains controversial. Some surgeons believe that débridement of the bullet track in the brain leads to better outcomes. Bone chips, hair, and bullet fragments, along with necrotic brain tissue, are removed. The craniotomy is carried out with standard techniques to adequately expose the bullet entry point. The dura is opened in a cruciate manner, and the bullet track is débrided. All hemorrhagic and devitalized brain tissue should be removed until normal-appearing white matter is visible. Handheld brain spatulas or a speculum can be used to provide exposure to enable débridement of the bullet track. Irrigation flushed down the bullet track helps débride in the deeper portions of the bullet track. An attempt to remove all bone fragments should be made. Once the bullet track has been débrided and hemostasis achieved, the dura is closed in a watertight manner to prevent postoperative cerebrospinal fluid leaks and infections. A pericranial tissue graft is usually necessary to achieve dural closure. Both the bone and skin should also be débrided. In addition, closure of the scalp with healthy viable tissue is important. Postoperatively, patients are administered broad-spectrum antibiotics, although the most common pathogens are gram-positive *cocci*.

Most studies of the treatment of gunshot wounds have arisen out of wartime experiences. Because of the high incidence of infection in these series, débridement became the standard approach. However, more recent experiences have demonstrated that local débridement and closure of the entry site, followed by a regimen of intravenous antibiotics, are also effective at preventing infectious complications of the gunshot wound. Although this more conservative treatment course may not be appropriate for all patients, it is appropriate for patients with poor neurologic function and poor prognosis. Poor prognosis is associated with bullet wounds that cross the midline or pass through the ventricle.

In addition to antibiotics, anticonvulsants are given, and a tetanus toxoid shot is administered. Steroids are not indicated.

Decompressive Craniectomy

The role of decompressive craniectomy in the management of medically intractable intracranial hypertension remains controversial. Clinical studies to date demonstrate that ICP is better controlled after decompressive craniectomy, but outcomes are not improved, and complications may be increased. Patients with prolonged elevation of ICP despite maximal medical therapy are potential candidates for these procedures. The most common decompressive procedures are (1) hemicraniectomy with duraplasty and (2) bifrontal craniectomy. The bone can be removed in one or more pieces and is placed in the bone bank for later replacement. For the hemicraniectomy, the bone flap should extend back to the occipital region. The dura should be opened in a cruciate manner to allow the swollen brain to expand outward. Large pieces of bovine pericardium are used to cover the brain so that a plane of dissection exists between the galea and the brain when the bone is replaced at a later date.

The goal of these procedures is to limit the secondary damage caused by extended intracranial hypertension. There is some suggestion in the clinical studies available that these procedures have more effect on outcome when performed earlier in the course of the injury.

NONSURGICAL MANAGEMENT

The nonsurgical management of head injuries includes that in the postoperative period and that of patients for whom surgery was not indicated. The primary management issue is control of the ICP. By controlling ICP in a normal range, the clinician maintains adequate cerebral perfusion and oxygenation, and ongoing secondary injury is thus limited.

In 1993, a task force established by the Brain Trauma Foundation examined 12 issues related to the medical management of patients with severe head injures. Within each category, a treatment was designated as a *standard* when the treatment represented principles of patient management that reflect a high degree of clinical certainty; as a *guideline* when the treatment represented a particular strategy or range of management strategies that reflect moderate clinical certainty; and as an *option* for remaining management strategies that reflect low clinical certainty.

Of the 12 categories evaluated, only 3 met the standards criteria:

1. Chronic prolonged hyperventilation therapy (partial pressure of carbon dioxide [$Paco_2$]of 25 mm Hg) should be avoided after severe traumatic brain injury.
2. The use of glucocorticoids is not recommended to improve outcome or reduce ICP in patients with severe head injury.
3. Prophylactic use of phenytoin carbamazepine or phenobarbital is not recommended for preventing late posttraumatic seizures.

Medical Management of Increased Intracranial Pressure

Who Should Be Monitored?

Most of the 12 guidelines addressed by the task force involve decisions to monitor ICP and the interventions to take to reduce ICP when it is elevated. Although the indications to monitor ICP did not reach standard criteria, the data in the literature strongly support ICP monitoring in patients with a GCS score of 3 to 8 and an abnormal CT scan. This includes both patients who have undergone surgery and those who have not. These patients are at high risk for increased ICP, and intervention to lower ICP can prevent secondary brain injury.

In patients with GCS scores of 3 to 8 and normal head CT scans, the risk for increased ICP is lower. However, among such patients, it has been shown that if patients demonstrated two of three adverse features (age >40 years, unilateral or bilateral motor posturing, or systolic blood pressure <90 mm Hg), then the risk for increased ICP was similar to that in patients with abnormal head CT scans. Therefore, patients meeting these criteria should also be monitored.

How Should Patients Be Monitored?

The two ways to monitor ICP are with a ventriculostomy, which is placed into the cerebrospinal fluid ventricular space, or with a device that measures only pressure. The advantage of the ventriculostomy is that cerebrospinal fluid can be drained so as to decrease ICP. Therefore, in patients in whom monitoring is recommended, a ventriculostomy should be placed when possible.

What Intracranial Pressure Is Considered High?

An absolute threshold of ICP at which point treatment should be initiated does not exist; however, current data support 20 to 25 mm Hg as an upper threshold.

How Should Elevated Intracranial Pressure Be Treated?

Osmotic diuretics such as mannitol have been used over the years to reduce ICP. Mannitol has become the most commonly used osmotic diuretic. Although its exact mechanism is still debated, it is effective at decreasing ICP. Mannitol can be administered in a large bolus (1 g/kg) when ICP increases above a threshold such as 25 mm Hg, or it can be administered in smaller doses (0.25 g/kg) every few hours regardless of the ICP. Serum osmolarity should be monitored closely and kept below 320 mOsm. If mannitol is used for several days continuously, the patient must be weaned off slowly because abrupt cessation can lead to increased ICP.

An alternative, now more commonly used, is hypertonic saline; a solution of 7.5% given in a 30-mL bolus is effective at acutely decreasing ICP. Treating patients with continuous infusions of 3% saline also can control ICP. The goal of hypertonic saline is to raise the sodium levels to 155 to 160 mEq/L. One advantage of the hypertonic saline treatment is that the patient's intravascular volume is maintained at a normal level, which is advantageous for maintaining cerebral perfusion. As with mannitol, patients must be weaned off the hypertonic saline infusions slowly.

In patients with a ventriculostomy in place, ICP can be controlled with constant cerebrospinal fluid drainage. However, it is often not possible to place a ventriculostomy in cases of trauma because of the compression of the ventricular space secondary to the brain injury.

For patients in whom osmotic or hypertonic saline therapy is ineffective, barbiturates are the next option. Barbiturate therapy is an option in patients who are hemodynamically stable. A loading dose of pentobarbital is given as a bolus, 10 mg/kg over 30 minutes, followed by 5 mg/kg every hour for three doses. This is then followed by a maintenance infusion of l mg/kg/hr. The correlation between

serum levels and therapeutic effect is poor. For this reason, all patients should have electroencephalographic monitoring with the goal of inducing a burst-suppression pattern; near-maximal reduction in cerebral metabolism and cerebral blood flow occurs when this pattern is present. After several days of pentobarbital coma, the drug is discontinued, and the effect allowed to wear off; this can take several days. When the pentobarbital has disappeared from the patient's system, the patient is reevaluated by a neurologic examination, ICP measurement, and head CT scan.

MANAGEMENT OF MILD TO MODERATE HEAD INJURIES

Many patients sustain head injuries that do not necessitate surgery and ICP monitoring. The extent of the injury can vary from alteration in neurologic function with normal head CT scan to abnormal head CT scan with the usual finding of subarachnoid blood or a brain contusion. Brain contusions caused by trauma are often located at the frontal and temporal poles. On the initial head CT scan, contusions appear to be of low density, often with punctate hemorrhages within the low density. These contusions can change over several days into large, consolidated hemorrhages, which can produce a mass effect. Neurologic deterioration may ensue when these contusions change into hematomas.

The management of such patients centers on close observation and frequent neurologic checks. Because these patients can be monitored with neurologic examinations, any changes occurring within the brain are reflected in the neurologic function of the patient. If a change in the patient's examination findings is noted, a head CT scan is obtained. If a new mass lesion has appeared, surgical evacuation may be indicated, depending on the size of the mass and its effect on the surrounding brain.

When admitted, patients with mild to moderate head injuries should be placed on two-thirds' maintenance fluid restriction. If intravenous fluids are given, normal saline should be used. The goal of this therapy is to increase the serum osmolality, which results in decreasing brain volume and ICP. Some patients may require an intensive care setting for observation and for receiving hypertonic saline or mannitol regularly over the first few days after the head injury. Steroids and anticonvulsants are not given routinely to these patients. If a patient has a seizure, anticonvulsants are started. All patients admitted with abnormal head CT scans after trauma should have undergo repeat head CT scanning 24 hours after the trauma. Patients with large contusions, especially temporal lobe contusions, should have several head CT scans over the first week while in the hospital in order to check for delayed development of an intraparenchymal hematoma.

Patients with mild head injuries can have persistent symptoms and cognitive dysfunction for many months after the injury despite imaging studies that yield unremarkable findings. Evaluation by experts in cognitive neurology and neuropsychology can be helpful.

COMMENTS

The prognosis for patients with severe head injuries is generally poor. The damage sustained at the moment of the trauma is irreversible. However, with rapid evaluation and treatment aimed at maintaining ICP in a normal range, ongoing and secondary injury can be halted and reversed.

CHEST WALL TRAUMA, HEMOTHORAX, AND PNEUMOTHORAX

Raul Coimbra, MD, PhD, FACS, and David B. Hoyt, MD, FACS

Chest trauma is common. Data suggest that approximately 30% to 50% of all blunt trauma patients admitted to trauma centers have sustained chest trauma. Thoracic injuries account for 20% to 25% of all trauma-related deaths, and complications of chest trauma contribute to another 25% of all deaths. Early deaths in patients with chest trauma are caused primarily by major respiratory problems, such as tension pneumothorax and massive hemothorax. These clinical situations must be recognized and managed promptly. The most common injury in thoracic trauma is chest wall trauma. Because of the high prevalence of rib fractures and the associated pneumothorax and hemothorax, most thoracic injuries can be managed with simple procedures such as thoracentesis, respiratory support, and adequate analgesia. Only 15% of patients with chest trauma need a thoracotomy for definitive management of intrathoracic injuries.

In this chapter, the most current concepts of diagnosis and management of chest wall injuries, pneumothorax, and hemothorax are reviewed.

INITIAL EVALUATION

The physical examination of the chest is extremely important in identification of life-threatening situations that necessitate immediate attention. These situations include tension pneumothorax, massive hemothorax, open pneumothorax, flail chest, and cardiac tamponade.

Assessment of the chest begins with removal of all clothing and visual inspection of the anterior and posterior chest and axillae. A thorough inspection for lacerations, ecchymoses, open wounds, air bubbling from wounds, symmetry of chest rise, paradoxical motion of any portion of the chest, and use of accessory muscle for respiration should be performed. Pulse oximetry should be applied as soon as the patient arrives. The chest should be palpated for crepitus, tenderness, and instability of the sternum or ribs. Auscultation for presence and symmetry of breath sounds and dullness of cardiac or breath sounds is also performed. A chest x-ray should be performed as soon as is feasible for radiographic evaluation of the soft tissues, bones, lung parenchyma, and thoracic cavities. Throughout the assessment, high-flow oxygen should be administered to the patient. The chest x-ray is of the utmost importance in thoracic trauma; however, the life-threatening injuries mentioned previously preclude the necessity of a chest x-ray for diagnosis and should be identified clinically. In hemodynamically stable polytrauma cases, a chest computed tomographic (CT) scan with contrast (angiographic CT scan) may be useful in identification of injuries not seen on the initial chest x-ray (Figure 1).

SPECIFIC INJURIES

Rib Fractures

Blunt chest wall trauma varies from an isolated rib fracture to bilateral multiple rib fractures from crush mechanisms of injury that lead to significant respiratory distress from pneumothorax, hemothorax, or marked pulmonary contusion. Mortality rates after blunt chest wall trauma range from 4% to 20%.

Rib fractures are the most common injuries after blunt chest injuries, and ribs 4 through 10 are usually fractured. An isolated single rib fracture without lung involvement, pneumothorax, or hemothorax is usually treated on an outpatient basis. However, the ideal management of patients with multiple rib fractures or significant chest wall trauma without life-threatening injuries is controversial. In the elderly population, decreased bone density, reduced chest wall compliance, and increased incidence of underlying parenchymal disease may cause rib fractures to lead to decreased ability to cough, reduced vital capacity, and increased incidence of infectious complications.

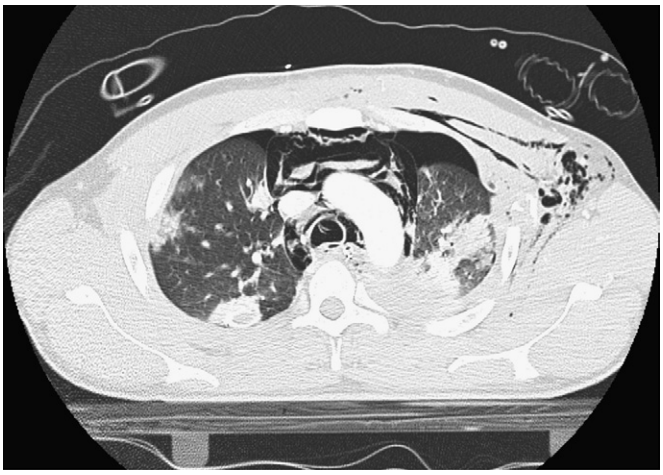

FIGURE 1 Computed tomographic scan of the chest shows deformity of chest wall, rib fractures, bilateral pulmonary contusions, subcutaneous emphysema, and bilateral pneumothoraces.

The primary clinical manifestation after rib fracture is pain. Other clinical signs associated with rib fracture include tenderness to palpation and crepitus. Rib fractures are confirmed with a chest x-ray or with chest CT scan. Approximately 55% of rib fractures are missed on routine chest radiographs. Special views, including an oblique view, may increase sensitivity but are not commonly used during the initial evaluation of a trauma patient. CT scans are the most sensitive study for diagnosis of rib fractures.

Multiple rib fractures are the hallmark of severe trauma from high-energy transfer. Patients with multiple rib fractures should undergo complete evaluation to rule out intrathoracic and abdominal injuries. Fractures of the lower ribs (9 to 12) are associated with increased incidence of solid organ injuries (liver and spleen), and fractures of the upper ribs (1 to 3), clavicle, or scapula are associated with major vascular injuries.

Poor pain control significantly contributes to complications after rib fractures, such as atelectasis and pneumonia. Pain control is attempted initially with oral or intravenous (IV) analgesics. Intercostal nerve blocks with bupivacaine are effective for pain control; however, bupivacaine is not feasible for multiple fractures, and it requires frequent injections. Epidural analgesia is adequate for patients with multiple or bilateral fractures; it provides adequate pain control and appropriate pulmonary toilet, decreasing the number of complications.

Flail Chest

A flail chest occurs when three or more contiguous ribs are broken in two places, creating a segment of bone and muscle that can move independently of the thoracic wall; however, it can also occur after costochondral separation. Fractures can be located in the anterior, lateral, or posterior chest wall. Flail chest occurs in 10% to 15% of patients with major chest trauma, and the chance of having an intrathoracic injury increases several fold. Closed traumatic brain injury is the most frequent associated extrathoracic injury; it contributes to higher morbidity and mortality rates. Isolated flail chest carries a low mortality rate in younger patients.

This independent segment of the chest wall moves paradoxically with spontaneous respirations, pulling inward with inspiration as a result of negative intrathoracic pressure. The paradoxical respiratory movement can cause significant pain to the patient and lead to a respiratory pattern characterized by rapid shallow breaths, which may lead to atelectasis and hypoxia. In addition, the force required to create a flail segment is excessive and usually also results in significant underlying pulmonary contusion, further increasing hypoxia. Sequential measurements of forced vital capacity, tidal volume, and inspiratory force are useful to predict which patients will need ventilatory support. The pathophysiologic effects may be present immediately or may progress over several hours and present as late respiratory decompensation. Lastly, the flail segment may be associated with a hemothorax or pneumothorax, which is treated with tube thoracostomy.

Treatment of the flail segment varies according to the patient's clinical presentation. If the patient's condition is stable from a respiratory standpoint, administration of supplemental oxygen, aggressive pulmonary toilet, and adequate analgesia is enough. Pain can be controlled with oral or intravenous analgesics, patient-controlled analgesia (PCA), intercostal nerve blocks, or catheters, which deliver a continuous stream of local anesthetic, or with epidural anesthesia. Evidence shows that epidural pain control is superior to other methods. In patients with development of respiratory distress,

intubation and positive pressure ventilation is the treatment of choice. The intubation allows more aggressive pain management and sedation, and the positive-pressure ventilation can be used to recruit atelectatic lung and support contused lung to improve oxygenation. In addition, the positive-pressure ventilation splints the flail segment so that the paradoxical motion is halted and the entirety of the thoracic wall can move in synchrony, relieving pain and allowing healing of the soft tissue and bones.

Elderly trauma patients are particularly susceptible to deterioration after chest wall trauma. In this special patient population, pain control and aggressive pulmonary toilet should be implemented early, with a low threshold for intubation. Care should be taken to avoid fluid overload in these patients because it may further impair respiratory function. Pneumonia is the most frequent complication, particularly in the elderly; it aggravates chronic lung diseases, increases ventilator days, and significantly contributes to mortality.

Open reduction and internal fixation (ORIF) of sternal or rib fractures are rarely needed and remain controversial. No class 1 data exist to support the routine use of rib fracture ORIF. The indications for operative intervention in rib fractures are presented in Box 1. The proponents of rib fracture ORIF cite shorter recovery time, shorter intensive care unit (ICU) and hospital length of stay, decreased incidence of pneumonia, and shorter duration of mechanical ventilation after the procedure. In addition to the indications presented in Box 1, other clinical situations that may be taken into account in the decision to perform operative intervention in chest wall injuries include pain induced with deep breaths during spontaneous breathing trials, failure of obtaining adequate pain control with narcotics, intercostal nerve block or epidural analgesia, significant decrease in thoracic volume from chest crush injuries, marked chest wall deformity, fracture nonunion, and persistent paradoxical respiratory movement.

Sternal Fractures

Although rare, sternal fractures may occur after blunt mechanisms that include motor vehicle accidents and falls. The presence of a fractured sternum suggests a significant trauma to the anterior chest wall with high-energy transfer. Signs and symptoms include chest pain, particularly over the sternum, and crepitus. A hematoma over the sternum or across the chest may be seen, and it is a common occurrence after frontal car crashes in patients wearing a three-point seatbelt. A lateral x-ray should be obtained in these circumstances and usually confirms the diagnosis. Sternal fractures also constitute a marker for serious associated injuries, including myocardial contusion, myocardial rupture, esophageal perforation, airway injury, and thoracic aortic rupture.

Treatment of sternal fractures is usually conservative, although patients with significant chest wall instability may need open reduction and internal fixation.

Pneumothorax

A pneumothorax occurs when air from an injured lung or airway is trapped within the pleural cavity, increasing the normal negative intrapleural pressure. It may be caused by penetrating or blunt mechanisms. After blunt trauma, pneumothorax is caused by rib fractures penetrating the lung parenchyma or by lung injuries without chest wall involvement. Deceleration injuries and sudden increases in intrathoracic pressure also may cause pneumothorax.

Clinical findings suggestive of a pneumothorax include decreased breath sounds, hyperresonance to percussion, and decreased expansion of the affected lung during inspiration. Pneumothoraces are classified according to the volume of lung loss or collapse identified on chest x-ray or according to respiratory and systemic signs. In a small pneumothorax, the volume loss is one third of the normal lung volume. In a large pneumothorax, the lung is completely collapsed, but no mediastinal shift or associated hypotension is found.

Tension pneumothorax is the most rapidly life threatening of all breathing problems. It occurs when air continuously enters the thoracic cavity from the lung, airway, or atmosphere and cannot escape. The pressure causes collapse of the lungs and prevents oxygenation and ventilation on the ipsilateral side and eventually causes deviation of the mediastinum to the opposite side. This causes compression of the superior and inferior vena cava, decreasing preload to the heart and resulting in hypotension. Tension pneumothorax should be recognized immediately with signs of air hunger, hypoxia, tachypnea, hyperresonance, unilateral absence of breath sounds, deviation of the trachea away from the affected side, distended neck veins, hypotension, and tachycardia. The tracheal deviation may be difficult to visualize and may be prevented from occurring if the patient is intubated. Distended neck veins may not be present if the patient is hypovolemic. Tension pneumothorax may be confused with pericardial tamponade because both result in distended neck veins, a feeling of impending doom or restlessness, and hypotension. However, tamponade results in muffled heart sounds and does not cause tracheal deviation or asymmetric breath sounds.

Tension pneumothorax is diagnosed clinically and constitutes a life-threatening emergency. Chest x-rays are not necessary to confirm the diagnosis, and delays to definitive treatment significantly increase the risk of circulatory collapse and cardiorespiratory arrest.

If tension pneumothorax is suspected, emergent decompression must be performed. Advanced Trauma Life Support (ATLS) recommends needle decompression with large-bore needles or angiocatheters placed in the second intercostal space in the midclavicular line. If the needle is properly placed, a rush of air should be observed with an immediate improvement in vital signs, as the tension pneumothorax is converted to a simple pneumothorax (Figure 2). This procedure should then be followed by the placement of a chest tube for more permanent decompression of the affected hemithorax and drainage of any blood that may be associated with the tension pneumothorax.

BOX 1: Indications for open reduction and internal fixation of rib fractures

Crushed chest with marked deformity
Flail chest
Rib fracture nonunion with chest wall deformity
Open rib fracture

FIGURE 2 Needle decompression for tension pneumothorax.

Occasionally, in the obese patient or in patients with significant soft tissue edema or hematomas, needle decompression may not be possible because the device may not be long enough to reach the thoracic cavity. In this situation, needle decompression may be skipped in favor of immediate chest tube placement. Reexpansion of the lung and reapproximation of the pleural surfaces usually seal the lung defect. All patients with a pneumothorax, regardless of its size, who will undergo positive-pressure ventilation should have a chest tube placed before the start of mechanical ventilation.

Open Pneumothorax

Open pneumothorax, also known as sucking chest wound, occurs when a significant defect in the chest wall (e.g., large-caliber gunshot wounds, traumatic thoracotomy) is large enough to exceed the laryngeal cross-sectional area, allowing the air to enter from the exterior into the pleural cavity and leading to lung collapse from a rapid equilibration between the intrathoracic pressure and the atmospheric pressure. The increased intrathoracic pressure also causes mediastinal shift and decreased venous return. Signs and symptoms include hypoxia, hypercarbia, hypotension, and respiratory and circulatory failure.

Management of open pneumothorax includes application of an occlusive dressing and placement of a chest tube before closure of the chest wall defect to avoid the development of a tension pneumothorax. When the initial assessment is completed and the patient's condition is stable, the wound should be cleansed, débrided, and closed in the operating room.

Occult Pneumothorax

Occult pneumothorax is defined by the presence of a pneumothorax seen on CT scan but not seen on conventional chest x-ray. The incidence rate of occult pneumothorax in trauma patients varies from 2% to 10%. The critical issues related to occult pneumothoraces are the question of clinical relevance; the identification of those with the potential to grow and cause problems, particularly in patients undergoing positive-pressure ventilation; and the question of preemptive treatment with tube thoracostomy. A recent multiinstitutional prospective observational study sponsored by the American Association for the Surgery of Trauma (AAST) was carried out to elucidate those issues. The objective of the study was evaluation of management strategies of occult pneumothoraces in an attempt to identify factors related to failure of observation to avoid unnecessary tube thoracentesis.

The authors analyzed 588 cases of occult pneumothoraces. Of those, 121 patients (21%) underwent immediate tube thoracostomy, and 448 (79%) were observed. Observation failure, defined by the need for tube thoracostomy after a period of observation, occurred in 27 (6%). The observation failure rate of patients undergoing positive-pressure ventilation was 14% (10 of 73). Increased hospital and ICU lengths of stay and ventilator days were observed in the failure of observation group. Univariate analysis identified size of the occult pneumothorax (7 mm), use of positive-pressure ventilation, progression of the occult pneumothorax (seen on subsequent chest x-ray films), respiratory distress, and the presence of a hemothorax as independent factors associated with failure of observation. Multivariate regression analysis identified only progression of the occult pneumothorax and respiratory distress as significant predictors of failed observation. Because no patients with failed observation had a tension pneumothorax develop or experienced any adverse events, the authors concluded that patients with occult pneumothorax can be carefully monitored and observed without tube thoracostomy.

Hemothorax

Blood may accumulate in the pleural cavity after blunt or penetrating injuries. Depending on the nature of the injury, bleeding may vary from minor to massive. Symptoms depend on the amount of blood accumulated in the pleural space. On physical examination, breath sounds may be decreased on the side of the injury. A chest x-ray obtained in the upright position may reveal accumulations of blood greater than 200 mL; however, a supine film may show a diffuse haziness or none at all. The pleural space can accumulate up to 3 L of blood.

Hemothoraces are initially treated with chest tube placement (36F tube); in approximately 85% of the cases, the bleeding stops as the lung is reexpanded as a result of the low pressure in the systemic circulation. A small number of cases have continued bleeding and need a thoracotomy. These cases are usually injuries in systemic arteries (intercostal arteries or internal mammary artery) or veins or major pulmonary vessels or are cardiac in origin.

Massive hemothorax is usually the result of major pulmonary vascular injury or major arterial wounds, and minor lung injuries cause small hemothoraces.

Massive hemothorax may present with tension physiology similar to tension pneumothorax. Hypotension may be a result of decreased preload from tension physiology or of massive blood loss (Figure 3). Treatment is immediate placement of a chest tube to the affected side. In contrast to tension pneumothorax, massive hemothorax rarely results in distended neck veins because of associated hypovolemia. Blood loss of greater than 1500 mL defines a massive hemothorax and is an indication for operative exploration. Additional indications for thoracotomy include massive continuous air leak that may indicate massive parenchymal lung injury or injury to a major airway and blood loss of 200 mL/h for greater than 4 hours (Box 2). Shed blood should be collected in a sterile fashion so that it may be autotransfused.

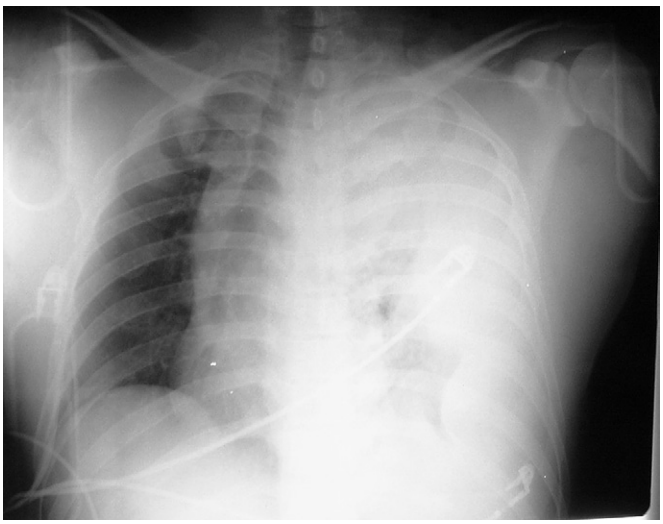

FIGURE 3 Massive hemothorax with tension component. Note the tracheal deviation to the right side and marked opacification of the left hemithorax.

BOX 2: Indications for thoracotomy after thoracentesis

Drainage of blood greater than 1500 mL on placement of chest tube
Persistent bloody drainage more than 200 mL/h
Persistent major airway leak
Suspicion of major airway injury with "flooding" of contralateral lung

Retained Hemothorax

Although retained hemothorax is common (approximately 10% of hemothoraces are treated with tube thoracostomy), the true incidence is unknown. Retained hemothorax is not only a complication of chest trauma and tube thoracentesis but is also recognized as a risk factor for the development of posttraumatic empyema and fibrothorax.

In modern trauma centers, the diagnosis of retained hemothorax is based on CT scan images of the chest because it seems to be a reliable method to characterize and quantify the volume of retained clot in the pleural cavity.

Treatment strategies include observation, image-guided drainage, thoracostomy, video-assisted thoracoscopy (VATS), intrapleural fibrinolytics, and thoracotomy. Although considered the gold standard, thoracotomy is associated with complications. In recent years, trauma surgeons have preferred to use less invasive modalities initially, leaving the open thoracotomy approach for cases that do not resolve with less invasive methods.

A recent AAST multiinstitutional prospective observational trial was carried out to determine current management strategies used in modern trauma centers in North America. The authors analyzed 328 cases of retained hemothorax from 20 centers over a 2-year period. Successful observation occurred in cases of hemothorax volume less than 300 mL. VATS was used in 33.5% of patients, and factors related to its success included hemothorax volume up to 900 mL, absence of a diaphragmatic injury, and use of periprocedural antibiotics for thoracostomy placement. Of note, several patients needed more than one, and sometimes more than two, VATS procedures to completely evacuate the pleural cavity of retained blood. Thoracotomy was necessary in 20.4%. The overall incidence rate of empyema was 26.8%.

TUBE THORACOSTOMY

Tube thoracostomy is the most common procedure performed in the management of thoracic trauma. In fact, 85% of the patients with chest injuries need only clinical observation or tube thoracostomy. A large-bore (36F to 40F) chest tube should be used in adolescents and adult patients. The chest tube should be placed in the midaxillary line in the fourth or fifth interspace at the level of the nipple in males and the inframammary fold in females. A small incision approximately 1.5 to 2 cm in length is made with a scalpel, and a clamp is used to bluntly dissect the subcutaneous tissue until the bony rib is felt. The clamp is then used to bluntly enter the thoracic cavity immediately over the top of the rib to avoid injury to the neurovascular bundle located beneath each rib. The index finger should be inserted into the pleural space before tube placement to ensure that the pleural cavity has been entered and is free of adhesions and that intraabdominal organs have not herniated through the diaphragm. The tube should be advanced posteriorly and superiorly in the pleural cavity. In most adults, insertion of 10 to 12 cm of the tube should be adequate to ensure the last side port is within the chest cavity. In all cases, further advancement of the tube should be stopped as soon as resistance is felt. The tube is then secured in place with a suture, and the insertion site is dressed with an occlusive dressing. The end of the tube should then be connected to a closed drainage system. After insertion, the tube should be secured in the skin of the chest wall and connected to a collection system with suction. The procedure should be performed with universal precautions. A cap, mask, gown, and sterile gloves should be worn by the surgeon, and a cap and mask should be worn by everyone in the room. Chlorhexidine preparations are preferred because they have a decreased risk of surgical site infections. The site should be properly cleansed and anesthetized and completely draped to avoid contamination of the site, instruments, or chest tube. A single dose of preprocedure antibiotics with gram-positive coverage has proven as effective as a 24-hour course of periprocedure antibiotic prophylaxis.

A chest x-ray is usually obtained after chest tube insertion to confirm adequate placement and positioning. General criteria for chest tube removal include absence of air leak and less than 150 mL of fluid drainage over a 24-hour period.

Chest tubes in experienced hands can be placed fairly rapidly and efficiently. The most important step is entry of the thoracic cavity to allow escape of the air trapped there, which is accomplished even more rapidly and occurs once the thorax has been entered with blunt dissection. A rush of air or blood should be observed on entry into the pleural cavity, with immediate relieving of intrathoracic tension and improvement in the patient's vital signs.

Abdominal Trauma

LD Britt, MD, MPH, D.Sc (Hon), FACS, FCCM, FRCSEng (Hon), FRCSEd (Hon), FWACS (Hon), FRCSI (Hon), FCS(SA) (Hon)

INITIAL MANAGEMENT

Before focusing on the specific anatomic region of an obvious traumatic injury, an initial assessment of the entire patient is imperative.

The concept of initial assessment includes the following components: (1) rapid primary survey; (2) resuscitation; and (3) detailed secondary survey (evaluation) and reevaluation. Such an assessment is the cornerstone of the Advanced Trauma Life Support (ATLS) program. Integrated into primary and secondary surveys are specific adjuncts. Such adjuncts include the application of electrocardiographic monitoring and other monitoring modalities, such as arterial blood gas determination, pulse oximetry, measurement of ventilatory rate and blood pressure, and insertion of urinary or gastric catheters, and the incorporation of necessary x-rays and other diagnostic studies, when applicable, such as focused assessment with sonography for trauma (FAST) and plain radiography of the spine/chest/pelvis and computed tomographic (CT) scan.

The focus of the primary survey is both identification and expeditious address of immediate life-threatening injuries. Only after the primary survey is completed (including the initiation of resuscitation) and hemodynamic stability is addressed should the secondary survey be conducted; this survey entails a head-to-toe (and back-to-front) physical examination, along with a more detailed history.

Only the emergency care disciplines of medicine have this two-tier approach to their initial assessment of the patient, with primary and secondary surveys as integral components. As highlighted previously, the primary survey is designed to quickly detect life-threatening injuries. Therefore, a universal approach has been established with the following prioritization:

- Airway maintenance (with protection of the cervical spine);
- Breathing (ventilation);
- Circulation (including hemorrhage control);
- Disability (neurologic status);
- And exposure and environmental control.

Such a systematic and methodical approach (better known as the ABCDEs of the initial assessment) greatly assists the surgical or medical team in the timely management of those injuries that could result in a poor outcome.

A. Airway assessment management (along with cervical spine protection).
 Because loss of a secure airway can be lethal within 4 minutes, airway assessment and management always has the highest priority during the primary survey of the initial assessment of any injured patient, irrespective of the mechanism of injury or the anatomic wound. The chin-lift and jaw-thrust maneuvers are occasionally helpful in attempting to secure a patent airway. However, in the trauma setting, the airway management of choice is often a translaryngeal, endotracheal intubation. If this cannot be achieved because of upper airway obstruction or some technical difficulty, a surgical airway (needle or surgical cricothyroidotomy) should be the alternative approach. No other management can take precedence over obtaining appropriate airway control. Until adequate and sustained oxygenation can be documented, administration of 100% oxygen is required.

B. Breathing (ventilation assessment).
 An airway can be adequately established and optimal ventilation still not be achieved: for example, in the case of an associated tension pneumothorax (other examples include a tension hemothorax, open pneumothorax, or a large flail chest wall segment). Worsening oxygenation and an adverse outcome ensue unless such problems are expeditiously addressed. Therefore, assessment of breathing is imperative, even with an established and secure airway. A patent airway but poor gas exchange still results in a poor outcome. Tachypnea, absent breath sounds, percussion hyperresonance, distended neck veins, and tracheal deviation are all consistent with inadequate gas exchange. Decompression of the pleural space with a needle or chest tube insertion should be the initial intervention for a pneumothorax or hemothorax. A large flail chest, with underlying pulmonary contusion, likely requires endotracheal intubation and the administration of positive-pressure ventilation.

C. Circulation assessment (adequacy of perfusion management).
 The most important initial step in determination of adequacy of circulatory perfusion is quick identification and control of any active source of bleeding, along with restoration of the patient's blood volume with crystalloid fluid resuscitation and blood products, if necessary. Decreased levels of consciousness, pale skin color, slow (or nonexistent) capillary refill, cool body temperature, tachycardia, and diminished urinary output are all suggestive of inadequate tissue perfusion. Optimal resuscitation requires the insertion of two large-bore intravenous lines and infusion of crystalloid fluids (warmed). Adult patients with severely compromised conditions need a fluid bolus (2 L of Ringer's lactate or saline solution). Children should receive a 20-mL/kg fluid bolus. Blood and blood products are administered as needed. Along with the initiation of fluid resuscitation, emphasis needs to remain on identifying the source of active bleeding and stopping the hemorrhage. For a patient in hemorrhagic shock, the source of blood loss is an open wound with profuse bleeding, or within the thoracic or abdominal cavity, or an associated pelvic fracture with venous or arterial injuries. Disposition (operating room, angiography suite, etc.) of the patient depends on the site of bleeding. For example, a FAST assessment that documents substantial blood loss in the abdominal cavity in a patient with a hemodynamically labile condition dictates an emergency celiotomy. However, if the quick diagnostic workup of a patient with a hemodynamically unstable condition who has sustained blunt trauma shows no blood loss in the abdomen or chest, then the source of hemorrhage could be from a pelvic injury that would likely necessitate angiography or embolization if external stabilization (e.g., a commercial wrap or binder) of the pelvic fracture fails to stop the bleeding. Profuse bleeding from open wounds can usually be addressed with application of direct pressure or occasionally with ligation of torn arterial vessels that can easily be identified and isolated.

D. Disability assessment and management.
 Only a baseline neurologic examination is required when performing the primary survey to determine neurologic function deterioration that might necessitate surgical intervention. A detailed neurologic examination is inappropriate to attempt initially. Such a comprehensive examination should be done during the secondary survey or evaluation. This baseline neurologic assessment could be the determination of the Glasgow Coma Scale (GCS), with an emphasis on the best motor or verbal response and eye opening. An alternative approach for a rapid neurologic evaluation is the assessment of the pupillary size and reaction, along with establishing the patient's level of consciousness (alert, responds to visual stimuli,

responds only to painful stimuli, or unresponsive to all stimuli). The caveat that must be highlighted is the fact that neurologic deterioration can occur rapidly and that a patient with a devastating injury can have a lucid interval (e.g., epidural hematoma). Because the leading causes of secondary brain injury are hypoxia and hypotension, adequate cerebral oxygenation and perfusion are essential in the management of a patient with neurologic injury.

E. Exposure and environmental control.
For a thorough examination, the patient must be completely undressed. This often requires cutting off the garments to safely expedite such exposure. However, care must be taken to keep the patient from becoming hypothermic. Adjusting the room temperature and infusing warmed intravenous fluids can help establish an optimal environment for the patient.

The secondary survey should not be done until the primary survey has been completed and resuscitation initiated, with some evidence of normalization of vital signs. This head-to-toe evaluation must be performed in a detailed manner to detect less obvious or occult injuries. This is particularly important in the unevaluable patient (e.g., with head injury or severely intoxicated). The physical examination should include a detailed assessment of every anatomic region, including the following:

- Head
- Maxillofacial region
- Neck (including cervical spine)
- Chest
- Abdomen
- Perineum (including the rectum and genital organs)
- Back (including the remaining spinal column)
- Extremities (musculoskeletal)

A full neurologic examination needs to be performed, along with an estimate of the GCS score if one was not done during the primary survey. The secondary survey and the utilization (when applicable) of the armamentarium of diagnostic adjuncts previously mentioned allow detection of more occult or subtle injuries that could, if not found, account for significant morbidity and mortality. When possible, the secondary survey should include a history of the mechanism of injury, along with vital information regarding allergies, medications, past illnesses, recent food intake, and pertinent events related to the injury.

It cannot be overemphasized that frequent reevaluation of the injured patient is necessary to detect any deterioration in the patient status. This sometimes requires repeating both the primary and the secondary surveys.

TOPOGRAPHY AND CLINICAL ANATOMY

The abdomen is often defined as a component of the torso that has for its superior boundary the left and right hemidiaphragm, which can ascend to the level of the nipples (fourth intercostal space) on the frontal aspect and to the tip of the scapula in the back. The inferior boundary of the abdomen is the pelvic floor. For clinical purposes, further division of the abdomen into four areas is helpful: (1) anterior abdomen (below the anterior costal margins to above the inguinal ligaments and anterior to the anterior axillary lines); (2) intrathoracic abdomen (from the nipple or the tips of the scapula to the inferior costal margins); (3) flank (inferior scapular tip to the iliac crest and between the posterior and anterior axillary lines); and (4) back (below the tips of the scapula to the iliac crest and between the posterior axillary lines). Most of the digestive system and urinary tract, along with a substantial network of vasculature and nerves, are contained within the abdominal cavity. A viscera-rich region, the abdomen can often be the harbinger for occult injuries as a result of penetrating wounds, particularly in the unevaluable abdomen as the result of a patient's compromised sensorium.

PHYSICAL EXAMINATION

A complete and thorough physical examination of the entire body is essential in the management of abdominal injury. Some findings (Box 1) on physical examination are absolute indications for operative intervention. The components of the physical examination should include careful inspection, palpation, and auscultation.

With respect to penetrating abdominal trauma, inspection can sometimes determine the trajectory of the missile or other wounding agents and, consequently, guide management decisions. Often this can be determined by the location, extent, and number of wounds. For example, a patient with a documented, superficial tangential gunshot wound (low-velocity) with no other remarkable physical findings is likely to be managed expectantly (observation). However, if a penetrating abdominal injury results in a patient presenting with an evisceration, exploratory laparotomy is the management option of choice. Palpation enables the examiner to elicit abdominal tenderness or frank peritoneal signs and to detect abdominal distention and rigidity. On occasion, missiles can be palpated lodged in the soft tissue. Unless the setting is controlled and sterile, such as the operative theater, probing of a wound should be avoided. Auscultation is also an important component of the physical examination. It can help determine diminished or absent bowel sounds that could be suggestive of evolving peritonitis. Also, auscultation could detect a trauma-induced bruit, suggestive of a vascular injury.

The examiner has to be keenly aware of situations in which the abdominal examination is unreliable because of possible spinal cord injury or a patient's altered mental state.

DIAGNOSTIC STUDIES

The abdomen is notorious for hiding its secrets: occult injuries. Access to an extensive diagnostic armamentarium is imperative in the optimal management of these injuries. The mainstay diagnostic modality for evaluation of blunt abdominal trauma is CT scan. Although CT scan is beginning to have a more pivotal role in the assessment of penetrating abdominal injuries, there are diagnostic options strongly advocated by some for abdominal stab wounds. Local wound exploration, for example, has the advantage of allowing the patient to be discharged from the trauma bay or emergency department if surgical exploration of the wound fails to show penetration of the posterior fascia and peritoneum. However, if the patient has to go to the operating room for other injuries, the local wound exploration should be done in the surgical suite that has better lighting and a more sterile environment. A positive finding during local wound exploration dictates a formal laparotomy or laparoscopy. However, even with local wound exploration as a guide, the nontherapeutic laparotomy rate can be high, given that only a third of the patients with stab wounds to the anterior abdomen need therapeutic laparotomy. In the patient who has an evaluable abdomen,

BOX 1: Absolute indications for exploratory laparotomy in abdominal injuries

A. Peritonitis
B. Evisceration
C. Impaled object
D. Hemodynamic instability (documented or suspected intra-abdominal source)
E. Associated bleeding from natural orifice

serial abdominal examinations are an acceptable alternative to local wound exploration, to determine the need for operative intervention. Local would exploration should only be done for stab wounds to the anterior abdomen. Such an approach is potentially too hazardous for thoracoabdominal penetrating injuries and back or flank wounds. Plain radiography (abdomen/pelvis/chest) can be pivotal in documenting the presence of missiles and other foreign bodies and determining the trajectory of the injury tract, particularly for wounds from firearms. Also, the presence of free air might be confirmed with plain radiography. Unless concern exists about a retained broken blade or some other object, plain radiography has little utility for stab injuries. The diagnostic peritoneal lavage (DPL) developed by David Root in 1965 was a major advance in the care of the hemodynamically labile case of blunt trauma. With the advent of FAST and rapid CT scan, DPL has very limited utility. Diagnostic peritoneal lavage has never had a broad appeal in the diagnostic evaluation of penetrating abdominal wounds. Although some have advocated its use with tangential wounds of the abdominal wall, the technique has failed to receive widespread support. Its reliability in detection of clinically significant injuries sustained as a result of penetrating abdominal injuries has been a prevailing concern. The reported sensitivity and specificity of DPL for abdominal stab wounds are 59% to 96% and 78% to 98%, respectively. Also, DPL is a poor diagnostic modality for detection of diaphragmatic and retroperitoneal injuries.

Diagnostic imaging has had the greatest impact in changing the face of trauma management, with CT scan taking the lead in this area. Its ubiquitous presence in the management of blunt abdominal trauma is well established. As underscored previously, it is becoming an important diagnostic study in the evaluation of penetrating abdominal injuries. In addition to its excellent sensitivity in detection of pneumoperitoneum, free fluid, and abdominal wall/peritoneal penetration, CT scan is helpful in identification of the tract of the penetrating agent. Hauser and colleagues recommended the use of triple-contrast CT scan in the assessment of penetrating back and flank injuries. CT scan evaluation is an essential diagnostic tool in the increasing advocacy for selective management of abdominal gunshot wounds, obviating the need for mandatory surgical exploration. However, two major limitations of CT scan still remain: detection of an intestinal perforation and finding of a diaphragmatic injury.

Unless the injury is confined to the solid organ of the abdomen, such as the liver or spleen, the matrix of intestinal gas patterns makes detection of penetrating injuries difficult. Kristensen, Buemann, and Kuhl were one of the first teams to introduce the role of ultrasound scan as part of the diagnostic armamentarium in trauma management. Kimura and Otsuka endorsed use of ultrasound scan in the emergency room for evaluation of hemoperitoneum. FAST does not have the same broad application in the evaluation of penetrating trauma as it does in blunt trauma assessment. Rozycki, Ochsner, Schmidt, and associates reported on the expanded role of ultrasound scan as the "primary adjuvant modality" for the injured patient assessment. Rozychi also reported that FAST examination was the most accurate for detection of fluid within the pericardial sac. Such a finding is confirmatory for a cardiac injury and possible cardiac tamponade, given a mechanism of injury that could result in an injury to the heart.

As a diagnostic modality, laparoscopy is not a new innovation. Other specialists have used this operative intervention for several decades. However, it was formally introduced as a possible diagnostic procedure of choice for specific torso wounds when Ivatury and colleagues did a critical evaluation of laparoscopy on penetrating abdominal trauma. Fabian and associates also reported on the efficacy of diagnostic laparoscopy in a prospective analysis.

No conventional diagnostic tool can conclusively rule out a diaphragmatic laceration or rent, so diagnostic laparoscopy becomes the study of choice for penetrating thoracoabdominal injuries, particularly left thoracoabdominal wounds. Laparoscopy can also be used to determine peritoneal entry from a tangential penetrating injury.

PENETRATING ABDOMINAL INJURIES AND THE HEMODYNAMICALLY STABLE AND UNSTABLE CONDITION

The management principles in patients with penetrating abdominal injuries whose conditions remain hemodynamically stable depend on the mechanism and location of injury, along with the hemodynamic status of the patient. Irrespective of the patient's hemodynamic parameter, the ATLS protocol should be strictly followed on arrival of the patient to the trauma bay.

EXPLORATORY LAPAROTOMY IN TRAUMA

The operative theater should be large enough to accommodate more than one surgical team, in the event the patient might need simultaneous procedures. In addition, the room should have the capability of maintaining room temperature as high as the lower 80°F-plus range to avoid hypothermia in the patient. Also, a rapid transfusion device should be in the room to facilitate the delivery of large fluid volume and ensure that the fluid administration is appropriately warm.

Abdominal exploration for trauma has basically four imperatives: (1) hemorrhage control; (2) contamination control; (3) identification of the specific injury; and (4) repair or reconstruction. The abdomen is prepared with a topical antimicrobial from sternal notch to bilateral mid thighs and extended laterally to the side of the operating room table followed by wide draping of the patient. Such preparation allows for expeditious entry into the thorax if needed and possible vascular access or harvesting. Exploration is initiated with a midline vertical incision that should extend from the xiphoid to the symphysis pubis for optimal exposure.

The first priority on entering the abdomen is control of exsanguinating hemorrhage. Such control can usually be achieved with direct control of the lacerated site or with proximal vascular control. After major hemorrhage is controlled, blood and blood clots are removed. Abdominal packs (radiologically labeled) are used to tamponade any bleeding and allow for identification of any injury bleeding. The preferred approach to packing is to divide the falciform ligament and retract the anterior abdominal wall. This allows manual placement of the packs above the liver. Abdominal packs should also be placed below the liver. This arrangement of the packs on the liver creates a compressive tamponade effect. After manual evisceration of the small bowel out of the cavity, packs should be placed on the remaining three quadrants, with care taken to avoid an iatrogenic injury to the spleen. During the packing phase, after ongoing hemorrhage has been controlled, the surgeon should communicate with the anesthesia team that major hemorrhage has been controlled and that this is an optimal time to establish a resuscitative advantage with fluid, blood, or blood product administration.

The next priority should be control or containment of gross contamination. This begins with the removal of the packs from each quadrant, one quadrant at a time. Packs should be removed from the quadrants that are least suspected as the source for blood loss, followed by removal of the packs from the final quadrant, the one that is believed to be the area of concern.

After control of major hemorrhage has been achieved, any evidence of gross contamination must be addressed immediately. Obvious leakage from intestinal injury can be initially controlled with clamps (e.g., Babcock clamp), staples, or sutures. The entire abdominal gastrointestinal tract needs to be inspected, including the mesenteric and antimesenteric border of the small and large bowel,

along with the entire mesentery. Rents in the diaphragm should also be closed to prevent contamination of the thoracic cavity.

Further identification of any and all intra-abdominal injuries should be initiated. Depending on the mechanism of injury and the estimated trajectory of wounding agent, a thorough and meticulous abdominal exploration should be performed, including entering the lesser sac to better inspect the pancreas and the associated vasculature. In addition, mobilization of the C-loop of the duodenum (Kocher's maneuver) might be necessary, along with medial rotation of the left or right colon for exposure of vital retroperitoneal structures.

The final component of a trauma laparotomy is definitive repair, if possible, of specific injuries. As highlighted subsequently in this chapter, the status of the patient dictates whether each of the components of a trauma laparotomy can be achieved at the index operation. A staged celiotomy ("damage control" laparotomy) might be necessary if the patient becomes acidotic, hypothermic, coagulopathic, or hemodynamically compromised.

Diaphragm

The diaphragm, a dome-shaped muscular structure with an aponeurotic sheath ("central tendon"), effectively separates the thoracic and abdominal cavities. It attaches to the first three lumbar vertebrae, the ribs, and the posterior aspect of the lower sternum. Because of the decussation of its crura and hiatal architecture, the diaphragm provides an avenue for many vital structures, including the aorta, esophagus, thoracic duct, vagi, azygos vein, and inferior vena cava. Physiologically, the wide excursion of the diaphragm during inspiration and expiration contributes to both respiratory function and venous return.

Blunt trauma accounts for up to 30% of traumatic diaphragmatic ruptures in the United States. Motor vehicle collisions and falls from heights are the most common mechanisms of injury. Diaphragmatic rupture occurs as a result of an acute increase in the intra-abdominal pressure. Probably because of the buttressing effect of the liver, right-sided diaphragmatic ruptures occur less frequently than those on the left.

In addition to ruling out a possible cardiac injury if the penetrating wound is more central, the paramount reason that the thoracoabdominal region (Figure 1) presents such a diagnostic challenge to the acute care surgeon is the possibility of an occult diaphragmatic injury. Patients who are hemodynamically labile or have peritoneal signs need mandatory exploration. Patients with clinically stable conditions should undergo a more selective approach. Although the imaging armamentarium is quite vast, no conventional diagnostic modalities can consistently and conclusively make the definitive diagnosis of a diaphragmatic injury. The diagnosis of a diaphragmatic injury is important for two basic reasons. First, the presence of an acute injury to the diaphragm mandates abdominal exploration because of the potential of risk for an associated intra-abdominal injury. Second, both acute and long-term risks exist for diaphragmatic herniation and possible incarceration or strangulation. Even with chest x-ray (CXR), CT scan, FAST, DPL, magnetic resonance imaging (MRI), and fluoroscopy, this dilemma persists, because none of these diagnostic modalities reliably detect a diaphragmatic rent. Because of this diagnostic challenge, the thoracoabdominal region was correctly underscored as "the ultimate blind spot" in penetrating trauma. This ongoing challenge was attributed to the presence of the diaphragm in this region. Documentation of a diaphragmatic injury has been a difficult task since it was first described by Sennertus in 1541. Patients who present with indications for exploration (Box 2) need no essential diagnostic studies. Without any definitive way of determining diaphragmatic injury, even with no absolute indication for operative intervention, a celiotomy was often the management approach of choice for such injuries, particularly *left* penetrating thoracoabdominal injuries. An expectant approach (observation only) does not address potential for the presence of an injury to the diaphragm and its sequela, such as the increased risk for the development of a herniation of abdominal viscera. This potential complication is thought to be secondary to nonhealing of the injury site. Factors proposed that may contribute to hernia formation include: (1) relative thinness of the diaphragm; (2) constant motion; and (3) pressure difference across the diaphragm that favors movement of abdominal contents from the abdomen into the thoracic cavity. Although the injury occurs acutely, clinical signs of a hernia are usually lacking and a high index of suspicion is imperative to prompt optimum investigation. The time from injury to presentation of a symptomatic diaphragmatic hernia may vary from days to many years after injury. This has led to the development of a classification system for diaphragmatic hernias based on time of presentation. The acute phase occurs during or shortly after the time of injury. The next phase is the interval, or latent, phase. During this phase, the patient may have abdominal pain that greatly resembles that of common etiologies for upper abdominal pain. The final phase is the obstructive, or strangulation phase; the patient may present with signs and symptoms of bowel obstruction or even peritoneal signs as a result of necrosis of the incarcerated bowel. Patients who present in the obstructive phase with necrotic viscera are common and have a documented mortality rate of greater than 40%. This further emphasizes the importance of diagnosis and repair of these injuries in the acute setting, to avoid such complications.

Several diagnostic modalities have been used in the evaluation of thoracoabdominal trauma in both the blunt and the penetrating settings. Chest x-ray is the usual screening diagnostic modality.

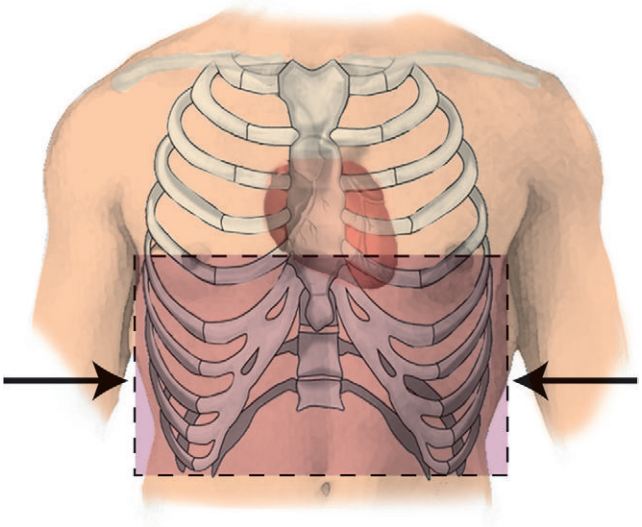

FIGURE 1 Areas of concern for thoracoabdominal injuries.

6. Impaled object

CT, Computed tomographic.

However, the diagnostic accuracy for diaphragmatic injuries ranges from as low as 13% to as high as 94% in the literature. Shah and associates looked at a collective series where CXR was diagnostic in 40.7% of cases reviewed. This approaches the 50% accuracy rate. They also found that the accuracy was increased when the study was repeated after the placement of a radiopaque nasogastric tube. However, the sensitivity of CT scan has been less than optimal. Shanmuganathan and colleagues looked retrospectively at CT scan as a diagnostic modality in thoracoabdominal injuries. Forty-one patients with both blunt and penetrating injuries were included. CT scan had a sensitivity of 63% and a specificity of 100% for diaphragmatic "rupture" in the blunt cases. CT scan failed to diagnose diaphragmatic injuries without associated visceral herniation. Patients with penetrating injuries are less likely to have visceral herniation; therefore, their injuries can easily be missed if CT scan is used as a mode of diagnosis. In the McQuay/Britt study, five patients would have fallen into this category. These and other radiologic studies are usually not accurate in the acute phase of penetrating injuries. This was the rationale for establishing a practice of mandatory exploration to evaluate better the integrity of the diaphragm and associated injuries.

The incidence rate of diaphragm injuries as a result of penetrating trauma ranges from 0.8% to 15%. Mandatory exploration of all penetrating thoracoabdominal injuries has been advocated for many years on the premise that it is the only way to assess definitively the diaphragm. The importance of adequate visualization cannot be underestimated, considering the increased morbidity and mortality as a result of a missed diaphragmatic injury.

Mandatory celiotomy for an injury with such a low incidence resulted in a high number of nontherapeutic explorations, prompting the need for an alternative approach. In 1992, Rao Ivatury and associates introduced for this cohort of patients diagnostic laparoscopy as the definitive modality for identification of diaphragmatic injuries in penetrating thoracoabdominal trauma. In the acute setting of penetrating thoracoabdominal injuries, few (if any) indications exists for performing diagnostic thoracoscopy to determine the integrity of the diaphragm. Such an intervention likely requires a double-lumen endotracheal tube insertion and lateral decubitus positioning of the patient. If a diaphragmatic through-and-through injury is actually confirmed (especially on the left side), the patient needs to be repositioned in the supine position and prepared and draped for a celiotomy. Therefore, a diagnostic laparoscopy is more appropriate and efficient management for these injuries.

Laparoscopy was introduced as a possible alternative for the evaluation of penetrating thoracoabdominal trauma. Fabian and colleagues studied 182 patients over a 19-month period. Laparoscopy revealed no peritoneal penetration in 55% of the patients reviewed. Of the remaining patients, 66% had therapeutic laparotomy, 17% had nontherapeutic laparotomy, and 17% had negative laparotomy. Ortega and colleagues studied 24 patients with penetrating thoracoabdominal injuries and reviewed their experience with diagnostic laparoscopy (DL). Their specificity and positive predictive values were 100% for lesions of the diaphragm, liver, spleen, and hollow viscus. Others have attempted to use DL not only to document peritoneal penetration but also to determine the extent and operative management of intra-abdominal injury. Zantut and associates looked at laparoscopy as both a diagnostic and a therapeutic modality. Retrospective data of 510 patients from 3 institutions were included. Laparotomy was avoided in 303 patients (59.4%) in whom laparoscopy was negative for peritoneal penetration. Livingston and colleagues prospectively evaluated 39 patients with hemodynamically normal conditions with penetrating thoracoabdominal injuries with DL. Laparoscopy correctly identified the presence of intra-abdominal injuries in 26 patients. The McQuay/Britt study revealed 22 unsuspected injuries, 17 of them with intra-abdominal organ injuries that necessitated operative repair.

The ability to adequately evaluate the diaphragm with the laparoscope provides an attractive diagnostic modality that benefits those patients with diaphragmatic injury and avoids an unnecessary celiotomy. As the technology and the laparoscopic skills of surgeons develop, diagnostic laparoscopy will become more of a therapeutic option.

In the acute setting, diaphragmatic injuries are preferentially repaired primarily in a two-layer fashion, with a heavy nonabsorbable suture. Although the implications are infrequent, a nonabsorbable mesh can be incorporated in the diaphragmatic closure where there is significant tissue destruction, which usually occurs in blunt trauma. In the unlikely event of a gross contamination, endogenous tissue can be used for a definitive repair. Such tissue includes a latissimus dorsi flap, tensor fascia lata, or omentum. Some practitioners advocate use of biologic tissue grafts, such as AlloDerm (human acellular tissue matrix; Life Cell Corporation). The durability of such a repair is questionable. Figure 2 is a treatment algorithm for generating thoracoabdominal injuries, the most common mechanism for diaphragmatic injuries.

Overall, the expected outcomes for diaphragmatic injuries are good (Table 1). Mortality and significant morbidity are related to associated organ injuries.

Stomach, Small Bowel, Colon, and Rectum

Stomach

The stomach is the second most common intraperitoneal hollow viscus injured. Its size and intraperitoneal location make this organ a vulnerable target, with size being affected by the intraluminal volume. Gastric injury from blunt trauma is quite infrequent. When it does occur, it is often the result of increased intraluminal pressure and distension. Seatbelt injuries and direct blows to the epigastrium are common causes of gastric injuries. With respect to penetrating wound of the stomach, a more frequent mechanism of injury, the anterior and posterior aspects of the stomach need to be meticulously inspected for accompanying through-in-through injuries. Penetrating injuries of the stomach should be repaired primarily after débridement of nonviable edges. The primary repair can be performed in either a single layer with nonabsorbable suture or as a double-layer closure with an absorbable suture (e.g., Vicryl, Ethicon, Inc., Somerville, NJ), with the first layer and the second layer closed with unabsorbable sutures (e.g., silk). This approach compromises the gastric lumen in only a very few penetrating injuries of the stomach. Fortunately, major resective procedures are not commonly necessary in gastric injuries. Because gross contamination is usually associated with stomach wounds, copious irrigation of the abdominal cavity is an essential component of the operative strategy.

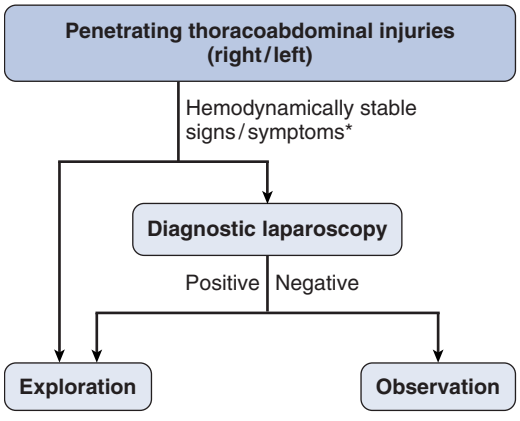

FIGURE 2 Treatment algorithm.

TABLE 1: Diaphragmatic injuries

Organ	Incidence rate	Diagnosis	Specific management	Outcome
Diaphragm	6% of all intra-abdominal injuries that result from penetrating trauma	Physical examination • Chest pain and shortness of breath • Scaphoid abdomen • Bowel sounds on auscultation of the hemithorax Plain radiography • Hollow viscus noted in the left hemithorax Nasogastric tube in the left hemithorax FAST examination • Unreliable DPL • Inconclusive; high false-negative CT scan • Inconclusive Laparoscopy, the diagnostic modality of choice	Preoperative antibiotics Primary closure is the preferred definitive management With documentation of a diaphragmatic rent (laceration), exploratory laparotomy is necessary	Associated injuries dictate morbidity and mortality

CT, Computed tomographic; *DPL,* diagnostic peritoneal lavage; *FAST,* focused assessment with sonography for trauma.

Small Intestine

Small bowel is the most common intraperitoneal hollow viscus injured. As with other hollow viscus injuries, nonoperative management has no place in a small bowel perforation or rupture. CT scan evaluation is usually not necessary with penetrating injuries, but it can be helpful in detection of a possible bowel injury. The two basic types of findings of bowel injury on CT scan are direct and indirect (Table 2). The management of injuries to the small intestine is well established, with control of bleeding and gross spillage being strategic mainstays. If bowel viability is questioned secondary to blunt or penetrating trauma, a segmental resection should be performed. Isolated small bowel enterotomies can be closed primarily with nonabsorbable sutures for a one-layer closure. If the edges of the enterotomy appear nonviable, they should be gently débrided before primary closure. However, multiple contiguous small bowel holes or an intestinal injury on the mesenteric border with associate mesenteric hematoma likely necessitate segmental resection and anastomosis of the remaining viable segments of the small bowel. The operative goal is always the reestablishment of intestinal continuity without substantial narrowing of the intestinal lumen, along with closure of any associated mesenteric defects. Application of noncrushing bowel clamps can contain ongoing contamination while the repair is being performed. Although a hand-sewn or stapler-assisted anastomosis is operator dependent, trauma laparotomies are time-sensitive interventions and expeditious management is imperative. In the immediate postoperative period, bowel decompression for 12 to 24 hours is prudent. As in most trauma laparotomies, antibiotics should be routinely given in only the perioperative period, unless an ensuing infectious complication occurs in the postoperative period.

Colon/Rectum

Penetrating trauma accounts for most of the colon and rectal injuries that occur in the civilian setting. Even today, a debate remains regarding the optimal treatment of colon injuries, with the preponderance of evidence supporting primary closure of the colonic wounds and segmental resection (with primary anastomosis) in most traumatic settings. Most colonic injuries are quickly diagnosed during the initial exploration and mobilization of the colon. With two thirds of the rectum being extraperitoneal and bordered by the bony pelvis, detection and direct management of a localized rectal injury is a challenge. Rectal injuries are usually a result of pelvic fractures and penetrating trauma. Oftentimes, rectal injuries are managed with proximal diversion. The segment of injured bowel should be thoroughly inspected for potential through-in-through enterotomies and associated mesenteric injuries. This requires adequate mobilization of the colon for visualization of the entire circumference of the bowel wall. As highlighted previously, initially controversial, an enterotomy (right-sided or left-sided injuries) of the colon can be closed primarily, irrespective of contamination or transient shock state. If the colon injury is so extensive that primary repair is not possible or would severely compromise the lumen, a segmental resection should be performed. Depending on the environmental setting, the remaining proximal segment can be anastomosed to the distal segment or a proximal ostomy and Hartmann's procedure can be performed. If the distal segment is long enough, a mucous fistula should be established. Documented rectal injuries below the peritoneal reflection should necessitate a diverting colostomy and presacral drainage (exiting from the perineum). Such drainage is, however, not universally endorsed.

TABLE 2: Computed tomographic scan findings of blunt bowel injury

Direct	Indirect
Oral contrast extravasation	Mesenteric hematoma
Free air	Mesenteric blush Bowel wall edema Unexplained ascites Fat streaking Unopacified (vascular contrast media) bowel loops

A capsule summary of the incidence, diagnosis, management options, and related outcomes for injuries of the stomach, small intestine, colon, and rectum is depicted in Table 3.

Retroperitoneal Injury

The retroperitoneum is an anatomic bonanza because several of the most vital structures reside in this area, including portions of the duodenum, the pancreas, the kidneys and adrenals, and major vessels

TABLE 3: Injuries of the stomach, small intestine, colon, and rectum: incidence, diagnosis, management options, and outcomes

Organs	Incidence	Diagnosis	Specific management	Outcome
Stomach	More common injury in penetrating trauma than in blunt 10% of penetrating injuries of the abdomen	Physical examination • Epigastric tenderness • Peritoneal signs • Bloody gastric aspirate Plain radiography • Free air under the diaphragm FAST examination • Unreliable DPL • Lavage RBCs WBCs Gross contamination CT scan • Pneumoperitoneum Laparoscopy • Operator dependent	Preoperative antibiotics Débridement when necessary Primary closure (two layers)	Associated injuries dictate morbidity and mortality
Small bowel	Highest incidence rate of injury of the intra-abdominal organ	Physical examination • Cannot rely on tenderness or peritoneal signs in the early stage of injury Plain radiography FAST examination: free fluid with CT scan shows no solid organ injury CT scan • High false-negative rate • Pneumoperitoneum • Free fluid	Preoperative antibiotics Primary closure of simple lacerations Segmented resection of complex injuries with functional end-to-end tensionless anastomosis One-layer (or double-layer) closure/anastomosis or stapled anastomosis	Outcome is good Negligible leak rate even in contaminated field
Colon	Majority Stab wounds Gunshot wounds Instrumentation Blunt trauma, infrequent	Physical examination • Tenderness/peritoneal signs • Gross blood on rectal examination	Preoperative antibiotics Primary closure of simple injuries (avoid narrowing the lumen) Segmental resection and fecal diversion of complex colonic wounds	Overall, favorable outcome Complications • Low leak rate • Wound infection • Intraperitoneal abscess

CT, Computed tomographic; *DPL,* diagnostic peritoneal lavage; *FAST,* focused assessment with sonography for trauma; *RBCs,* red blood cell counts; *WBCs,* white blood cell counts.

(aorta, inferior vena cava, and other vasculature), along with other organs. The specific retroperitoneal injury is usually easily detected with advanced diagnostic imaging, such as CT scan. However, on occasion, such injuries are found during an abdominal exploration for blunt or penetrating trauma. In this setting, the only suggestion of an injury to a structure in this region might be discovery of a retroperitoneal hematoma.

Retroperitoneal Hematomas

The retroperitoneum, an organ-rich region, has several key structures that can be injured when its boundaries are penetrated. The retroperitoneal hematoma can be a major potential site for hemorrhage in patients with either penetrating or blunt trauma because of the substantial vascularity, along with bleeding, that can occur from an associated solid organ wound (e.g., kidney). In the central region (zone I) of the retroperitoneum resides the abdominal aorta, celiac axis, and the superior mesenteric artery, vena cava, and proximal renal vasculature. The lateral retroperitoneum (zone II) encompasses the proximal genitourinary system and its vasculature. The pelvic retroperitoneum (zone III) contains the iliac arteries, veins, and their tributaries. In addition to the vasculature and the kidneys (plus ureters) highlighted previously, the retroperitoneum contains the second, third, and fourth portion of the duodenum, along with the pancreas, the adrenals, and the intrapelvic portion of the colon and rectum. Table 4 underscores the management principles of traumatic retroperitoneal hematomas. Ideally, proximal (and when applicable, distal) control needs to be achieved before exploration of any retroperitoneal hematoma. For retroperitoneal hematomas in zone I, irrespective of a penetrating or blunt mechanism, mandatory exploration is required. Also, a retroperitoneal hematoma in any of the three zones requires exploration for all penetrating injuries. For zone II retroperitoneal hematomas that result from blunt trauma, all pulsatile or expanding hematomas should undergo exploration. Gross extravasation of urine also necessitates exploration. Zone III (pelvic

TABLE 4: The "Zones" of penetrating cervical injuries

Zone	Blunt	Penetrating
I (Central)	Explore	Explore
II (Perinephric)	Observe	Explore
III (Pelvic)	Observe	Explore

retroperitoneum) hematomas should be explored only for penetrating injuries to determine whether there is a specific intrapelvic colorectal, ureteral, or vascular injury. However, such an approach should not be taken for blunt trauma because the injury is likely venous and application of an external compression device is the preferred intervention. An arterial injury could be addressed with arteriography or embolization.

Specific Injuries

Table 5 provides an overview of specific injuries.

TABLE 5: Retroperitoneal

Organs	Incidence	Diagnosis	Specific management	Outcomes
Duodenum/ pancreas	Isolated injuries are uncommon High percentage of associated injuries	Physical examination • Abdominal tenderness • Peritoneal signs Plain radiography • Free air • Retroperitoneal air FAST DPL CT scan	Preoperative antibiotics Duodenal injury: operative armamentarium • Primary repair with gastrostomy retrograde • Jejunostomy: feeding • Jejunostomy • Pyloric exclusive Pancreatic injury: operative armamentarium • Drainage • Débridement • Partial resection • Pancreaticoduodenectomy	Highly lethal as a result of associated injuries Increased mortality with delayed diagnosis of duodenal injury
Kidney	20% of renal injuries result from penetrating trauma	Physical examination Penetrating wound or trajectory in close proximity to the kidney • Hematuria Plain radiography • Nonspecific FAST DPL CT scan (if peritoneal penetration not suspected in a gunshot wound) • Perinephric hematoma • Extravasation	Preoperative antibiotics Operative armamentarium Primary repair with viable tissue buttress • Partial nephrectomy • Nephrectomy	Mortality related to the associated injuries
Bladder	Usually an occult injury found during intraoperative abdominal exploration	Physical examination • Penetrating wound or trajectory in close proximity to the bladder • Hematuria Plain radiography • Nonspecific FAST DPL CT scan (if peritoneal penetration not suspected) Perinephric hematoma • Extravasation of contrast agent	Preoperative antibiotics Multilayer closure with absorbable sutures with indwelling bladder catheter	Excellent outcomes Morbidity and mortality relate to associated injuries
Ureter	Infrequent injury in penetrating trauma	Usually an intraoperative diagnosis	Preoperative antibiotics Management armamentarium Primary repair/stenting Delayed repair and suprapubic cystostomy Diverting nephrostomies	Good outcome if no major associated injuries

CT, Computed tomographic; *DPL,* diagnostic peritoneal lavage; *FAST,* focused assessment with sonography for trauma.

Duodenum and Pancreas

The most frequent retroperitoneal hollow viscus injury, particularly in blunt trauma, is the duodenum. Full-thickness duodenal wounds demand operative management.

Duodenal injuries can be repaired primarily in a one-layered or two-layered fashion if the penetration is less than half the circumference of the duodenum. However, for more complex duodenal injuries, an operative procedure is needed to divert gastric contents away from the site (where closure of the wound has been attempted). A pyloric exclusion with the establishment of a gastrojejunostomy is such a procedure.

Superficial or tangential penetrating wounds of the pancreas, in which there is no injury to the main pancreatic duct, can be externally drained. However, a penetrating injury that transects the pancreas, including the main pancreatic duct, requires extirpation of the distal pancreas (distal pancreatectomy), particularly if the transection site is to the left of the superior mesenteric vessels. A more proximal penetrating injury that involves the main pancreatic duct, with associated complex duodenal injury (e.g., injury to the ampulla) likely necessitates a pancreatoduodenectomy. Unfortunately, because of the rich vascular network that surrounds the pancreas, penetrating pancreatic wounds can be lethal injuries.

In blunt abdominal trauma, assessment of pancreatic injuries to determine whether surgery is required can be extremely challenging. Clinical symptoms, physical examination, and diagnostic imaging (e.g., CT scan) are all important parameters in making the correct decision regarding operative intervention. If a patient presents with abdominal pain and examination has associated abdominal tenderness, along with CT confirmation of pancreatic injury, then that patient needs to proceed to the operative theater for exploration. If the patient is relatively asymptomatic and CT scan findings are consistent with a likely pancreatic injury, endoscopic retrograde cholangiopancreatography (ERCP) can assist in determining whether there is a major ductal injury. Such a finding necessitates exploration for definitive management.

Genitourinary System

Less than 10% of patients with penetrating abdominal wounds sustain genitourinary tract injuries, with most of the injuries being renal. Penetrating injuries that result in a grade IV (cortical/calyceal injury and associated vascular injury with contained hemorrhage) or grade V (shattered kidney and vascular avulsion) invariably necessitate a nephrectomy, particularly if there is a viable contralateral kidney. Lacerations or more superficial wounds of the kidney might require renorrhaphy, with approximation of the disrupted capsule with pledgeted sutures or a prosthetic (mesh) wrap. Absorbable interrupted suture should be used, and all repairs should be drained. On occasion, the injury pattern dictates the need for a partial nephrectomy. Ureteral injuries can be extremely difficult to identify in penetrating wounds with an accompanying retroperitoneal hematoma. When possible, the ureter should be repaired primarily with interrupted absorbable suture over a double J stent. A complete transection of the ureter requires débridement of the nonviable edges, spatulation of the ends, and primary repair over a stent. All repair sites should be adequately drained. If the anastomosis cannot be performed in a tension-free fashion, a bladder flap (Buari's) could be surgically constructed, with implantation of the proximal segment of the transected ureter into the flap. A psoas "hitch" might be necessary if there is any tension on the flap and the tunneled ureter.

Penetrating injury to the intraperitoneal bladder requires surgical repair. After confirmation of no involvement of the trigone, the bladder should be closed with a two-layer closure with absorbable suture (the second layer incorporates Lembert sutures to imbricate the first layer). Suprapubic drainage should only be done selectively; however, a Foley catheter should be left in place.

Abdominal Vascular Injury

With no suggestion of an abdominal visceral injury, a patient who is hemodynamically labile with increasing abdominal distension has a vascular injury, either secondary to a mesenteric rent or specific vessel wound. Several major intra-abdominal vessels can, if injured, result in substantial bleeding. In the central area (zone I), these include the abdominal aorta, the celiac axis vessels, the superior mesenteric artery or vein, the portal vein, and the inferior vena cava. The perinephric region (zone II) encompasses the renal artery and vein, bilaterally. Zone III represents the pelvic region where the iliac arteries and veins and their tributaries lie. Although blunt trauma can result in mesenteric avulsions with associated bleeding, most vascular injuries occur from penetrating abdominal and transpelvic trauma.

The role of aggressive crystalloid resuscitation in the initial management of patients who are in shock from intra-abdominal hemorrhage is still being debated. However, less aggressive fluid resuscitation has been reported to have some benefit, particularly in situations in which the time between the prehospital setting and the definitive hospital management is relatively short. Also, some investigators advocate for performing an emergency thoracotomy, with cross clamping of the descending aorta, to sustain intracranial and coronary flow while decreasing arterial inflow into the abdomen to temporarily address ongoing intra-abdominal hemorrhage in a patient who is in profound shock. In the trauma bay, the quickest method of confirming intra-abdominal hemorrhage is by performing the FAST examination. Such an assessment can be done while the patient is undergoing expeditious ATLS protocol, with the establishment of an optimal airway and the insertion of large-bore intravenous catheters.

On entering the abdomen, free blood and clots should be removed followed with gauze (laparotomy pads) packing of each of the four quadrants. Areas of concern should be manually compressed as the pads are carefully removed from the other quadrants. Also, operative prioritization of intra-abdominal hemorrhage should be done, expeditiously, with identification and control of aortic and inferior vena caval injuries, followed by management of bleeding solid organs. Afterwards, contained retroperitoneal hematomas should be addressed. When appropriate, the fundamental principle of obtaining proximal and distal control of an injured vessel before repair remains the same. Definitive management of specific arterial and venous injuries is elucidated in Tables 6 and 7. Two fundamental maneuvers in gaining access to the central vasculature are medial mobilization of right-sided and left-sighted intra-abdominal viscera (Figures 3 and 4). In addition to having a prepared blood bank, a trauma surgeon encountering a major abdominal vascular injury should have certain adjuncts (e.g., conduits for establishment of temporary shunts and material for silo development in the open abdomen) to assist in the management of the injured patient.

Approximately 25% of patients with major abdominal injuries have significant vascular trauma. No other intra-abdominal presentation defines time-sensitive management like this cohort of injuries.

SUMMARY

Although the concept of standard-of-care management is broadly accepted and adamantly advocated, such care is at times institution dependent. Unfortunately, resource-rich trauma facilities and systems are *not* uniform throughout the country and regionalization has not been perfected nationwide.

However, the overarching mission remains the same: optimal management for everyone, irrespective of where the patient receives trauma care.

TABLE 6: Abdominal arterial injuries: exposure and management options

Site of abdominal vascular injury	Principle route of operative exposure	Preferred management options
Infrarenal aorta	Midline inframesocolic retroperitoneum	Lateral suture, patch repair, or interposition graft (rare) Ligation requires extraanatomic bypass reconstruction
Suprarenal aorta	Left-to-right medial visceral rotation (spleen, pancreas, and left colon)	Lateral suture or patch repair Interposition graft requires bypass to celiac, superior mesenteric, or renal arteries (rare) No ligation
Celiac axis	Left-to-right medial visceral rotation (spleen, pancreas, and left colon)	Lateral suture if feasible; ligation otherwise preferred; interposition graft if collaterals disrupted (rare)
Hepatic artery	Hepatoduodenal ligament	Lateral suture, interposition graft, or ligation (may require bypass graft)
Splenic artery	Through lesser sac	Ligation preferred
Superior mesenteric artery	Left-to-right medial visceral rotation (spleen, pancreas, and left colon); base of mesentery	Lateral suture, patch repair, or ligation and distal bypass
Inferior mesenteric artery	Midline inframesocolic retroperitoneum	Ligation preferred
Proximal renal arteries	Midline inframesocolic retroperitoneum, right-to-left medial visceral rotation (right colon and left duodenum), or left-to-right medial visceral rotation	Lateral suture, patch repair, litigation and bypass, or nephrectomy
Distal renal arteries	Right-to-left medial visceral rotation (right colon and duodenum) on right; left-to-right medial visceral rotation on left	Lateral suture, patch repair, interposition graft or nephrectomy
Common and external iliac arteries	Midline pelvic retroperitoneum; medical reflection of sigmoid colon on left	Lateral suture, patch repair, interposition graft, or ligation with bypass to external iliac artery (may be extraanatomic)
Internal iliac arteries	Midline pelvic retroperitoneum	Ligation preferred

Penetrating Abdominal Trauma

Fredric M. Pieracci, MD, MPH, and Gregory J. Jurkovich, MD

Penetrating abdominal trauma may cause life-threatening injuries that can only be treated with emergent operative intervention. However, in some patients, a nonoperative approach of careful observation is both safe and cost-effective. The initial management of penetrating abdominal trauma is thus directed towards rapid identification of those who need immediate operative intervention, those who may be safely observed for the development of delayed signs of injury, and those who need no further therapy and may be discharged from the emergency department. Although various diagnostic modalities, discussed herein, aid in this decision, a thorough physical examination remains the cornerstone of this triage decision scheme.

HISTORICAL PERSPECTIVE

Nonoperative management of all penetrating abdominal trauma was the standard of care before the late 1800s. That dictum was initially challenged by the southern surgeon J. Marion Sims. Sims criticized the high mortality associated with a nonoperative approach to abdominal gunshot wounds (GSWs), which likely contributed to the death of many famous Americans, including President James Garfield. So began the era of mandatory exploration of all injuries, which remained in effect until G.W. Shaftman introduced the concept of "selective conservatism" in the 1960s. Selective conservatism was based primarily on Shaftman's observation that most penetrating abdominal trauma did not result in injuries that necessitated operative repair. Ignited by Shaftman's hypothesis, work by several traumatologists, including the Western Trauma Association Multicenter Trials Committee, has helped to better define the subset of patients with anterior abdominal stab wounds (AASWs) who may be managed safely with nonoperative algorithms. Similarly, mandatory exploration of abdominal GSWs has been revisited by select high-volume trauma centers, particularly in those patients who are morbidly obese and in whom the trajectory appears tangential, or limited to the high right upper abdominal quadrant. Although this was initially met with skepticism, many trauma surgeons now agree that a selective nonoperative approach for abdominal GSWs may be instituted safely in certain situations and centers. Finally, the introduction of damage control surgery in the late 1970s has changed the conduct of laparotomies for patients with major vascular injuries from penetrating abdominal trauma. It is now recognized that the acidotic, hypothermic, and coagulopathic condition is better served by an abbreviated operation, in which major sources of bleeding and intestinal contamination are controlled, followed by a period of resuscitation before definitive injury repair. This damage control approach has saved innumerable lives compared with the prior strategy of initial definitive management of abdominal injuries in the face of worsening shock.

ANATOMIC DEFINITIONS

In development of management strategies for penetrating abdominal trauma, division of the abdomen into the following three regions is useful: anterior abdomen, flank and back, and thoracoabdomen (Figure 1).

Anterior abdomen: The anterior abdomen is bound by a transverse line through the inferior costal margins superiorly, the groin creases inferiorly, and the anterior axillary lines laterally. Penetrating wounds to the anterior abdominal wall have the highest incidence rate of intraperitoneal injury and are least amenable to a nonoperative approach. Furthermore, injury to intraperitoneal structures (as opposed to retroperitoneal structures) is usually apparent with both a competent clinical examination and a focused abdominal sonography for trauma (FAST) examination.

Flank and back: The flank is bounded superiorly by the inferior costal margin, anteriorly by the anterior axillary lines, posteriorly by the posterior axillary lines, and inferiorly by the anterior superior iliac spines. The back is bounded superiorly by a transverse line through the inferior scapular tips, laterally by the posterior axillary

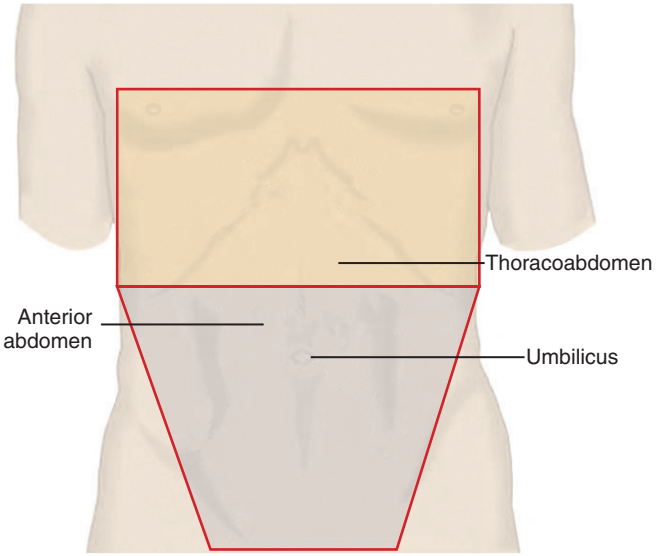

FIGURE 1 Anatomic boundaries of the anterior abdomen and thoracoabdomen.

lines, and inferiorly by a transverse line through the posterior superior iliac spines. Organs of specific concern in these locations include the retroperitoneal portion of the colon, the diaphragm, the kidney, the liver and spleen, and less commonly, the pancreas, duodenum, aorta, inferior vena cava, and ureters. Penetrating wounds to both the flank and the back are associated with a much lower incidence of injury that requires operative intervention as compared with anterior abdomen wounds. However, injury to retroperitoneal structures often eludes the diagnostic capabilities of both physical examination and FAST examination, and delayed diagnosis leads to severe morbidity and often mortality. For this reason, evaluation of these injuries often includes additional imaging methods, most commonly contrast-enhanced computed tomographic (CT) scan.

Thoracoabdomen: The thoracoabdominal region is bounded superiorly by a horizontal line through the nipples in men and inframammary fold in women, inferiorly by a transverse line crossing the inferior costal margins, and laterally by the anterior axillary lines. Management of penetrating wounds to the thoracoabdominal region deserves special consideration for the following reasons. First, with exsanguination, a decision must be made regarding the cavity responsible for the hemorrhage (thoracic, abdominal, or both). These potentially multiple sources of bleeding must then be prioritized vis-a-vis the operative approach. Physical examination, chest radiography, and FAST examination may be useful in this regard. Second, the diaphragm is particularly vulnerable to injury after penetrating thoracoabdominal trauma. Thoracoabdominal wounds that injure the diaphragm have the potential to result in delayed herniation of abdominal contents into the thoracic cavity. Incarceration and eventual strangulation may ensue. This is particularly germane for left-sided thoracoabdominal injuries because right-sided diaphragmatic injuries are extremely unlikely to result in bowel herniation as a result of coverage by the liver. Accordingly, diaphragmatic injury must be considered in all left-sided thoracoabdominal penetrating trauma. The rate of associated intraabdominal injury in patients with left-sided diaphragmatic injuries approaches 90%.

MECHANISM OF INJURY

The next important consideration beyond the location of the wound is the mechanism of injury. The mechanism of abdominal penetration is of relevance primarily with respect to the likelihood of associated intraabdominal injury requiring operative repair. Missile injuries (most commonly as the result of GSWs) are associated with an approximately 90% incidence rate of abdominal injury requiring operative intervention. This relatively high proportion has led to the traditional recommendation of mandatory laparotomy for all patients with abdominal GSWs. However, further stratification is possible. Specifically, patients with a GSW to either the flank or the back have a much lower rate of abdominal injury requiring operative intervention (most series estimate 10% to 15%). Other clinical scenarios associated with a low incidence rate of significant abdominal injury (and thus need for immediate operative intervention) include isolated right upper quadrant GSWs and GSWs in the morbidly obese patient. In addition to a higher likelihood of direct intraabdominal injury compared with stab wounds, GSWs also carry the potential for significant blast effect to organs that are not in the immediate trajectory of the missile.

Shotgun blasts represent a subcategory of missile injuries that may lead to severe blast effect from the simultaneous impact of multiple pellets (buckshot). In general, the greater the distance between the shotgun and the patient, the greater the scatter and the lower the chance of intraabdominal injury requiring operative repair. This principle has been translated into the following classification schema for shotgun injuries: type I, >25 cm scatter; type II, 10 to 25 cm scatter; and type III, <10 cm scatter. A direct relationship is found between the scatter grade and the likelihood of intraabdominal injury; more than one third of patients with a type I injury do not need operative intervention.

In contrast to anterior abdominal GSWs, only 50% to 75% of AASWs enter the peritoneal cavity, and only 50% to 75% of these cause an injury that necessitates operative repair. Consequently, only a minority of stable, asymptomatic cases with AASWs (approximately 20%) need operative intervention. Similar to GSWs, the likelihood of intraabdominal injury after a stab wound is higher for the anterior abdominal region as compared with both the back and the flank.

INITIAL MANAGEMENT

The initial management of patients with penetrating abdominal trauma proceeds according to the guidelines espoused by the American College of Surgeon's Advanced Trauma Life Support. Evaluation begins with the primary survey, which includes assessment of airway, followed by breathing, followed by circulation (ABCs), and the establishment of intravenous assess and institution of resuscitative fluids. The primarily survey also includes a focused neurologic examination (D, disability) and complete exposure (E) of the patient. Patients in shock should receive immediate blood product transfusion. In general, lower extremity access points (e.g., femoral vein) should be avoided in patients with suspected abdominal vascular trauma because venous extravasation limits efficacy. Both nasogastric and urinary bladder tubes, and emergency room x-rays, are considered adjuncts to the primary survey. Insertion of these tubes may be both diagnostic (e.g., bleeding, diaphragm injury) and therapeutic. Abdominal injury does not preclude concomitant thoracic injury, particularly in the case of thoracoabdominal trauma. Thus, the search for immediately life-threatening injuries, such as tension pneumothorax, massive hemothorax, and cardiac tamponade, should be pursued aggressively with physical examination, FAST examination, and chest radiography. Results from each of these tests may be obtained rapidly and are invaluable with respect to ruling out extraabdominal sources of shock. Once these injuries have been ruled out, the patient with a hemodynamically unstable condition should be transported promptly to the operating room because the most likely source of hemorrhagic shock is a major vascular injury. Patients who are transient responders to resuscitation fluids may be further stratified by obtaining a marker of end-organ perfusion, such as a serum lactate concentration or base deficit. These rapid measurements may unmask occult hypoperfusion in the patient with relative

hypotension and should preclude an unnecessary and potentially dangerous trip to radiology. Finally, patients with either agonal or absent vital signs may be candidates for emergency department resuscitative thoracotomy provided: (1) signs of life were at some point noted; and (2) a relatively short period of time has elapsed between arrest and presentation (e.g., less than 15 minutes).

DIAGNOSTIC ADJUNCTS

Patients with hemodynamic instability rarely need adjunctive testing before operation. Important exceptions are extraabdominal sources of shock such as tension pneumothorax and cardiac tamponade, in which both the FAST examination and chest radiograph are useful. The patient with an otherwise stable and hemodynamically normal condition should receive a complete secondary survey, with identification and marking of all wounds. Standard trauma laboratory panels, including a hemoglobin determination and type and cross matching of blood, are obtained routinely. Measurement of a baseline global marker of tissue perfusion, such as lactate or base deficit, is also useful in both detecting occult shock and tracking resuscitative efforts. In general, patients with missile injuries to the abdomen should undergo plain films of both the abdomen and one cavity in either direction (i.e., chest and pelvis films). All wounds should be marked with radiopaque markers (e.g., paper clip, electrocardiogram lead). A single missile wound with nonvisualization of a foreign body on radiograph is suggestive of bullet embolism. Differentiation of "entrance" from "exit" missile wounds is not recommended because this is often not possible and may hamper forensic investigations. The presence of two wounds may represent either a through-and-through missile injury or two separate missiles that remain intracorporeal.

Because of the relatively low incidence of intraabdominal injury from AASWs, local wound exploration (LWE) has emerged as the standard initial diagnostic maneuver in the patient with a hemodynamically normal and stable condition and AASW with a normal physical examination of the abdomen. The goal of the LWE is to assess fascial penetration; if the injury stopped short of the anterior fascia, there is virtually no chance of intraperitoneal injury and the patient may be discharged (negative LWE). In contrast, if the anterior fascia was penetrated, tracking the wound through the muscle is difficult; hence, peritoneal violation must be assumed (positive LWE), and the patient is carefully observed.

The technique of LWE involves administration of local anesthesia and extension of the wound such that adequate evaluation of the track and its distal extent is possible. In some cases, substantial lengthening of the skin incision is necessary, and at no time should wounds be probed blindly, lest a clot occluding a major vascular injury be dislodged. Although the exact definition of a positive LWE has been debated, a generally accepted one is penetration of the anterior fascia (either anterior rectus sheath or external oblique aponeurosis, depending on the location of the wound). When performed properly, LWE allows for approximately one half of asymptomatic, stable AASW cases to be discharged from the emergency department. Patients with positive examination results are observed with serial clinical assessments (discussed subsequently). Importantly, LWE may be nondiagnostic in certain situations, including morbidly obese patients and patients with long, tangential wound tracks. Furthermore, LWE may not be practical in patients with multiple (i.e., ≥3) stab wounds. In these patients, an alternative diagnostic modality, such as abdominal CT scan or laparoscopy, may be considered. Alternatively, if the pretest probability of an intraabdominal injury that necessitates operative repair is low, admission for serial clinical assessments may also be selected.

The FAST examination has now become a routine part of the emergency department evaluation of all trauma patients in many institutions. A "positive" abdominal FAST examination is defined as the presence of fluid on one or more of the three abdominal views (hepatorenal, splenorenal, pelvic). The utility of the FAST examination in the setting of penetrating abdominal trauma rests in three main areas: (1) delineation of an abdominal source of hemorrhagic shock in patients with an unstable condition with multiple possible sources of bleeding (e.g., multiple bullet wounds spanning multiple body cavities); (2) delineation of peritoneal penetration, and thus diaphragm injury, in patients with a thoracoabdominal stab wound; and (3), delineation of peritoneal penetration in patients with AASWs. A positive abdominal FAST examination thus obviates the need for LWE because the peritoneal cavity must have been entered to cause the accumulation of fluid. Importantly, a negative abdominal FAST examination does not rule out intraabdominal injury that necessitates operative repair. The negative predictive value in this setting is approximately 70%; hence, a nonpositive FAST should be called "nondiagnostic" and not "negative." Conversely, the positive predictive value of abdominal FAST examination for detection of intraabdominal injury that necessitates operative repair in the stable case is only 50%. Patients explored solely based on FAST examination findings thus incur an unacceptably high rate of nontherapeutic laparotomy, and FAST examination findings alone should not be the sole deciding factor in the decision to operate on patients with penetrating abdominal trauma.

Diagnostic peritoneal lavage (DPL) involves an infraumbilical incision and passage of a catheter into the peritoneal cavity with local anesthesia, saline solution infusion, withdrawal of the effluent, and testing for blood, enzymes, and foreign material. Once widely applied in the evaluation of abdominal injuries of all mechanisms, this technique has largely been supplanted by CT scan and FAST examination. However, great utility remains for the diagnostic peritoneal aspirate (DPA), the initial step after insertion of the catheter into the peritoneal cavity. If the initial aspirate contains more than 10 mL of gross blood, bile, succus entericus, or food, it is considered positive, and laparotomy is undertaken. If not, 1 L of warm normal saline solution is instilled and recovered with gravity siphonage, and the lavage effluent is sent for biochemical analysis. Generally accepted criteria for a positive DPL include more than 100,000 red blood cells (RBCs)/mm^3, more than 500 white blood cells/mm^3, or elevated amylase, alkaline phosphatase, or bilirubin values in the lavage effluent. Important limitations to the DPL technique include the time necessary to perform the procedure and analyze the effluent, the inability to evaluate for retroperitoneal injury, and the potential for iatrogenic complications.

DPL remains a useful technique in the patient with a hemodynamically normal and stable condition with a benign abdominal examination in whom massive intraabdominal fluid is observed on FAST examination. In this case, DPA is useful in documenting the etiology of the fluid, which is likely preexisting ascites in the aforementioned scenario. The second involves evaluation of the unexaminable, hemodynamically normal, stable case with intraabdominal fluid in the absence of a solid organ injury (as determined with abdominal CT scan). Because solid organ injury is likely to cause at least some amount of hemoperitoneum, the finding of intraabdominal fluid in association with a solid organ injury is expected. In contrast, patients with intraabdominal fluid and without solid organ injury must be considered to have a hollow viscus or mesenteric injury until proven otherwise. In general, the physical examination is used to monitor the patient for signs of bowel injury. However, the inability to examine the patient's abdomen (most commonly because of intoxication, concomitant brain injury, or prolonged exposure to general anesthesia for associated injuries) necessitates an additional diagnostic modality. In this case, DPL can rapidly rule out a bowel injury with high sensitivity and according to the aforementioned criteria.

The final contemporary application of DPL relates to thoracoabdominal wounds in the presence of a normal chest x-ray (CXR) and FAST examination. In this setting, a DPL RBC value below threshold may effectively rule out a diaphragmatic injury and obviate the need for costly additional procedures such as laparoscopy or laparotomy. In this specific setting, the RBC threshold above which further

investigation should proceed has been debated and generally ranges from 1000 to 10,000 RBCs/mm^3. The authors' group currently uses a threshold of 5000 RBCs/mm^3; patients with cell counts below this are observed, whereas those above the threshold undergo laparoscopy with the intent of diagnosis and repair of a diaphragm injury.

Although abdominal CT scan may provide valuable information, it stands out as the only diagnostic modality that involves transport of the patient from the relatively controlled setting of the emergency department. Thus, the hemodynamic integrity of the patient must be ensured before embarking on a journey to radiology, which may involve fatal misadventures, such as inadvertent endotracheal tube dislodgement, loss of intravenous access, and failure to closely monitor and respond to changes in vital signs. Despite this admonition, the ease of obtaining CT imaging, the breadth of information it provides, and the avoidance of direct physician involvement in this diagnostic study are all seductions reminiscent of the Greek mythologic sirens. Abdominal CT scan should thus be relegated to the hemodynamically stable and normal case and has limited utility even within this subgroup. Data from the Western Trauma Association studies indicate a 47% positive predictive value and 91% negative predictive value for intraabdominal injury that necessitates operative repair among hemodynamically stable cases of AASWs. Most false-negative results relate to either hollow viscus or diaphragmatic injuries, both of which are notoriously elusive on CT scan. As a result of this nonspecificity, abdominal CT scan is used primarily to evaluate penetrating trauma to either the back or flank, as retroperitoneal structures are well visualized by this modality and may evade detection with both physical examination and FAST examination. Although patients were traditionally given triple contrast (oral, intravenous, and rectal), rectal contrast is of primary value in left-sided back and flank stab wounds because adequate colonic contrast to the right side of the colon is difficult and uncomfortable for the patient.

Abdominal CT scan has been used to determine the wound track in morbidly obese patients. Contemporary scanners usually provide adequate resolution to determine peritoneal violation and avoid hospitalization in such patients with a low pretest probability of intraabdominal injury. One final scenario in which abdominal CT scan is useful relates to isolated right upper quadrant GSWs in the patient with a hemodynamically stable condition without peritonitis. Documentation of a bullet track isolated to the liver may assist in successful nonoperative management of these patients, although the risk of a missed injury, delayed bile leak, and even hemobilia are consequences that must be anticipated.

The role of laparoscopy in the management of penetrating abdominal trauma continues to evolve. Select situations in which laparoscopy may be beneficial include determination of peritoneal penetration in the setting of a nondiagnostic LWE (e.g., morbidly obese patient, oblique wound track, multiple wounds) and determination of a diaphragm injury in patients with left-sided thoracoabdominal wounds, normal CXR, and normal FAST examination. Although routine laparoscopy in patients with thoracoabdominal wounds is accurate in ruling out diaphragmatic injury, it is not cost effective. The role of laparoscopy may evolve further to include complete abdominal exploration as both surgical skill and technology improve.

INDICATIONS FOR OPERATIVE INTERVENTION AND PRACTICAL ALGORITHMS

Indications for operative intervention in patients with penetrating abdominal trauma may be divided into immediate and delayed. Absolute indications for immediate operative intervention are listed in Box 1. Patients in shock, and those with peritonitis, evisceration, impalement, or blood from a natural orifice, should be explored, regardless of anatomic region or mechanism of injury.

BOX 1: Indications for immediate laparotomy after penetrating abdominal trauma

Shock
Peritonitis
Evisceration
Impalement
Bleeding from any nature orifice

The distinction between omental and bowel evisceration has been entertained with respect to the need for exploration. The observation that as many as one third of patients with omental evisceration do not have an intraabdominal injury that necessitates repair has led some authorities to recommend against mandatory exploration. However, the authors believe that because the patient has, at the very least, a symptomatic hernia, it should be repaired, and given the relatively high likelihood of finding an associated intraabdominal injury, it should be repaired in the operating room rather than the emergency department.

The remaining discussion of specific injury patterns assumes that the aforementioned indications for mandatory exploration are absent. Most patients with GSWs to the anterior abdomen should be explored. A selective nonoperative approach in patients with stable conditions with either isolated right upper quadrant GSWs as documented with abdominal CT scan or in morbidly obese patients without evidence of peritoneal penetration on abdominal CT scan should be undertaken with caution and in the presence of adequate resource for frequent reexamination. Patients with stable conditions with GSWs to the flank and back should undergo abdominal CT scan to delineate the bullet track and diagnose associated injuries. Patients with GSWs to the left thoracoabdomen should undergo abdominal exploration. Both chest radiography and FAST examination should precede laparotomy to rule out concomitant thoracic trauma. Patients with either massive hemothorax or uncontrolled air leak should in general undergo anterior thoracotomy before laparotomy. However, preparation must be made for rapid laparotomy because intrathoracic blood may originate from an abdominal source via a diaphragmatic laceration.

Patients with stable and hemodynamically normal conditions with AASWs should undergo FAST examination. If results are positive, patients are admitted for serial clinical assessments or laparotomy with any change in a physical examination or vital signs. If FAST examination results are nondiagnostic (negative), LWE is performed. Patients with positive LWE results are also admitted for serial clinical assessments. Patients with negative FAST and negative LWE results are discharged from the emergency department, assuming no other injuries require investigation. Patients with nondiagnostic LWE results are either observed with serial clinical assessments or undergo further diagnostic modalities, including abdominal CT scan or laparoscopy, depending on the pretest probability of intraabdominal injury.

Serial clinical assessments involve the repeated determination of vital signs, hemoglobin concentration, leukocyte concentration, and abdominal examination. Although many algorithms for serial clinical assessments exist, the authors' algorithm involves reassessment of vital signs, complete blood count, and abdominal examination every 8 hours for a total of 24 hours. If results are normal, the patient is fed and discharged if food is tolerated. With this protocol, approximately 15% of patients in the Western Trauma Association studies underwent laparotomy during the 24-hour period of observation, each within 8 hours of presentation. The vast majority underwent exploration for the development of peritonitis and harbored bowel injuries. No complications were found among this group, and hospital length of stay did not differ significantly from patients who were managed with immediate laparotomy. The seemingly equivalent morbidity in the "delayed" laparotomy group has been used to justify

a routine strategy of serial clinical examination for stable AASW cases with positive LWEs. Importantly, this course differs markedly from that of blunt small bowel injuries, in which relatively minor delays in diagnosis translate into increased morbidity. Successful implementation of serial clinical assessments is contingent on both adequate resources and a cooperative coherent patient. Although most intoxicated patients retain the ability to manifest abdominal tenderness, caution must be exercised in interpretation of the abdominal examination of an obtunded, confused, or drug-altered patient. If the reliability of the abdominal examination is in question, alternative diagnostic modalities, such as DPL, laparoscopy, or laparotomy, must be used.

In summary, patients with stable AASW with negative LWEs may be discharged from the emergency department. Patients with stable AASW with positive LWEs may be observed for occult intraabdominal injury via serial vital sign, hemoglobin, and leukocyte determination and abdominal examination. Approximately 15% of these patients need laparotomy, which should be manifest and acted on within 8 hours of initial presentation to avoid undue morbidity. The most common reason for progression to laparotomy is the development of peritonitis, underscoring the importance of serial thorough abdominal examinations. The authors' algorithm for the management of AASW is shown in Figure 2.

Stable cases of flank or back stab wounds should undergo abdominal CT scan with contrast to delineate the track and diagnose any associated injuries. Patients with left-sided thoracoabdominal stab wounds should undergo chest radiography and FAST examination (Figure 3). If both results are normal, a DPL is performed with a RBC threshold of 5000/mm^3. A positive DPL mandates laparoscopy or laparotomy. If a hemothorax or pneumothorax is found with a negative FAST examination, thoracoscopy is performed. Because the patient already needs tube thoracostomy, this adds little additional morbidity. If a diaphragm injury is found (as expected in approximately 25% of patients), laparotomy is performed to exclude injury below the diaphragm. Finally, with positive FAST examination results, laparotomy is necessary because diaphragmatic penetration is assumed.

OPERATING ROOM CONDUCT AND MANAGEMENT OF SPECIFIC INJURIES

As soon as the decision to operate is made, blood should be made available and the operating room warmed. If major vascular injury is suspected, a massive transfusion protocol should be activated. Intravenous access should be ensured. The patient is placed supine on the operating table, prepped, and draped from the neck to the knees, allowing for maximal exposure and harvesting of the saphenous vein should it become necessary for a vascular repair. Access to the chest allows for extension into a sternotomy or anterolateral thoracotomy incision. A long midline incision is made and carried through the fascia with the scalpel blade. With the exception of patients with agonal conditions, release of tamponade with incision of the peritoneum should proceed only after adequate intravenous access is obtained and blood products are available. After the abdomen is opened, blood and clot are removed only to the extent that exposure is obtained. The four abdominal quadrants are packed with laparotomy pads, and a systematic exploration for bleeding is undertaken. If the peritoneal cavity is filled with blood, the location of clots is often a clue as to the source of hemorrhage. Immediately life-threatening injuries include solid organ injuries and injuries to major abdominal vessels. With few exceptions, bleeding from the liver and spleen may be transiently controlled with a combination of packing and manual compression of the hilar structures. After this, the retroperitoneal zones are examined for evidence of bleeding: central (zone I), paracolic gutters (zone II), and pelvis (zone III). Although distinction by zones is made for blunt retroperitoneal hematomas, all retroperitoneal hematomas from penetrating trauma should be explored. One notable exception includes a stable, nonpulsatile, retrohepatic hematoma. In this specific case, release of the tamponade effect on the retrohepatic caval or hepatic venous injury is ill advised and almost uniformly fatal. In contrast, expectant management is associated with a much higher survival rate from hemorrhage control through venous thrombosis.

Rapid exposure of major vessels is imperative in patients with exsanguinating hemorrhage. The general principal of proximal and distal vascular control should be used whenever possible. Exposure of a zone I retroperitoneal hematoma is dependent on location; supramesocolic hematomas usually involve injury to the proximal abdominal aorta and are best addressed via either supraceliac control at the diaphragmatic hiatus or a left-sided medial visceral rotation. The former approach is favored when exsanguination is imminent, the latter when time permits. Access to the inframesocolic aorta is obtained at the root of the transverse mesocolon, after evisceration of the small bowel to the patient's right and lifting of the transverse colon superiorly. Right-sided zone II hematomas usually represent either renal hilar or inferior vena caval injuries and are best

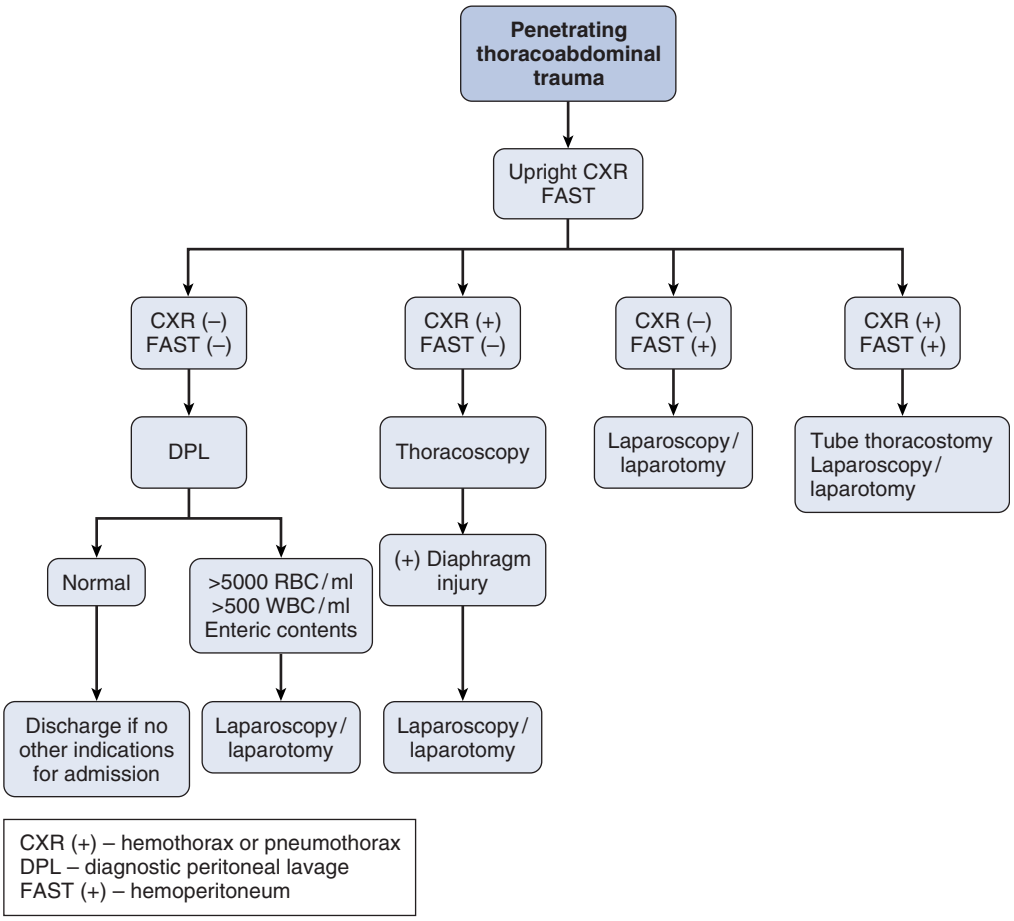

FIGURE 3 Management of patients with stable conditions with penetrating thoracoabdominal trauma. *CXR,* Chest x-ray; *DPL,* diagnostic peritoneal lavage; *FAST,* focused abdominal sonography for trauma; *RBC,* red blood cells; *WBC,* white blood cells. *(Reproduced with permission from Biffl WL, Moore EE: Management guidelines for penetrating abdominal trauma,* Curr Opin Crit Care *16:609, 2010.)*

approached via a right-sided medial visceral rotation, with the right kidney left in situ. Left-sided zone II hematomas are approached via a left-sided medial visceral rotation. Some authors recommend obtaining vascular control of the renal vessels through the posterior midline peritoneum before exploring left-sided zone II injuries. Zone III (pelvic) hematomas are approached by obtaining proximal aortic control at the root of the mesentery. Distal control of the external iliac arteries is then obtained near the femoral canal. Transection of the common iliac vessels may be necessary to obtain exposure to the proximal common iliac veins and their confluence. Finally, portal hematomas are approached initially via Pringle's maneuver (hilar occlusion), with subsequent isolation of the hepatic artery and portal vein. If hemodynamic embarrassment occurs at any time, the supraceliac aorta is occluded at the diaphragmatic hiatus. Once vascular control is obtained, resuscitation should proceed before attempts at further dissection or definitive repair. In patients with profoundly acidotic, coagulopathic conditions, intravascular shunts may be used to maintain perfusion during a period of resuscitation (damage control).

A detailed description of specific organ injuries and their management is presented elsewhere in this text. Some general guidelines follow. In the damage control scenario, all hollow viscus injuries are rapidly sutured to minimize subsequent contamination. In the patient with a stable condition, management ranges from simple repair to resection and exclusion, dependent on the severity of injury. Severe injuries to the duodenum are débrided and may be treated with either pyloric exclusion or Roux-en-Y jejunoduodenostomy. Distal pancreatic injuries may be treated with resection and drainage. Proximal injuries are treated in general with drainage alone with evaluation and possible endoscopic management of the ductal system in the postoperative period. Gallbladder injuries are treated with cholecystectomy, and biliary ductal injuries with choledochoenterostomy. Liver and spleen injuries are treated based on the size and degree of hemorrhage, ranging from manual application of pressure to resection. Finally, primary closure or resection with primary anastomosis of simple, right-sided colon wounds results in acceptable postoperative morbidity. In contrast, left-sided colonic injury is best managed with fecal diversion. If bowel viability is in question, a second look laparotomy is planned.

SUMMARY

Effective management of penetrating abdominal trauma involves an early, systematic differentiation of patients who need immediate operation from those who may be safely observed with serial examinations. Although laboratory testing, FAST examination, DPL, abdominal CT scan, and laparoscopy all have their place in the management of these patients, thorough and serial physical examinations of the abdomen remain the cornerstone of diagnostic evaluations. The algorithms presented herein allow for the safe discharge from the emergency department of many patients with penetrating trauma and minimize the incidence of nontherapeutic laparotomy. However, there are many nuances to these and other similar algorithms for nonoperative management of penetrating abdominal trauma, and in unusual situations, one should err on the side of definitive abdominal exploration via laparotomy. The trauma surgeon should be prepared to rapidly expose and control all major sources of intraabdominal hemorrhage and be familiar with the indications for and technique of damage control surgery.

Diaphragmatic Injuries

Philip T. Ramsay, MD, and David V. Feliciano, MD

INTRODUCTION

Diaphragmatic injuries have always been a diagnostic challenge for the surgeon. A high index of suspicion is necessary to avoid delays in diagnosis and missed injuries with resultant visceral herniation and strangulation. The objectives of this chapter are to review the incidence and mechanisms of diaphragmatic injury and the anatomy of the diaphragm as it pertains to surgical repair and to provide an approach to diagnosis and treatment.

EPIDEMIOLOGY

Diaphragmatic injuries are infrequent, but the true incidence is difficult to estimate because an unknown number are occult or overlooked. The reported incidence rate of acute diaphragmatic injury in the literature varies widely and ranges from 0.8% to 8% after thoracoabdominal trauma. The incidence rate of penetrating injury is higher than blunt injury with a ratio of 2 to 1.

The most common mechanisms for blunt injuries to the diaphragm are motor vehicle crashes and falls from a height. In these patients, a transfer of kinetic energy to the diaphragm occurs through an acute increase in intraabdominal pressure. Because blunt diaphragmatic injuries are more common on the left than the right in a ratio of 9 to 1, the general consensus is that the acute increase in intraabdominal pressure is absorbed by the liver, which protects the right hemidiaphragm. The liver also prevents herniation, which may lead to an underdiagnosis of this uncommon injury. Of interest, autopsy studies show an equal incidence of right and left injuries to the diaphragm after blunt trauma. In such patients, the most common associated intraabdominal injuries are to the spleen, liver, bowel, and kidney. Other associated injuries in patients with blunt rupture of the diaphragm are to the lung, ribs, thoracic aorta, brain, spinal cord, and pelvis.

The location of a diaphragmatic injury after penetrating trauma is dependent on the trajectory, but most injuries from stab wounds are to the left hemidiaphragm. This is believed to result from most assailants being right hand dominant. In contrast, gunshot wounds to the abdomen have an equal distribution between injuries to the right and left hemidiaphragms. Stab wounds to the thoracoabdominal area (nipple to costal margin medial to anterior axillary line) cause an injury to the diaphragm 15% of the time, and this increases to 45% when a gunshot wound is the mechanism of injury.

ANATOMY

The diaphragm is a dome-shaped musculotendinous partition that separates the abdominal cavity from the thoracic cavity (Figure 1). The muscle fibers of the diaphragm originate peripherally from the lower ribs, upper lumbar vertebrae, and sternum and insert into the central tendon. The diaphragm has separate hiatuses for the esophagus, aorta, and inferior vena cava. The aorta, thoracic duct, and azygous vein pass through the aortic hiatus. The esophagus and vagus nerves pass through the esophageal hiatus, and the only structure that passes through the caval hiatus is the inferior vena cava.

The arterial blood supply to the diaphragm comes from the phrenic arteries, branches of the abdominal aorta, and intercostal arteries, and venous drainage is to the inferior vena cava. Motor innervation to the diaphragm comes from the phrenic nerves. Sensory innervation to the central tendon and peritoneum is carried by the phrenic nerves as well, and sensory innervation to the periphery is carried by the intercostal nerves. The left and right phrenic nerves divide into a varying number of branches above the diaphragm (Figure 2). They most commonly branch anteriorly, posteromedially, and laterally. These branches enter the medial portion of the diaphragm and run obliquely, resulting in a pattern that is often described as a "double handcuff." Knowledge of this pattern is important because injury to the phrenic nerve should be avoided, if at all possible, during repair of the diaphragm.

DIAGNOSIS

The goal of early diagnosis of diaphragmatic injuries is to avoid the added morbidity and potential mortality of herniation of an abdominal viscus and strangulation. Diagnosis is especially difficult in patients without indications for an emergency laparotomy for other associated intraabdominal injuries. The mechanism of injury, and the location of impact, can raise the index of suspicion.

A diaphragmatic injury can cause thoracic or abdominal symptoms and signs. Thoracic symptoms include dyspnea, respiratory distress, orthopnea, chest pain, and referred pain to the ipsilateral shoulder, and thoracic signs include dullness to percussion, decreased breath sounds, bowel sounds in the chest, crepitus, and chest wall movement from associated rib fractures. Abdominal symptoms range from mild upper abdominal pain on one side of the abdomen to severe diffuse abdominal pain, and abdominal signs include tenderness and a scaphoid abdomen from herniated abdominal viscera.

The surgeon-performed focused assessment with sonography for trauma (FAST) examination with a 3.5-MHz ultrasound probe is the first screening test used in most adult patients with blunt trauma to the thorax or abdomen. A break in or the absence of the usual hyperechoic curved line characteristic of a hemidiaphragm above the liver or spleen is presumptive evidence that a large blunt rupture has occurred. The FAST examination usually does not detect small perforations that occur with stab or gunshot wounds.

A chest x-ray is part of the initial workup of the trauma patient and is the next screening modality used to detect injuries to the diaphragm; however, the initial study in the trauma room may be normal or inconclusive and miss 20% to 50% of diaphragmatic injuries. The accuracy of the chest x-ray is lower in penetrating injuries to the right hemidiaphragm as compared with the left because the liver may prevent herniation of abdominal contents into the right hemithorax through a small hole as previously noted. In contrast, the liver may herniate into the chest with a large blunt tear of the right hemidiaphragm (Figure 3). On the left side, gastric, small bowel, or colonic air fluid levels may be visualized in the thorax on the admission chest x-ray. Other findings on a chest x-ray include elevation of a hemidiaphragm, obscured diaphragmatic silhouette (Figure 4), failure of a hemothorax to clear after insertion of a thoracostomy tube, and associated rib and sternal fractures. In a patient with a "suspicious" chest x-ray, a nasogastric tube may be seen coiled in the

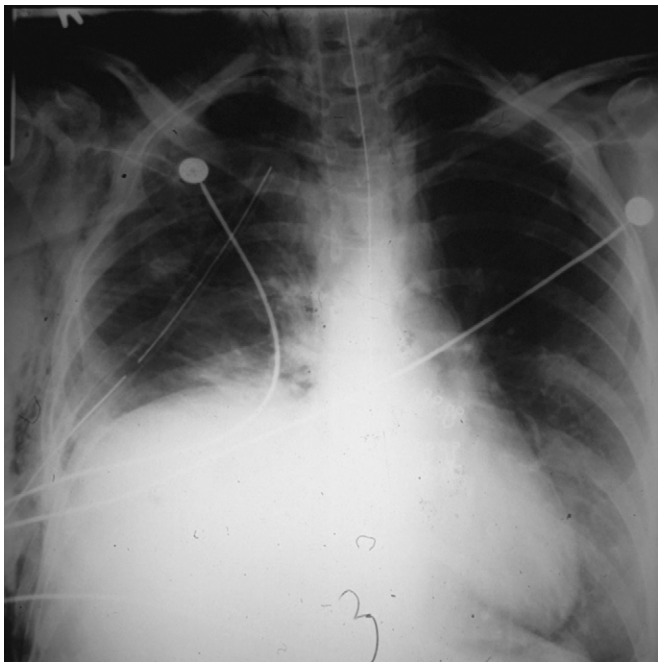

FIGURE 3 A suspicious admission chest x-ray of a 41-year-old woman who was a front-seat passenger in a lateral impact motor vehicle collision. Computed tomographic scan confirmed a large blunt rupture of the right hemidiaphragm.

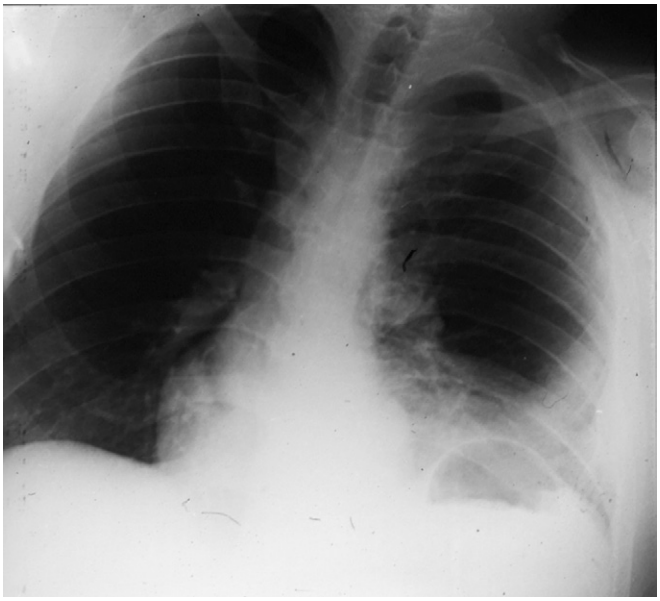

FIGURE 4 A 34-year-old man with a gunshot wound through the left diaphragm and gastric fundus had an abnormal chest x-ray on admission, but the diagnosis was delayed for 4 days. *(With permission from Feliciano DV, Cruse PA, Mattox KL, et al: Delayed diagnosis of injuries to the diaphragm after penetrating wounds, J Trauma 28:1135-1144, 1988.)*

left hemithorax on a repeat film. If the patient is intubated in the trauma room, positive airway pressure from mechanical ventilation may, however, prevent herniation. On rare occasions, an injury to a hemidiaphragm can be diagnosed with finger palpation during insertion of an ipsilateral chest tube.

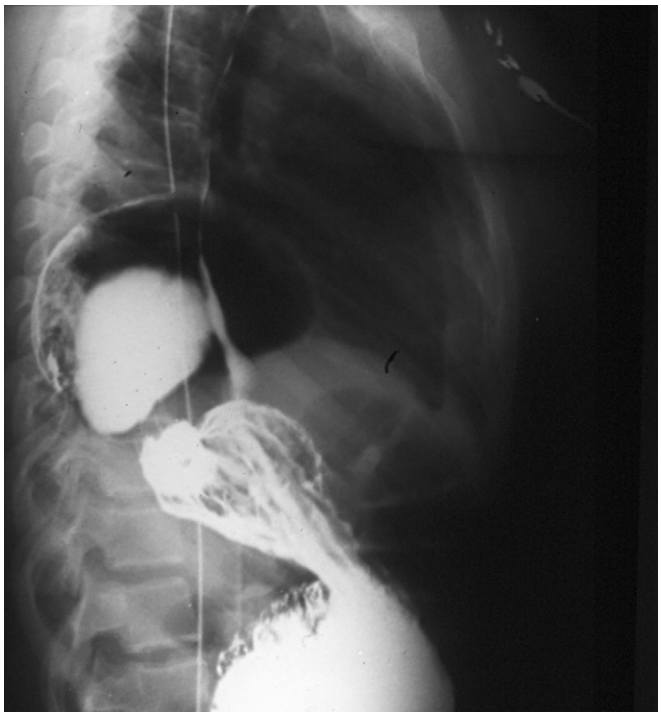

FIGURE 5 An 18-year-old woman with a left thoracoabdominal stab wound and herniation of the stomach into the left pleural cavity shown on an upper gastrointestinal x-ray series.

Contrast studies may be useful when the initial chest x-ray is suggestive of an injury to the diaphragm, but the position of the nasogastric tube is not diagnostic. An upper gastrointestinal series can document gastric herniation (Figure 5), and a barium enema can be used to diagnose colonic herniation. Computed tomographic (CT) scan has a low sensitivity for diaphragmatic injuries, and results are variable. The reported sensitivity and specificity of conventional CT scan in diagnosing of diaphragmatic rupture are 14% to 61% and 76% to 99%, respectively. Thick axial slices, respiratory motion, and poor reconstructions likely contribute to the low sensitivity. CT findings include discontinuity of the diaphragm and intrathoracic herniation of abdominal contents. The "collar sign" is a constriction of a herniated viscus through the diaphragmatic defect, and the "dependent viscera sign" is the abnormal dependent position of the viscera against the posterior ribs. With the introduction of helical CT scan, the accuracy has improved as a result of better quality images. Magnetic resonance imaging (MRI) is impractical in the acute setting but may be useful in the evaluation of a possible chronic diaphragmatic hernia.

Laparoscopy with general anesthesia in the operating room is indicated in patients in whom concern still exists about a possible diaphragmatic injury after the usual imaging studies. It is particularly indicated in patients whose conditions are hemodynamically stable with no other indications for laparotomy. The use of a 30-degree or 45-degree telescope aids in evaluation of the entire diaphragm; a risk of a tension pneumothorax exists when the pneumoperitoneum is introduced. If thoracoscopy is necessary to evacuate a clotted hemothorax, the ipsilateral hemidiaphragm should always be evaluated.

ACUTE MANAGEMENT

Diaphragmatic injuries are graded on a scale of I to V in the Organ Injury Scale developed by the American Association for the Surgery of Trauma in 1994 (Table 1). Injuries from blunt trauma tend to be of a higher grade (III to V) and occur in the posterolateral

TABLE 1: Organ injury scale

Grade	Injury description
I	Contusion
II	Laceration ≤ 2 cm
III	Laceration 2-10 cm
IV	Laceration > 10 cm with tissue loss ≤ 25 cm^2
V	Laceration with tissue loss > 25 cm^2

hemidiaphragm. Penetrating injuries are typically of a lower grade (I to II) and can occur anywhere in the diaphragm. Almost all diaphragmatic perforations and lacerations, regardless of size, should be repaired to reduce the risk of herniation of intraabdominal viscera and strangulation. The one exception is an isolated injury to the right hemidiaphragm from a penetrating wound where a subsequent CT scan documents that there is no bleeding from an associated hepatic or renal injury and no injury to the gastrointestinal tract.

Several operative approaches are used for the treatment of diaphragmatic injuries. The operative approach is determined by whether the diaphragmatic injury is acute or chronic (see subsequently), by the hemodynamic stability of the patient, the presence or absence of associated injuries, and by the surgeon's comfort level with the particular approach. For acute diaphragmatic injuries, laparotomy is the preferred method. After the patient is placed on the operating table in the supine position, the operative field is prepared and draped, with the chest included. A nasogastric or orogastric tube should be carefully placed to allow for decompression of the stomach, but this may be difficult in the patient with gastric herniation. A midline laparotomy incision is made, and after control of bleeding and contamination, the entire abdominal cavity should be explored. Any abdominal viscus that has herniated through a diaphragmatic defect should be carefully reduced. The thoracic cavity should be inspected through the diaphragmatic defect for any ongoing bleeding or contamination from spillage of gastrointestinal contents. If any thoracic contamination has occurred, the thoracic cavity should be thoroughly irrigated with normal saline solution containing antibiotics until returns through the suction device are clear. This often mandates enlargement of the diaphragmatic defect.

The left side of the diaphragm is fully exposed by mobilizing and retracting the spleen, splenic flexure of the colon, stomach, and left lobe of the liver inferiorly and medially. The left triangular ligament of the liver may need to be divided to allow for adequate exposure as well. The right side of the diaphragm is fully exposed by dividing the falciform ligament and the right triangular ligament and retracting the right lobe of the liver inferiorly and medially.

For most injuries, primary closure can be achieved. Long Allis clamps are placed on the edges of the perforation or laceration to allow for elevation of the defect and easier visualization. After nonviable tissue is débrided, #0 or #1 permanent suture is used in a continuous locking fashion or with interrupted simple or vertical mattress sutures to repair large defects. Interrupted simple or vertical mattress sutures can be used to repair small defects as well. Because the diaphragm is highly vascular, the repair is inspected at completion to rule out continuing hemorrhage. If contamination, a concomitant injury to the lung, or risk of a hemothorax is found, then a large ipsilateral thoracostomy tube should be placed. If no injury to the lung or a hemothorax is found, there is no need to place a tube. A catheter may be inserted through the diaphragmatic defect to evacuate any air as anesthesia hyperventilates the patient just before the final suture is placed.

In patients undergoing a "damage control" trauma laparotomy, diaphragmatic repair is unnecessary. Any smaller defect can be covered with folded laparotomy pads used as packs. A larger defect can be covered with opened laparotomy pads held in place with staples or packs.

For acute diaphragmatic injuries in patients with a hemodynamically stable condition with no other indication for laparotomy, laparoscopy can be used. The decision is dependent on the individual surgeon's comfort level with laparoscopic techniques of suturing. The risk of a tension pneumothorax with laparoscopy is significant, as previously noted, and the patient must be carefully monitored.

SPECIAL SITUATIONS

Diaphragmatic Detachment From Chest Wall

In cases that involve detachment of the diaphragm from its posterolateral attachments, any devascularized diaphragmatic muscle is débrided. The diaphragm is reattached to the body wall with placement of interrupted #1 polypropylene sutures through the edge of the detached diaphragm, around the adjacent rib, and then through the edge of the diaphragm again before tying. Visualization is improved by placing all sutures before tying the knots.

Loss of Diaphragmatic Tissue

In cases of massive diaphragmatic destruction, the insertion of the remaining hemidiaphragm may be translocated to a more superior rib level to allow a tension-free repair. The technique involves dividing the anterior, lateral, and posterior attachments of the hemidiaphragm to the chest wall as needed to decrease tension as the hemidiaphragm is sutured around a more superior rib (Figure 6). In addition, nonporous synthetic mesh can be used as a bridge. In cases of contamination, a significant risk of infection exists if synthetic mesh is inserted, and biologic mesh may be used to provide temporary repair. Once the infection has been adequately treated, biologic mesh can be replaced by synthetic mesh if there is evidence of a diaphragmatic hernia on serial chest x-rays. Alternatively, autologous tissue such as omentum, tensor fascia lata, or a latissimus dorsi flap may be used.

Loss of Chest Wall

In patients with large open defects of the chest wall from a thoracoabdominal shotgun wound, any perforations of the hemidiaphragm are repaired before it is translocated to a more superior rib level. The defect in the chest wall is then essentially converted to an abdominal wall defect that can be managed with local wound care. This includes covering the defect with absorbable mesh, performing daily gauze dressing changes above this, and applying a split-thickness skin graft after granulation tissue appears.

Injury to the Central Tendon

Rupture of the central tendon involving the pericardium is a rare event. The heart may herniate inferiorly into the peritoneal cavity, or abdominal viscera may herniate superiorly into the pericardium and cause cardiac tamponade. The heart must be inspected for associated injuries, and careful attention must be given during suture repair of the rupture to avoid injury to the myocardium.

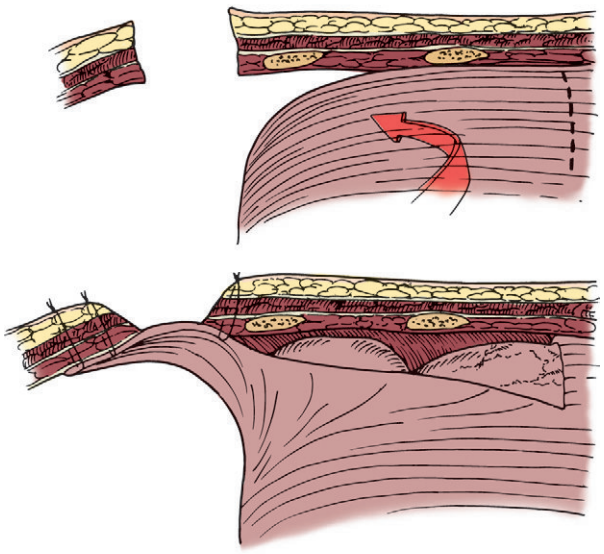

FIGURE 6 Immediate reconstruction of the chest wall after destructive types of injury may be accomplished by detaching the affected hemidiaphragm anteriorly, laterally, and posteriorly. The diaphragm is then resutured to the muscle of a higher intercostal space, thus effectively translocating it to a position above the full-thickness chest wall defect and converting such a defect functionally into an abdominal wall defect. The abdominal wall defect is then managed with local wound care in anticipation of further reconstruction with either split-thickness grafts or myocutaneous flaps at a later date. *(With permission from Asensio JA, Demetriades D.)*

Injury to the Esophageal Hiatus

In cases of injury to the esophageal hiatus, the esophagus should be clearly visualized before suture repair is performed. If any concern exists that the repair may narrow the esophagus, a bougie should be passed down the esophagus to confirm that the lumen is patent.

MANAGEMENT OF THE CHRONIC POSTTRAUMATIC HERNIA

Missed diaphragmatic injuries can appear years after injury as chronic diaphragmatic hernias (Figure 7). Patients may be asymptomatic or report worsening respiratory compromise from progressive visceral herniation. Some patients may present with signs and symptoms of obstruction, strangulation, or perforation of the stomach or colon. All chronic posttraumatic hernias should be repaired in patients at reasonable risk to avoid these secondary gastrointestinal complications. With time, adhesions develop between the herniated abdominal viscera and the pleural cavity. Also, the diaphragm retracts and atrophies, making reduction of herniated viscera and repair more difficult. Therefore, a thoracic approach is preferred because this allows for easier division of chronic adhesions. The decision between thoracotomy and thoracoscopy is dependent on the individual surgeon's comfort level and experience with thoracoscopy. A small hernia into the pleural cavity, however, can still be approached through a laparotomy. In some patients, prosthetic mesh may be required to cover a chronic rigid defect (see previous). Occasionally, reduction of a giant chronic hernia has the potential to cause a secondary abdominal compartment syndrome from loss of abdominal domain. The technique of creating and gradually increasing a pneumoperitoneum before surgery is appropriate in such a patient. If the surgeon is unwilling or uncomfortable to use this uncommon approach, insertion of a permanent prosthesis into the abdominal wall may be necessary at the time of the reduction and repair to expand the volume of the peritoneal cavity.

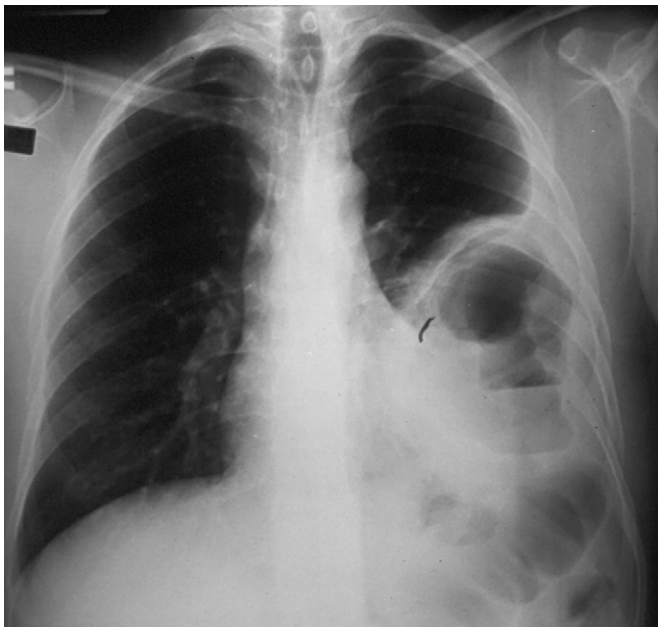

FIGURE 7 A 28-year-old man with a chronic posttraumatic diaphragmatic hernia 1 year after a stab wound to the left chest.

MORBIDITY AND MORTALITY

The morbidity and mortality from diaphragmatic injury depends on several factors, including the mechanism of injury, the severity of injury to the diaphragm itself, the presence or absence of associated injuries, and the extent of surgery required to repair the injury and associated injuries. Most complications and deaths are caused by injuries to other organs. The reported mortality rate has ranged from 4.3% to 41%, with a higher mortality rate in patients with blunt injuries as opposed to those with penetrating trauma. Early complications from repair of the diaphragm include breakdown of the repair, paralysis of the hemidiaphragm from injury to the phrenic nerve, and respiratory embarrassment.

On rare occasions, a patient with a penetrating wound to the right lower lobe of the lung, right hemidiaphragm, and liver has a bronchobiliary fistula develop. This results from a biliary fistula eroding through the repair of the diaphragm and connecting to the hole in the lung. The patient has respiratory distress, may cough up bile, and has a worsening appearance of the right lower lobe on chest x-ray. Any delay in transabdominal drainage of the biliary leak, repair or rerepair of the hemidiaphragm, and débridement of the right lower lobe leads to progressive necrosis of the lung.

As previously noted, patients with chronic posttraumatic diaphragmatic hernias can have complications develop from visceral obstruction, strangulation, and perforation. Delays in treatment can lead to postoperative empyema and subdiaphragmatic abscesses and sepsis and multiple organ failure.

The Management of Liver Injuries

Stephanie A. Savage, MD, MS, FACS, and Martin A. Croce, MD, FACS

INTRODUCTION

The liver, due to its size and location, which spans a large portion of the right thoracoabdominal region, is the most frequently injured abdominal organ. As a relatively low-pressure system, operative exploration is frequently unnecessary after blunt injury. Over the past 30 years, trauma surgeons have gradually abandoned most surgical exploration of hepatic trauma in hemodynamically stable patients suffering a blunt mechanism. Regardless, operative indications remain. The decrease in hepatic explorations has also resulted in decreased familiarity by trauma surgeons with the technically challenging management of devastating hepatic injuries. Careful nonoperative observation, the decision to proceed to the operating room, and techniques for the control of hemorrhage of the liver remain important skills in the trauma armamentarium.

Management of traumatic liver injuries begins with the arrival of the patient to the trauma bay. Advanced Trauma Life Support principles remain the foundation of care and will not be reiterated here. For critically injured patients, early efforts should be focused on avoiding the deadly triad of hypothermia, acidosis, and coagulopathy. Resuscitation should quickly transition to blood products in a 1-to-1 ratio, with active warming of the patient. A focused assessment with sonography for trauma (FAST) should occur early in the evaluation of the patient. FAST exam is notoriously unreliable for hemoperitoneum less than 300 to 600 cc and may be confounded by additional factors, including body habitus of the patient, operator skill, and the presence of associated injuries such as subcutaneous emphysema or pelvic fracture. A positive exam is a valuable piece of information which, when combined with the hemodynamic status of the patient, is instrumental in the decision making for or against operative exploration.

Computed tomographic (CT) scan may also play an invaluable role in patient assessment. Intravenous contrast is, of course, required to achieve maximum benefit from the exam. CT allows quantification of the degree of hepatic trauma. Lacerations may be categorized according to their severity grade (Figure 1). Though potentially all grades of liver injury may be candidates for nonoperative management (excluding grade VI), multiple studies have demonstrated that nonoperative management fails more frequently with increasing severity of liver injury. Perhaps up to two thirds of grade IV and V liver injuries will ultimately fail observation. Further, CT delineates the presence of pseudoaneurysm within the parenchyma of the liver, hemoperitoneum, and associated injuries (Figure 2). Obviously patients must be hemodynamically stable to travel to radiology for this study. Finally, although not routinely used in penetrating trauma, CT may be useful in determining trajectory or peritoneal penetration in selected patients.

Ultimately, decision algorithms will vary somewhat depending on whether an injury is blunt or penetrating. Multiple algorithms have

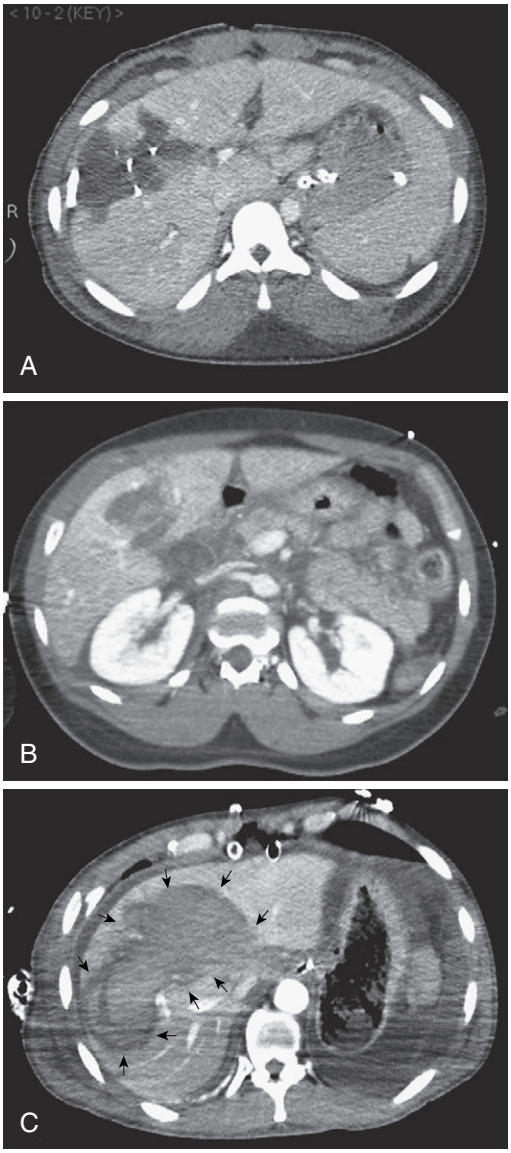

FIGURE 1 **A,** Grade III liver laceration with greater than 50% subcapsular hematoma or liver laceration of greater than 3 cm depth. **B,** Grade IV liver laceration with disruption of 25% to 75% of hepatic parenchyma. **C,** Grade V liver laceration with greater than 75% hepatic parenchyma disruption or major venous injury. The arrows mark the extent of the hepatic laceration.

been published on the management of blunt hepatic trauma, with decision making focused on the degrees of hepatic injury and patient stability (Figure 3). Penetrating trauma has generally been taken directly to the operating room, though published series do exist regarding observational management of highly selected patients. Management decisions must be made with a focus on the particular physiology of the liver, in addition to patient status, mechanism, and associated injuries.

BLUNT HEPATIC TRAUMA

Evaluation of patients suffering a blunt mechanism of injury may be challenging, as the extent of the injury can be much greater and more difficult to define than seen in penetrating trauma. Initial assessment includes the evaluation of airway, breathing and circulation (the "ABC's"), as well as imaging techniques. The patient's progression will largely depend on hemodynamic status. In current practice, more than 80% of cases of isolated liver trauma will result in nonoperative management. Patients who are eligible for observation must be hemodynamically stable, must not require laparotomy for associated

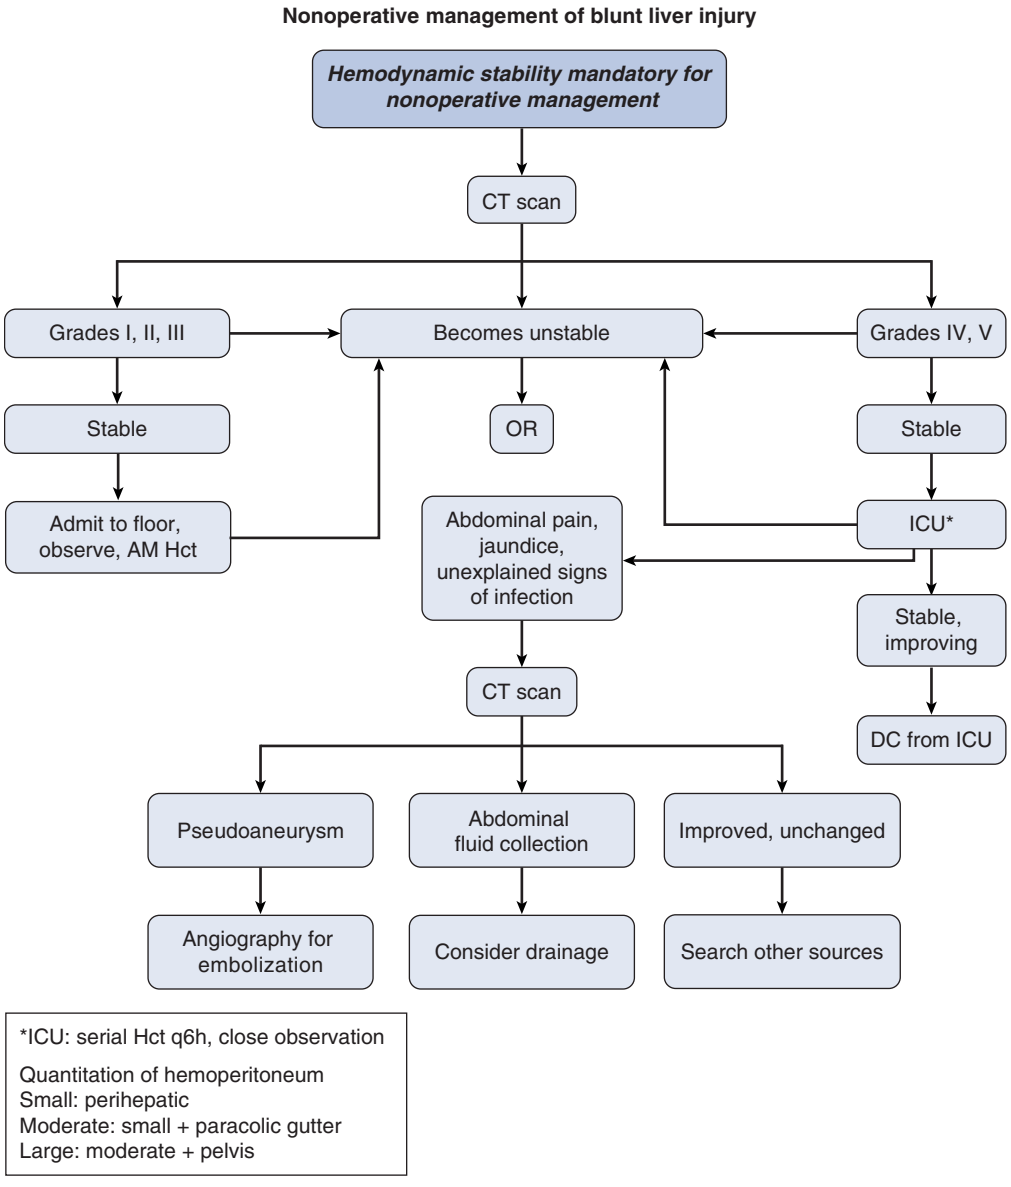

FIGURE 3 Memphis algorithm for the nonoperative management of blunt hepatic trauma. *CT,* Computed tomography; *DC,* discharge; *ICU,* intensive care unit; *OR,* operative therapy.

injuries, and should not have an ongoing unexplained transfusion requirement. The presence of a blush from the liver on contrasted CT scan or the presence of a moderate to large volume of hemoperitoneum is not an absolute indication for intervention. It is important to remember that bleeding from the liver differs greatly from active bleeding from that other oft-injured intra-abdominal solid organ: the spleen. In general, bleeding from the hepatic parenchyma is low pressure and will stop, whether spontaneously or secondary to compression by the hemoperitoneum (though this may not be true of bleeding from a lacerated hepatic artery). Therefore, even patients with these findings on CT may be observed if they meet other criteria.

The most important consideration in observational management of blunt hepatic injuries is that this modality can ultimately be more labor-intensive than surgical exploration. The patient must be admitted to a monitored setting so that any deterioration in hemodynamic status is immediately detected. Serial hemoglobin and hematocrit studies should be followed to assess for ongoing bleeding. Serial lactate levels, and the evaluation of base deficit, are also useful in trending the success of the resuscitation. Finally, it is mandatory for a surgeon to perform serial abdominal exams over the first 24 hours. Observation that results in a trip to the operating room immediately upon a change in status is successful observational management. Fortunately, most patients do well following nonoperative management.

INTERVENTIONAL RADIOLOGY

The scope and availability of interventional radiology (IR) has increased exponentially over the last 10 to 15 years. IR has been a key player in the growing success of nonoperative management of traumatic spleen injuries. The applicability of IR to hepatic trauma is somewhat more limited. The persistence of a pseudoaneurysm in the hepatic parenchyma may benefit from angioembolization. IR is also superior to evaluate patients who develop hemobilia with upper gastrointestinal bleeding following hepatic trauma. Access to IR should not be considered a crutch or a method to avoid operative intervention. As noted, for unstable patients with high-grade liver injuries, the appropriate setting for evaluation and management is the operative, not IR, suite. Mobilization of IR resources, even in the most responsive centers, typically takes more than 1 hour—time that bleeding patients may not be able to tolerate. It is also important to remember that IR suites are often remote from trauma care and intensive care unit (ICU) areas of the hospital and cannot provide the monitoring and resuscitative capabilities over the necessary 1 to 2 hours that these patients require. Further, for higher-grade liver injuries, even a successful embolization will not address the potential morbidity of a bile leak, thus necessitating a return trip to IR for a later percutaneous drain. Undoubtedly, avoidance of a laparotomy is beneficial for some patients. However, all these factors must be taken into consideration when opting for IR.

PENETRATING HEPATIC TRAUMA: CLINICAL DECISION MAKING

Decision for laparotomy in penetrating hepatic trauma is usually fairly straightforward. In most cases, the remainder of the abdominal cavity must be assessed for associated injuries. Clearly the right colon and duodenum are at significant risk, as are the biliary system and diaphragm. There are factors, however, that may delay or alter the decision for surgical therapy. Clearly, stab wounds have a more limited area of affect, and the trajectory is typically easier to define. In gunshot wounds or penetrating injuries from blasts (as seen in the military setting), the trajectory is much more difficult to anticipate. Transabdominal penetration or hemodynamic instability requires exploration immediately. In stable patients for whom trajectory is unclear, imaging can be helpful. Plain AP and lateral abdominal films, in conjunction with site of missile entry, can suggest trajectory. CT scan is both more sensitive and specific, as subcutaneous air can demonstrate missile path, in addition to defining the extent of liver injury, the presence of hemoperitoneum, and evidence of hematoma at other sites. These modalities, however, may be misleading in low-velocity gunshots. If the missile is present in the abdominal cavity, trajectory is relatively unimportant, as the patient will need abdominal exploration.

In stable patients with minimal abdominal pain, injury may be limited solely to the liver. While exploration may still be required, a nontherapeutic laparotomy imposes significant morbidity burden on patients. In these cases, diagnostic laparoscopy is a reasonable compromise. The laparoscope allows evaluation of peritoneal penetration, volume of hemoperitoneum, inspection of the liver surface for signs of active bleeding or bile leak, and evaluation of other intra-abdominal organs. Hepatorrhaphy may be performed, if needed, and hemoperitoneum may be evacuated. If bleeding or bile leak is difficult to control, or if specific conditions prevent an adequate evaluation of associated structures, conversion to laparotomy is indicated.

OPERATIVE TECHNIQUES FOR HEPATIC TRAUMA

The initial operative approach to hepatic trauma is the same as any abdominal exploration. The patient should be widely prepped, with special care to include the thoracic cavity, lest sternotomy is necessary for intrapericardial inferior vena cava control. Broad-spectrum antibiotic prophylaxis should be chosen if there is a concern of a hollow viscus injury, but otherwise antibiotics may focus on coverage of skin flora. Even if the surgeon is aware of hepatic injury preoperatively, a midline incision is preferred over a right upper quadrant subcostal incision, as the former allows more complete exploration of the entire abdominal cavity. Adequate blood should be available to anesthesia in the event of ongoing hemorrhage; uncrossmatched blood is given if there is no time for a type and cross.

Upon entering the abdomen, it is important to evacuate the blood present in the peritoneal cavity in order to identify any bleeding vessels. Bleeding areas may then be packed with gauze laparotomy pads more effectively than random placement of packs in all four quadrants. The ligamentum teres is then clamped, divided, and ligated, and the falciform ligament is divided close to the abdominal wall back to the hepatic veins to allow better exposure of the liver. To completely mobilize the liver and thoroughly inspect the surface, the right and left triangular ligaments, as well as the coronary ligament, should be divided. This will allow nearly complete rotation of the liver for inspection and repair. Care should be taken if significant hematoma is contained within these ligaments, which may suggest hepatic venous injury. Injudicious entry into the hematoma may release physiologic tamponade, allowing potential exsanguination from a caval or hepatic vein injury. In these cases, the ligaments are best left undisturbed.

When the liver is unpacked, it must be inspected for injury. Superficial to moderate lacerations may respond well to compressive packing, and this may be the only therapy required. When hemorrhage from raw surfaces is controlled, the substance of the liver should be inspected to determine if small vessels or biliary tributaries require ligation. Persistent bleeding or a bile leak should always be addressed with suture ligature. In many cases, the involved lumen is located at the base of a laceration deep within the substance of the liver. In these cases, a finger-fracture or clamp-and-crush technique should be employed to allow adequate exposure to the area in question. In short, the obstructing parenchyma is crushed either between the surgeon's fingers or in a Kelly clamp (for finer control). This results in a separation of the substance of the liver to expose small

branches of the hepatic artery or biliary tributaries. These small branches are then ligated and divided. If available, a harmonic device may perform all of these steps at once to more rapidly reach the injured region. Once at the level of injury, the bleeding vessel or bile duct may then be suture ligated for definitive control.

Whether or not finger-fracture is required, blunt lacerations or penetrating parenchymal wounds often leave exposed raw parenchyma and large empty spaces within the substance of the liver. These are prone to continued bleeding, persistent bile leak, and potential abscess formation. Ideally, if the patient's anatomy is amenable, a long tongue of omentum may be mobilized and packed into the hepatic wound. The parenchyma may then be closed over the "omental pack" with a running monofilament suture. The viable omental pedicle fills the dead space nicely, is hemostatic, and may allow better migration of immune mediators into the injury. In actual practice, however, the omentum is often inadequate or destroyed by the same mechanism that injured the liver. This leaves the trauma surgeon searching for some other option to fill the deadspace and achieve hemostasis. A nice alternative is the hemostatic tampon. Constructed of an absorbable gelatin-compressed sponge wrapped in woven hemostatic fabric, it can be constructed on the field, to any size, to fill bleeding cavities within the liver. Alternatively, if second-look laparotomies are planned for the future, the injury site may be packed with laparotomy sponges, which will afford hemostasis and allow for continued resuscitation.

Wounds that traverse the entire liver, such as a transhepatic gunshot wound, may be especially challenging. With a tendency to bleed vigorously, it is difficult to reach the vessels in question, and attempts to do so may disrupt healthy liver. A popularly described technique is construction of a balloon for tamponade. Utilizing a large Penrose drain and a red rubber catheter, the catheter is trimmed to create additional ports in the body of the device. The catheter is then passed through the Penrose, and the drain is secured at either end to the catheter with suture (the distal opening of the red rubber catheter must be occluded). The "balloon" is passed into the tract of the injury and inflated with a syringe until bleeding ceases. The balloon is left inflated until the second-look operation. It may be reinflated at that time, if needed.

The role of abbreviated laparotomy cannot be overstated in trauma surgery, especially in regards to liver injuries. Compression is a very effective therapy for most hepatic hemorrhage, and the role of packing is central to this. Except in cases of major arterial hemorrhage from the liver or noncompressible hemorrhage from sites such as the retrohepatic cava, packing in conjunction with an abbreviated laparotomy, consisting of an open abdomen and planned second look, is a reliable management choice. Second look should occur between 48 and 72 hours from the initial surgery, late enough to allow adequate resuscitation and stabilization but prior to increased risk of sepsis from retained packs. It is generally useful to place a tongue of sterile cassette cover or other nonadherent item between the packed liver and bowel contents, as adjacent bowel can quickly dry, become adherent to sponges, and be difficult to free without iatrogenic injury to large or small bowel. Once unpacked, the liver is examined, and any residual bleeding may be ligated or addressed with electrocautery or argon-beam cauterization. Omental packing at this point will stop minor bleeding. Persistent significant bleeding may warrant repacking and, in some cases, evaluation in the IR suite. An additional benefit of a second-look laparotomy is that nonviable parenchyma may be evaluated for the need for resection as well.

The role of hepatic resection in trauma is limited. Resection should never occur at the initial laparotomy when injuries are still being defined and the patient is undergoing active resuscitation and can poorly tolerate a prolonged, anatomic resection. Additionally, parenchyma that initially looks questionable may be viable upon second look, when the patient is stable and perfusion is better. Unless the substance of the liver is grossly macerated by the injury mechanism, the liver should be packed for hemostatic control. At second look, frankly necrotic liver may be debrided. A formal anatomic resection will be needed in rare cases, and primarily in events where massive hemorrhage or injury necessitated ligation of vascular inflow. If the operative surgeon is not familiar with formal hepatectomy, an experienced hepatic surgeon should be consulted for assistance at the take-back procedure.

Torrential hepatic bleeding, uncontrolled by packing, may be encountered on laparotomy. True difficulty arises when the bleeding is too brisk to allow visualization and control. The classic method for control of hepatic bleeding is the Pringle maneuver, named after J. Hogarth Pringle. The lesser sac is entered, and rotation of the hand clockwise will access the Foramen of Winslow, leaving the structures of the porta hepatis in the surgeon's hand. Immediate manual compression is achieved, followed by placement of a Rommel tourniquet or vascular clamp to free the surgeon's hand and allow further access to the field. Some controversy exists as to the length of time the porta may be occluded before significant damage to the liver occurs, but most agree that occlusion for up to 60 minutes is safe. In some cases, primarily in incidences of juxtahepatic caval injury or damage to the suprahepatic veins, hepatic isolation may be required. In these circumstances, control of the distal inferior vena cava (IVC) is required, preferably above the renal veins. This is followed by control of the proximal IVC. No attempt should be made to control the proximal IVC from within the abdomen. A sternotomy must be performed with access to the IVC obtained within the pericardial sac. Escalation to total abdominal vascular exclusion is completed with cross-clamping of the supraceliac aorta.

Some recent case reports in the literature have advocated a multidisciplinary approach to these injuries, especially retrohepatic caval injuries, by trauma surgery and either IR or vascular surgery. Endovascular occlusion of the IVC above and below the injury is obtained, and, in some cases, stenting of the IVC may occur. This is only a viable option if the patient is stable and the injury is identified prior to laparotomy. The logistics of the multidisciplinary approach are unrealistic when the abdomen is open and torrential bleeding is in progress. Angioembolization may be a viable option for persistent arterial bleeding from a grade IV or V liver laceration discovered at laparotomy. If hemorrhage is controllable with packing, the patient may proceed to the IR suite for definitive control, rather than attempting surgical exposure and subsequent ligation in the face of ongoing hemorrhage.

Many of these patients will benefit from staged laparotomies. Second-look procedures provide the opportunity to ensure that bleeding is controlled and to debride any nonviable liver. At time of abdominal closure, it is important to leave close-suction drains for higher-order lacerations, as the postoperative rate of bile leak in these situations is significant.

MUSEUM PIECES

In particularly difficult cases of liver injury with hemorrhage, traditional techniques have at times proven inadequate to salvage patients. Extraordinary efforts at patient rescue have resulted in the development of aggressive techniques that are used rarely and have a poor success rate. The classic atriocaval shunt, as described by Schrock in 1968, involves introduction of a bypass (usually constructed from a thoracostomy tube) into the right atrium, to end at the level of the distal IVC. In theory, the shunt bypasses a presumed retrocaval or similar injury until the injury can be identified and repaired. In practice, survival following an atriocaval shunt is uniformly poor. Venovenous bypass is another option described for use in exsanguinating hemorrhage due to liver trauma or associated major vascular injury. Once the patient is placed on the bypass circuit, repair can proceed in a relatively bloodless field, while the heart and brain remain perfused. Though theoretically appealing, venovenous bypass requires some experience at cannula placement by the operative surgeon and immediate availability of a pump and technician. This option is not readily available in most level one trauma centers. Liver

explantation with back-table repair and autotransplant has proven interesting in case reports but has little practical applicability. Finally, liver transplant has occurred in a small number of cases in which the liver has either been destroyed (grade VI injury) or has necrosed due to the requirement to ligate inflow to control hemorrhage. Transplantation is not a viable option for most trauma patients, due to limited donor availability over a very short time frame and the frequent presence of disqualifying related injuries in the recipient. The common variable among all these techniques is that, although they represent heroic measures to save the patient, they are resource intensive and impractical and should be abandoned in all but the most unusual cases.

CONCLUSION

While hepatic trauma is the most common intra-abdominal injury, the need for operative therapy is less common than in the past. Decision for surgical therapy rests upon mechanism of injury, patient status, and concern for associated injuries. Upon laparotomy, compression via packing is frequently all that is required for control of hemorrhage, and abbreviated laparotomy is an important component of this technique. Mobilization of the liver for further exposure, with finger-fracture when indicated, is often required to allow access and ligation of bleeding vessels and biliary tributaries. Hepatic resection and vascular isolation are less commonly required, as is the assistance of interventional radiology both pre- and postoperatively. However, these options may be invaluable adjuncts in certain patients. More aggressive techniques have largely been abandoned due to poor success rates. Though infrequently requiring laparotomy on their own, the successful operative management of hepatic trauma is dependent on well-considered operative plans, cool judgment, and meticulous technique for success.

PANCREATIC AND DUODENAL INJURIES AND CURRENT SURGICAL THERAPIES

Juan Carlos Duchesne, MD, FACS, FCCP, FCCM, Eric R. Simms, MD, and Norman McSwain, Jr., MD, FACS

EPIDEMIOLOGY AND MANAGEMENT PRIORITIES

Overall, pancreatic and duodenal injuries are uncommon, representing less than 10% of patients admitted with blunt abdominal trauma or explored for penetrating trauma. The types of injuries to the duodenum and pancreas vary depending on the makeup of the various trauma center "clientele." Trauma centers with a high percentage of penetrating injuries are more likely to have severe injuries to the duodenum or pancreas than those with mainly blunt trauma; reported series vary from 1.5% to 6% of the population. Isolated duodenal or pancreatic injuries are relatively rare, with only 20% of blunt trauma patients having pancreatic injury with no other organ injury, and exceedingly rare in penetrating abdominal trauma. Because of their location, pancreatic and duodenal injuries are usually associated with concomitant injuries to the spleen, liver, stomach, or the vascular structures associated with these. Therapeutic strategies must include management of both organs and effective hemorrhage control. Management of duodenal and pancreatic injuries are usually associated with hemorrhage control because the vena cava, intestinal vessels, and aorta are in the anatomic region and are frequently injured concomitantly. Greater than 70% of mortality associated with pancreaticoduodenal trauma is attributable to hemorrhage, so the immediate focus should be on hemorrhage control with damage control strategies, if necessary.

The four management priorities based on life-threatening conditions for patients managed with damage control surgery for pancreaticoduodenal injuries are:

1. Control of hemorrhage from major vessel injuries.
2. Control of hemorrhage from solid organs.
3. Control of contamination or spillage from hollow organ injuries.
4. Stabilization of major bony injuries.

KINEMATICS (MECHANISM OF INJURY)

Blunt Trauma

Blunt trauma to the duodenum or pancreas is usually from direct compression. For example, in a frontal motor vehicle impact, the torso continues to move forward after the vehicle stops, and the continued motion of the posterior abdominal wall compresses the duodenum and pancreas against the spine. This is like placing the duodenum and pancreas on an anvil and hitting them with a hammer. The result is crushing of the bowel wall, rupture of the lumen, fracture-disruption of the pancreatic parenchyma and possibly the duct, and vascular injury to surrounding vessels. A common pediatric compressive injury is associated with a deceleration injury of the abdomen against bicycles handlebars, which traps the duodenum and pancreas against the vertebra.

Penetrating Trauma

At the time of operative exploration, the surgeon must assess the trajectory of the penetrating object to assess injury potential. The two components in the assessment of penetrating trauma injury potential are:

1. The anatomic structures in the vicinity of the penetrating object's trajectory
2. The energy exchanges into the tissue:
 a. Crush
 b. Cavitation

Diagnosis of pancreatic or duodenal injuries depends on mechanism of injury. For penetrating trauma, a surgeon must follow the trajectory of penetration during exploratory laparotomy, and all parts of the duodenum and pancreas must be inspected visually and manually. Blunt trauma, on the other hand, requires a high index of suspicion and a thorough understanding of the kinematics of blunt trauma at the time of impact. The pancreas and duodenum are located retroperitoneally, so physical examination in the first 24 hours after blunt trauma is difficult for discerning injuries to these organs. There are often no peritoneal signs in retroperitoneal organ injury, and hemorrhage from associated vascular structures may not be immediately evident because of retroperitoneal tamponade or a lack of abdominal distention. Focused assessment with sonography for trauma (FAST) scan is not suited for evaluation of retroperitoneal structures, and laboratory assays (including serum amylase levels) may be normal immediately after pancreatic injury. Because of this, most diagnoses of pancreatic injury after blunt trauma are made with contrast-enhanced computed tomographic (CT) scan, in particular in hemodynamically stable cases. Hemodynamic instability or penetrating trauma with clear intraperitoneal or retroperitoneal involvement warrants exploratory laparotomy, which reveals a pancreatic injury. The CT scan findings diagnostic of pancreatic injury are seen in Table 1.

TABLE 1: Contrast-enhanced computed tomographic scan findings suggestive and diagnostic of pancreatic injury

Suggestive findings	Diagnostic findings
Transverse mesocolon hematoma	Parenchymal laceration or hematoma
Fluid in the lesser sac/ posterior to pancreas (between pancreas and splenic vein)	Transection of the parenchyma, with fluid in the lesser sac
Duodenal laceration or hematoma	Disruption of the head of the pancreas
Injury to left kidney, adrenal gland, or spleen	Diffuse swelling consistent with posttraumatic pancreatitis
Thickening of the left anterior renal fascia	
Lumbar spine transverse fracture (chance fracture)	

DUODENUM

Unfortunately, rupture of the duodenum does not produce abdominal pain, and it is often only when bacterial infections develop that an isolated duodenal injury is evident on physical examination. Other surrounding structures, such as the pancreas and vessels, can produce signs and symptoms of shock or peritoneal inflammation. Examination of the duodenum should always be performed during any abdominal exploration for blunt trauma. Because of the positioning of the duodenum and pancreas, laparoscopic assessment is extremely difficult and is not recommended for blunt or penetrating trauma evaluation with suspected pancreaticoduodenal injury.

In patients with minimal abdominal examination findings, contrast-enhanced CT scan assessment of the duodenum and pancreas is frequently not positive in the first 12 to 24 hours after injury. Evidence of abdominal inflammation such as fat stranding or even presence of free air or fluid in the abdominal cavity can be indicative of duodenal injury. Because the duodenum is only partially intraabdominal, retroperitoneal air or fluid with associated inflammatory changes are extremely suggestive of duodenal perforation.

Anatomy

The unique anatomy and associated structures of the duodenum make usual assessment and management techniques for the duodenum quite different from the rest of the gastrointestinal (GI) tract. The duodenum is only partially covered by peritoneum, so the usual signs of peritoneal inflammation are usually not present. Because the peritoneum does not cover a significant portion of the duodenum, repair can likewise be challenging.

With the development of the Murphy button in the mid 18th century, we discovered that peritoneal closure in any anastomosis is critical to healing. Repair of injuries in the anterior first, second, and third portion of the duodenum are readily achieved because the peritoneum and serosa are present; however, the posterior parts of the duodenum are without the anastomotic protection of the peritoneum, so other considerations must be entertained. The duodenum is composed of four parts. The proximal (first) part begins at the pyloric valve and continues until the first bend of the duodenum around the head of the pancreas. Along the head of the pancreas is the second portion of the duodenum. The close association of the third portion of the duodenum to the pancreas is called the J portion because it turns medially around the head of the pancreas to traverse the posterior pancreas and proceed under the colon, finally entering the peritoneal cavity at the ligament of Treitz.

The blood supplies to the duodenum and head/body of the pancreas are continuous with each other. The anterior and posterior pancreaticoduodenal arteries are frequently in the groove between the pancreas and duodenum and supply both organs with multiple side branches. The pancreaticoduodenal arteries connect superiorly to the hepatic artery via the gastroduodenal artery and inferiorly connect to the superior mesenteric artery anterior to the superior mesenteric vein. The dual-source blood supply is critical to the management of duodenal trauma because either end of the pancreaticoduodenal artery can be tied off with adequate blood supply coming from the other end.

Because of the retroperitoneal, retrocolic position of the fourth portion of the duodenum and its blood supply associations with the pancreas, anastomoses of the fourth portion are fought with hazard. It is much better to remove the fourth portion and anastomose the jejunum to the second or third portion to maintain GI continuity for enteral feeding. An understanding of the details of the duodenal anatomy is critical in the management of patients with duodenal trauma.

Assessment

Assessment of the duodenum begins in the emergency department with a high index of suspicion based on the mechanism of injury. Especially with blunt trauma, a specific diagnosis of duodenal trauma is virtually impossible without radiographic or direct visual (operative) evidence. The first step should nonetheless be a detailed physical examination looking for signs of trauma anteriorly, such as tenderness to deep palpation, rebound tenderness, guarding, and the absence of bowel sounds. These are clear signs of peritoneal irritation, not specific signs related to the duodenum. CT scan can augment the physical examination, demonstrating free air or fluid in the abdomen and increasing suspicion for bowel perforation or injury.

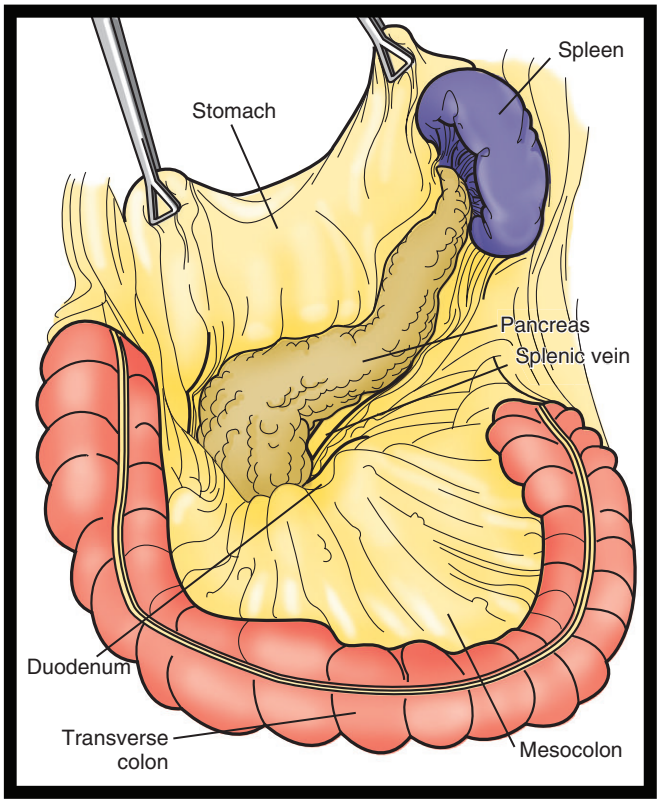
Operative assessment of the duodenum begins with visualization of the entire first, second, and third portions of the duodenum. Kocher's maneuver may be used to assess the posterior aspects of the duodenum. A digital assessment of the length of the fourth portion of the duodenum is necessary from the beginning to the other side of the ligament of Treitz because visual evaluation of the fourth portion is frequently difficult. At the very minimum, the surgeon's left hand should traverse posteriorly toward the ligament of Treitz, and the right hand should carefully palpate from the ligament of Treitz toward the left hand until the fingers touch. The entire portion of the fourth part of the duodenum can then be felt, with the index finger or middle finger posterior to the duodenum and the thumbs of the right and left hand anterior to the duodenum.

Operative Management

Priorities in operative management for duodenal trauma are:

- Assessment is needed of the entire duodenum for integrity or perforation, intramural clots, and blood supply.
- Closure is performed of serosa-covered duodenum, usually with intestinal two-layer closure.
- Closure is performed of nonserosa components of the duodenum, closed in layers and assisted with a serosal patch when possible.
- Extraluminal drains increase the risk of intra-abdominal abscess and fistula formation.
- Intraluminal decompression (either antegrade, retrograde, or both) is critical when nonserosal duodenum has been closed or there is otherwise compromise or potential compromise of the anastomosis or closure.
- Duodenal cavity diversion with creation of a Bilroth II–type gastroenterostomy may be required for severe trauma or compromised anastomoses (see subsequent).
- Continued controversy exists as to the actual benefits of temporary duodenal diversion; only use it as a last resort.
- Assessment is needed if there is injury to the pancreas.

A simple repair of a duodenal injury is done the same way as repair of any serosa-covered GI tract injury: a two-layer closure (absorbable on the inside) with diagonal not longitudinal closure to prevent tension or stricture of the repair. When injury extends to the portions of the duodenum that do not have serosa or peritoneum exteriorly to facilitate healing, or if the injury is more than 50% of the circumference of the duodenum, other protective steps have to be taken. For a simple injury, an adequate closure can be obtained with two-layer repair and other steps to ensure sealing. This is similar to operative management of the esophagus, such as swinging of peritoneum over the nonperitonealized portion of the injury. Abdominal wall is a very good source of peritoneum on occasion, as the peritoneum from the peritoneal wall itself can be rotated around similarly to esophageal injuries or from another piece of small bowel that can be placed over the injury (Thal patch).



As injuries become more complex (e.g., greater than 50% of the duodenum affected, two or more adjacent injuries, etc.), a concern exists for pressure gradients between the intraluminal and extraluminal areas. The Bernoulli principle identifies the rate of leak as proportional to intraluminal pressure versus extraluminal pressure. Therefore, the intraluminal pressure needs to be reduced in the duodenum. An intraluminal drain, such as a nasogastric tube, passed through the pylorus into the duodenum, or a similar tube passed retrograde from the jejunum through fourth portion into the second portion of the duodenum, is an acceptable method. Placement of drains outside the lumen is not appropriate because this violates several surgical principles, including avoiding foreign bodies in the anastomotic regions to reduce extraluminal pressure relative to intraluminal pressure, forming connections between sterile abdomen and external environments, and avoiding other sources of potential contamination.

The theory behind protecting the nonperitoneal side of the duodenum includes the reduction of intraluminal pressure without addition of pressure of a foreign body to the extraluminal area, reduction of food passage through the injured and repaired areas, and sometimes total diversion (e.g., Roux-en-Y gastrojejunostomy with stapling across the duodenum at the pylorus). All of these techniques have proponents and adversaries; however, almost all research on duodenal injuries is anecdotal, and no single institution has developed a large enough sample size to perform adequately powered comparison studies. This leaves us at the mercy and discretion of the operating surgeon. Several years ago, diverticularization and exclusion were encouraged, and they may be coming back into favor. Since 1980, several studies (again anecdotal, with some retrospective reviews without controls) have questioned the usefulness of simply cross clamping or sewing up the pylorus. In most series, either stapling across the duodenum at the pylorus or sewing up the pylorus does not provide a permanent solution because most of these open up in 3 to 6 weeks. Some studies have even proposed that such surgical constructs become nonfunctional within a week. It is the experienced opinion of the author that with very extensive wounds of the first, second, or third portion of the duodenum, diverticularization is probably the correct approach. For lesser injuries, with only a short term of decreased functionality of the duodenum predicted, either cross clamping below the pylorus or sewing up the pylorus with diversion allows protection of the duodenum for up to 3 weeks. Both approaches, however, emphasize internal decompression as very important. Whichever approach the surgeon attempts, these rules apply. In summary, the duodenum is unfortunately not protected fully about its circumference or along its length by serosa, as are other parts of the small bowel. Therefore, extra attention is warranted to allow healing.

PANCREAS

Assessment

Assessment and classification of pancreatic injuries depends on the status of the duct and the site of the injury. Nonoperative assessment usually relies on trauma CT scan findings, although CT scan misses pancreatic injuries in approximately 31% of abdominal trauma cases. In penetrating trauma or with unstable blunt trauma, operative assessment involves the pancreas being completely exposed to assess it. Patients with hemodynamically unstable conditions, especially those with acidosis, coagulopathy, or hypothermia, should undergo damage control management. This includes immediate surgical exploration with control of major hemorrhage or contamination, packing or drainage, followed by intensive care unit (ICU) stabilization, and return to the operating room in 12 to 24 hours to definitively expose, assess, and repair the pancreas and associated injuries. Direct palpation and visualization of all parts of the pancreas should

Eric R. Simms

FIGURE 1 Exposure of the pancreas.

be possible with the following maneuvers but may be complicated by the amount of damage to surrounding structures:

1. Opening of the lesser sac through the gastrocolic ligament and omentum, below the gastroepiploic arteries.
2. Extension of this opening towards the splenic flexure and mobilization of the transverse colon, which can be retracted inferiorly as the stomach and spleen are gently retracted superiorly. This allows an approach to the body of the pancreas for circumferential palpation.
3. Performance of Kocher's maneuver to assess the pancreatic neck, head, and uncinate process.
4. Potential mobilization of the hepatic flexure to fully access the head and uncinate process.
5. Mobilization of the splenic flexure and spleen with freeing of the lateral peritoneal attachments, and any attachments between the kidney and spleen/pancreatic tail, and mobilization of the spleen and pancreatic tail medially and anteriorly. This allows for inspection of the distal body and tail of the pancreas (Figure 1).

The American Association for the Surgery of Trauma (AAST) Committee on Organ Injury Scaling works well, in coordination with the Abbreviated Injury Scale (AIS), for classification of pancreatic injury (Table 2), in a way meaningful to management decisions. Status of the duct and site of injury are the most important factors, with major ductal injuries treated differently than distal ductal injuries or parenchymal injuries. In general, grade I and II injuries can be managed nonoperatively or sometimes with external drainage; severe combined pancreaticoduodenal injuries are preferentially managed with trauma Whipple's procedure, or damage control strategies with interval Whipple's procedure; and extensive pancreatic parenchymal damage with or without major duct injury can be managed with external drainage based on the locus of injury.

TABLE 2: The American Association for the Surgery of Trauma pancreas organ injury scale

Grade*	Type of injury	Description of injury
I	Hematoma	Minor contusion without duct injury
	Laceration	Superficial laceration without duct injury
II	Hematoma	Major contusion without duct injury or tissue loss
	Laceration	Major laceration without duct injury or tissue loss
III	Laceration	Distal transection or parenchymal injury with duct injury
IV	Laceration	Proximal† transection or parenchymal injury involving ampulla
V	Laceration	Massive disruption of pancreatic head

*Advance one grade for multiple injuries up to grade III.
†Proximal pancreatic injuries are injuries to the patient's right of the superior mesenteric vein.

Ductal Injury

Injuries to the major duct are present in 15% to 20% of pancreatic trauma. For penetrating trauma, most ductal injuries can be assessed with careful survey of the trajectory and path of the injury, after the aforementioned exposure techniques. If the status of the duct is not clear after direct evaluation, intraoperative pancreatography may be necessary in an otherwise stabilized case. A patient with an unstable condition may need damage control measures followed by postoperative endoscopic retrograde cholangiopancreatography (ERCP). For blunt trauma that warrants exploratory laparotomy, the extent of pancreatic disruption determines management. Minor lacerations or contusions may be managed just with placement of drains. In the rare instances when the major duct is transected without parenchymal, transection requires a high index of suspicion, meriting intraoperative pancreatography or postoperative ERCP. Needle cholecystocholangiopancreatography or postoperative ERCP remain preferable to duodenotomy with ampullary cannulation.

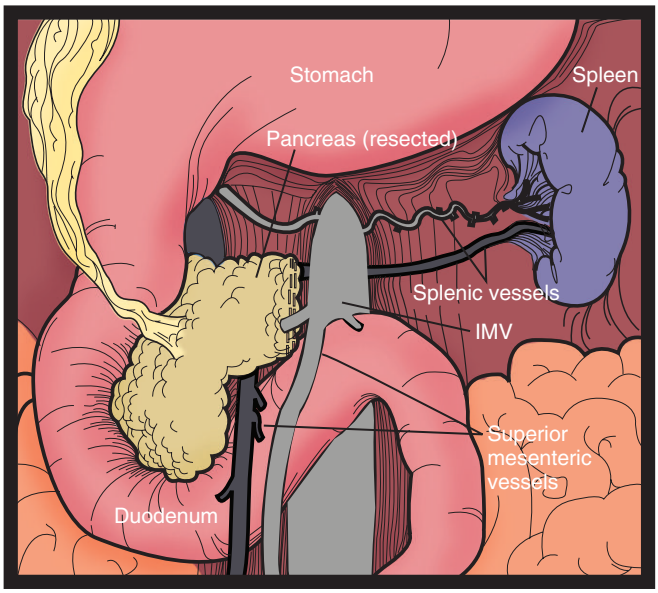
Operative and Nonoperative Management

Grade I and II Injuries

In patients without hemodynamic instability, peritoneal signs, or clear intraperitoneal or retroperitoneal penetrating trauma, contrast-enhanced CT scan may suggest only minor pancreatic parenchymal injury. Minor parenchymal lacerations or contusions (without extensive parenchymal decimation) in the absence of ductal injury can be managed nonoperatively, or with external drainage. Grade I pancreatic injuries (minor contusion, hematoma, or capsular laceration) represent about half of all pancreatic injuries. Grade II injuries (pancreatic lacerations without major tissue loss or ductal injury) represent another 25% of pancreatic injuries. Both of these injuries can be managed nonoperatively, even if peripancreatic fluid collection is noted on CT scan. Often a follow-up contrast-enhanced CT scan is prudent 5 to 7 days after injury, to reassess peripancreatic fluid collections, or in the presence of worsening laboratory findings,

abdominal symptoms, or physical examination findings. If detected during exploratory laparotomy, they can be managed with external drainage alone, after careful exposure and inspection of the entire gland and hemostasis. Lacerations in the absence of major ductal injury are managed without surgical repair of the laceration because of the high risk of pseudocyst formation associated with these attempts. Closed-suction drains are preferred to Penrose drains or Davol sumps because of less skin excoriation and complications such as abscess. Drains are left in place until there is no longer evidence of pancreatic leak. Nutrition should focus on enteral feedings as soon as possible to improve outcomes.

Grade III Injuries



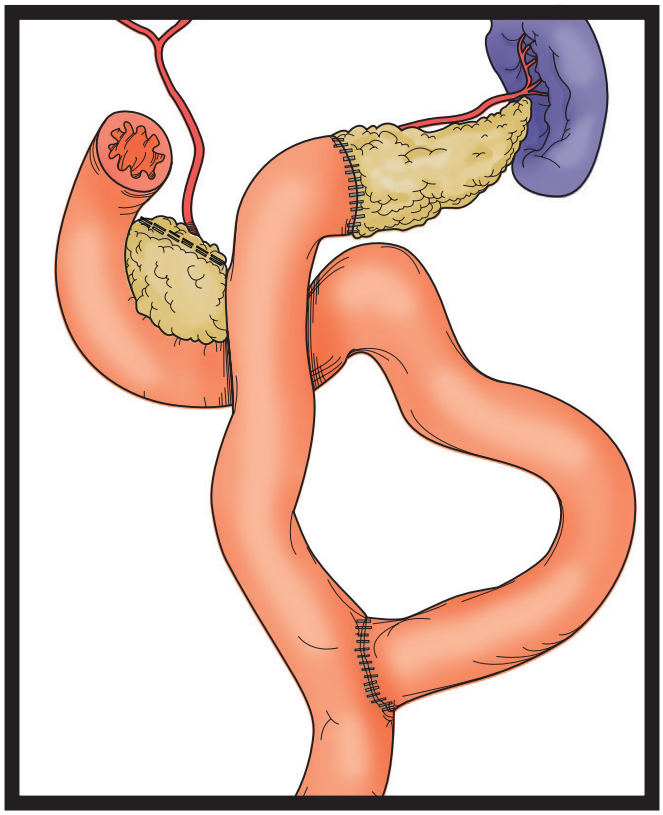
Distal pancreatic injuries (defined as distal to the level of the superior mesenteric vessels) with involvement of the major duct (grade III) are best managed with distal pancreatectomy. These injuries can be recognized via CT scan (if performed at least 4 hours after injury), or at the time of exploratory laparotomy, with or without the aid of pancreatography. Often mid-to-distal pancreatic duct injuries are associated with notable fat necrosis in the lesser sac and can be considered to be evidence of ductal injury, especially with evidence of local penetrating trauma.

As long as at least 20% of pancreatic tissue is left, there should be adequate endocrine and exocrine function after distal pancreatectomy. Usually, pancreatectomy at the level of the portal vein provides enough residual parenchyma to preserve endocrine and exocrine function, and resection at the level of the common bile duct does not. Nonoperative management for grade III injuries usually fails or has extensive complications, including repetitive drainage interventions, failed stenting or endoscopic management attempts, abscesses, pseudocysts, or persistent fistulas. If any doubt exists about the integrity of the proximal duct, intraoperative pancreatography should be performed with cannulation of the transected end of the proximal duct. Some experts recommend closing the remaining duct with a U stitch of nonabsorbable suture and approximating the pancreatic parenchyma with absorbable mattress sutures, with the belief that staplers crush excess parenchyma. TA (thoracoabdominal) staplers can be safely and effectively used to close the proximal pancreas, however, with fewer complications. Either technique often benefits from the use of an omental patch to buttress the distal end of the proximal remnant.

Grade III injuries in the pancreatic tail may have splenic involvement that necessitates splenorrhaphy or splenectomy. If splenectomy is not mandated by injuries, a splenic salvage may be attempted. To accomplish this, the spleen and pancreas must both be very well mobilized. 3-0 or 4-0 silk or Vicryl ties (Ethicon, Somerville, NJ) may be used to ligate small pancreatic vessels on the side of the splenic artery and vein, with clips used on the pancreatic vessels near the segment to be resected. Difficulties include avoiding damage to the splenic artery or vein while ligating the small pancreatic branches off of each and splenic vein thrombosis. Splenic salvage requires an average of 50 additional minutes of operative time, so it should only be attempted in patients without signs of acidosis, coagulopathy, or hypothermia. If pancreatectomy/splenectomy is performed, the splenic artery should be suture ligated with 4-0 polypropylene approximately 2 cm proximal to the pancreatic segment to be resected. Similar ligation should then be performed for the splenic vein. The vessels may also be covered by an omental patch after resection of the pancreatic segment and spleen, to protect them against pancreatic enzymatic erosion (Figure 2).

Grade IV and V Injuries

Injuries to the pancreatic head are the most difficult to manage, especially if there is parenchymal transection or injury to the proximal duct. Immediate management priorities are control of hemorrhage and limiting of gross spillage or contamination. This may be accomplished with damage control methods (for hemodynamically unstable cases with present or worsening acidosis, coagulopathy, or hypothermia), with ICU stabilization and subsequent return to the operating room for definitive repair, or definitive repair at the time of original operation if the patient's condition is otherwise stable. Before any definitive management, the anatomy must be clearly defined to assess the extent of injury. The duct status can usually be discerned with careful direct inspection after appropriate mobilization techniques previously described. If the integrity of the main duct cannot be clearly determined with local operative exploration, intraoperative pancreatography must be considered, either via needle cholecystocholangiopancreatography or external drainage followed by postoperative ERCP. In rare instances when the proximal duct is injured in the absence of concomitant duodenal/ampullary injury, extended distal (subtotal) pancreatectomy or Roux-en-Y pancreaticojejunostomy (tail-sparing) may be performed. Subtotal pancreatectomy should be performed with external drain placement for control of leaks from the transected edge and ultimately results in the small portion of residual proximal gland draining into the duodenum. If the residual amount of pancreas is likely insufficient for endocrine and exocrine function (e.g., proximal to the plane of the superior mesenteric vessels), distal Roux-en-Y pancreaticojejunostomy (end-to-end or end-to-side) may be performed to preserve pancreas distal to the injury. To perform this, after débridement of devitalized tissue, the pancreas is divided at the site of injury, and the proximal duct and parenchyma closed via TA stapler or U stitch. The distal duct opening is anastomosed to the Roux-en-Y jejunal limb, as a cuff-type pancreaticojejunostomy. A tube stent may be placed through the anastomosis to decrease the possibility of pancreatic fistula formation (Figure 3).



Eric R. Simms

FIGURE 2 Distal pancreatectomy with splenic salvage. *IMV,* Inferior mesenteric vein.

Combined Pancreatic and Duodenal Injury

Combined pancreaticoduodenal injuries are rare and are usually the result of penetrating trauma. These injuries are usually associated with multiple other intra-abdominal trunk injuries, and mortality from pancreaticoduodenal injury is usually the result of associated vascular injuries. Immediate damage control techniques are mandatory to control hemorrhage and contamination, especially in the face

Eric R. Simms

FIGURE 3 Roux-en-Y pancreaticojejunostomy.

of hemodynamic instability or metabolic/coagulation derangements. If a patient is stabilized (in the ICU after damage control surgery, or rarely, at the time of initial operation), the status of the common bile duct, main pancreatic duct, and ampulla must be assessed via intraoperative cholangiogram/pancreatogram, or postoperative ERCP, to determine the best definitive management. Most cases have an intact ampulla and common duct, so the duodenal injury can be primarily repaired and the pancreatic duct injury managed as previously described.

If the pancreatic head and duodenum are devitalized or not amenable to primary repair (e.g., common bile duct, pancreatic duct, and ampullary injury), Whipple's procedure (pancreaticoduodenectomy) can be used. Even if only the duodenum or only the pancreas are

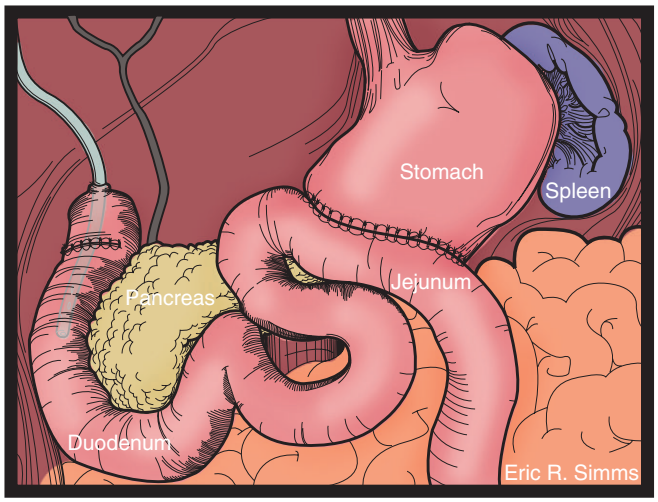


FIGURE 4 Duodenal diverticularization.

decimated, complete resection of one often results in ischemia of the other because of their intimately associated vasculature. Some surgeons may opt to control hemorrhage/contamination and perform the resections for Whipple's procedure at the initial operation and then return after stabilization for reconstruction (staged Whipple's). If pancreaticoduodenectomy is not mandated by injury, it is often necessary to divert gastric and biliary contents from the repaired duodenum. One technique for this is duodenal diverticularization, wherein the duodenal injury is closed primarily, and antrectomy/vagotomy performed with end-to-side gastrojejunostomy (Figure 4). The common bile duct is decompressed with T-tube drainage, and duodenal fistulization is controlled by duodenostomy tube. Enteral nutrition is then performed through the gastrojejunostomy. Even if this technique is not used, a Witzel jejunostomy should be performed for all patients undergoing Whipple's procedure for pancreatic or pancreaticoduodenal trauma, to provide enteral feeding access.

Injuries to the Small and Large Bowel

Syed Nabeel Zafar, MB, BS, MPH, and Edward E. Cornwell, III, MD, FACS, FCCM

Small and large bowel injuries are infrequent but potentially morbid sequelae of abdominal trauma. Of the 2.5 million patients in the National Trauma Databank, years 2007 to 2010, full-thickness small and large bowel injuries occured in approximately 0.3% and 0.4%, respectively (Table 1). Of these injuries, approximately 92% are secondary to penetrating trauma, particularly from gunshot wounds and stab wounds. Mortality rates are significant—9.7% for small bowel injuries and 9.2% for large bowel injuries—and death results largely from associated injuries. Mean lengths of hospital stays are 11% and 14 days, respectively. In 2003, the Eastern Association for the Surgery of Trauma published results of a multiinstitutional survey of hollow viscus injuries, collecting data from 95 participating centers between the years 1998 and 1999.The incidences of perforating small and large bowel injuries were 0.3% and 0.2% of all trauma admissions. However, the mortality rates were significantly higher than the death rates reported by the recent National Trauma Databank: 15%

TABLE 1: Small and large bowel injuries reported by the National Trauma Data Bank, 2007 to 2010

	Small bowel injury (*N* = 7558)	Large bowel injury (*N* = 11,164)
Blunt injury	480 (6.4%)	656 (5.9%)
Gunshot wound	4597 (60.8%)	8290 (74.3%)
Stab wound	2340 (30.9%)	2005 (17.9%)
Mortality	691 (9.7%)	981 (9.2%)
Mean length of hospital stay (in days with standard deviations)	11.2 (±15.8)	14.3 (±18.5)

for small bowel injuries and 19% for colorectal injuries. The marked improvement in mortality rates since then can be attributed to advances in diagnosis and management of traumatic injuries overall. This chapter reviews the mechanisms, the diagnosis, and the surgical management of traumatic small and large bowel injuries.

MECHANISM OF INJURY

Any penetrating wound between the nipples and the groin should raise the suspicion of bowel injury. The actual incidence of bowel injury varies according to factors such as length of knife, velocity and type of bullet, location and trajectory of the penetrating injury, and body habitus of the victim. For example, the index of suspicion would be high for a gunshot wound to the anterior abdomen with an exit wound through the back in a lean victim, and it would be lower for a pocket knife stab wound through the flank of an obese individual.

Blunt trauma, in contrast, poses an ongoing challenge to the clinician. Such bowel injuries are not as clinically obvious as in the case of penetrating injuries, and the incidence of bowel injury after blunt trauma is low. However, delays in diagnosis can lead to significant morbidity and mortality. Motor vehicle crashes and impact injuries in pedestrians have been shown to produce a higher incidence of bowel injuries than do falls and other modes of blunt trauma. Mechanisms of bowel injury include shearing of the bowel from its mesentery secondary to sudden deceleration, and "blow-out" of a loop of bowel as a result of a sudden increase in intraluminal pressure. The latter occasionally occurs when a high-riding automobile lap-belt squeezes a loop of bowel against the retroperitoneum or spine. The degree of suspicion for this type of injury should be high when the so called seatbelt sign—a transverse ecchymosis visible on the lower abdominal wall, corresponding to the position of the seatbelt on the patient—is present. The presence of a seatbelt sign alone is associated with a markedly increased risk of a bowel injury.

DIAGNOSIS

Because the overwhelming majority of small and large bowel injuries are caused by penetrating trauma, they are most commonly discovered during trauma laparotomy. This is performed on the basis of the clinical presentation of patients with abdominal gunshot or stab wounds: hemodynamic instability, omental or visceral evisceration, and peritoneal signs or tenderness away from the entry wound. For selected patients in stable condition with stab wounds or even gunshot wounds to the abdomen, nonoperative management may be pursued in the appropriate setting. Selective nonoperative management should be undertaken only if the following two conditions are met: (1) the patient is hemodynamically stable with no signs of evisceration, peritonitis, or intra-abdominal hemorrhage and (2) the clinical decision occurs in a setting with 24-hour availability of a surgeon, in which the patient can be monitored continuously and serial abdominal examinations are routinely performed.

Frequently, physical examination findings are not reliable because the patient is affected by alcohol or drug intoxication, head injuries, heavy sedation, or neurologic deficit. In these circumstances, other adjunct tests are helpful. An upright chest radiograph may show air under the diaphragm or a Chance fracture of the lumbar vertebral body. Chance fractures have been associated with bowel injuries and are caused by decelerating mechanisms, as with high-riding automobile seatbelts in high-speed motor vehicle crashes. Another useful tool is the focused assessment with sonography for trauma (FAST) examination, which may identify free fluid in the abdominal cavity.

Computed tomographic (CT) scanning has become the standard diagnostic tool for occult abdominal injuries. Because of advances in technology and availability, its use has become widespread. Helical CT scanners have been shown to have a high accuracy in detecting gastrointestinal injuries, with sensitivities ranging from 83% to 94% for bowel injuries. Although opinions vary on the use of oral contrast material in detecting gastrointestinal injuries, it is not used in the authors' trauma center. It causes unnecessary delays in diagnosis, increases risk of aspiration, and has not conclusively been demonstrated to increase the accuracy of scans. CT findings suggestive of small or large bowel injury include pneumoperitoneum, intraperitoneal fluid not associated with solid organ injury, bowel wall thickening, mesenteric fat streaking, mesenteric hematoma, and extravasation of luminal content. If free fluid is the only CT finding in a hemodynamically stable patient, then the surgeon either can continue to observe the patient if the patient is able to cooperate with serial clinical examinations or can perform diagnostic laparoscopy or even exploratory laparotomy.

Preparation for diagnostic laparoscopy must always include preparation for a possible exploratory laparotomy. The technique for a diagnostic laparoscopy varies, depending on the surgeon. In general, the patient is administered a general anesthetic and placed in the Trendelenburg position. A single umbilical port or single left upper quadrant port may be placed to advance the laparoscope. At any signs of peritoneal penetration or intraperitoneal injury, many surgeons convert the procedure to exploratory laparotomy. Others, depending on skill and experience, place three ports, explore all intraperitoneal organs and quadrants for signs of injury, and investigate the entire length of bowel with the use of graspers.

The "gold standard" for diagnosing bowel injuries remains the exploratory laparotomy. However, this procedure can also produce morbidity. Thus the resultant challenge is the need to combine the aforementioned adjunct diagnostic tests to create a composite sensitivity of 100% for detecting bowel injuries, balanced by the importance of minimizing nontherapeutic laparotomies. Once detected, bowel injuries are managed surgically.

SURGICAL MANAGEMENT

Perioperative Care

All patients should receive perioperative antibiotics for 24 hours; the first dose should be administered immediately when the need for surgery is recognized. A broad-spectrum third-generation cephalosporin has been proven effective. As with all major operations, early ambulation, chemical and mechanical prophylaxis for deep venous thrombosis, incentive spirometry, appropriate wound care, and early diet advancement are recommended.

Although variations exist in technical management, a few general principles are recognized and hold true for both small and large bowel injuries. These principles are described in Box 1.

Small Bowel

In general small bowel injures are primarily repaired. If the perforation is less than 50% of the circumference of the bowel (grade II injury), then the defect can be repaired transversely with absorbable running sutures. A second interrupted nonabsorbable seromuscular layer may be placed. However, if the perforation is greater than 50% of the circumference (grade III and worse injuries), then resection and primary anastomosis are recommended. If multiple injuries are present in close proximity, then all of these can be managed by a single resection and anastomosis (Figure 1). Another option is to perform stapled anastomoses. Although the role of gastrointestinal staplers is established in an elective setting, the use of staplers in patients with traumatic injuries is somewhat controversial. Retrospective analysis suggests a higher incidence of complications and anastomotic leaks when staples are used; this analysis does not adequately account for the tendency to use this time-saving device in the more challenging setting with multiple injuries. No randomized controlled trials have yet been conducted to compare these techniques. If stapled anastomoses are performed, however, care must be taken to use appropriate sized staples and to account for bowel edema secondary to resuscitation. The surgeon should always pause between locking and firing the stapler to allow edema around the staple line to dissipate. The skin can be closed in cases of small bowel injury, unless for some reason surgery is delayed and there is gross contamination with succus or purulent material, in which case the fascia are closed and the skin is left open to heal by secondary intention.

In general, any mesenteric hematoma that extends to the bowel wall or is enlarging must be explored and any hemorrhage controlled. In the setting of damage control surgery, in which the objective is to stop the bleeding and control the contamination in the shortest amount of time as possible, many surgeons staple both ends of the bowel and leave it in discontinuity. After the patient is resuscitated and organ function is restored, the anastomosis can be made during the second definitive operation. The authors' preference is to perform a stapled anastomosis of the two bowel segments, even in the damage control setting, so as to avoid adding a closed loop obstruction to the challenges of a patient in physiologic extremis. The time required to perform a stapled anastomosis is minimal, and the anastomosis can be revised during the second, definitive operation.

Complications such as anastomotic leaks, intra-abdominal abscesses, and enterocutaneous fistulas occur in up to 10% of patients after repair of a small bowel injury. There is no conclusive evidence on the association between rate of complications and surgical technique. However, damage control procedures and the presence of associated injuries such as pancreaticoduodenal injuries have been associated with higher rates of complications.

BOX 1: Operative principles for managing small and large bowel injuries

1. Completely define all injuries with proper dissection.
2. Grade injuries according to severity.
3. Decide on type of repair: simple repair or resection and repair.
4. Débride all devitalized tissue.
5. Resect bowel that has any evidence of ischemia.
6. Establish clean bowel edges in the area of repair.
7. Use absorbable suture if a stapling technique is not employed. A second interrupted seromuscular layer may be added.
8. Repair lacerations transversely to avoid strictures.
9. Close mesenteric defects.
10. Irrigate peritoneal cavity with warm saline solution.

Large Bowel

There is now significant level 1 and level 2 evidence supporting primary repair or resection and anastomosis of colon injuries in the vast majority of cases. As a result, resection and anastomosis are recommended for patients in stable condition with penetrating wounds and minimal associated injuries or comorbid conditions. The prior practice of routine colostomy formation is not recommended and should be practiced only in very specific settings (to be described). Simple lacerations can be débrided and repaired with hand-sewn sutures in single or double layers, as previously described. Care must be taken to débride the area of perforation. Most destructive colon injuries can be resected, and primary anastomosis can be performed with side-to-side or end-to-side techniques. There is no difference in the leakage rates between hand-sewn and stapled anastomoses, and the choice of technique is left to the surgeon's discretion. The authors utilize a running absorbable full-thickness suture for the inner layer and an outer seromuscular layer of interrupted 3-0 silk.

Consideration of colostomy creation is reserved for "high risk" patients with destructive injuries; such patients are defined as those with a high penetrating abdominal trauma index score (≥25), those with high transfusion requirements (greater than six units), and those in whom surgery is delayed. Another area in which colostomy formation is still strongly considered is with extraperitoneal rectal injuries.

Diversion of the fecal stream away from colon injuries can be achieved by an end colostomy (Hartmann's procedure), end colostomy with creation of a mucous fistula, loop colostomy with closure or occlusion of the distal limb, or loop colostomy alone. Each of these techniques has been shown to be effective in the management of penetrating injury to the colon in the civilian population. Although purists have long advocated Hartmann's procedure or end colostomy and mucous fistula for complete fecal diversion, Rambeau and associates demonstrated that this can also be achieved with a properly constructed loop colostomy. Keys to this technique include (1) maintenance of the posterior wall above the level of the skin with a rod or red Robinson rubber catheter that occludes the distal lumen and is secured to the skin; (2) an anterior wall colotomy; and (3) maturation of the colon edges to the skin (with a 4-0 absorbable suture on a cutting needle). A "rosebud" appearance is created by passing the suture through full-thickness colon edge, then through a more proximal seromuscular bite, and finally through the dermis (Figure 2). A loop colostomy created in this manner has the advantage of allowing colostomy closure through a paracolostomy incision, as opposed to reentering the midline laparotomy wound. It also prevents the challenge of dissecting out the distal stump under what are often challenging conditions. The authors are so impressed with these advantages that even with destructive rectal injuries and associated risk factors, it is their practice to perform resection, primary anastomosis, and proximal fecal diversion with a loop colostomy.

Although the authors recognize the existing variation in opinion, the era of popularized running fascial closures has enhanced their commitment to leaving the skin incision open after repair of traumatic colon injuries. Even thin patients with minimal gross fecal spill receive "sleeper stitches" in the skin with large air knots placed in 3-0 nylon suture, allowing for wet-to-dry gauze dressing changes. Because the overwhelming majority of patients with gunshot wounds to the colon are still in the hospital at day 5, the appearance of a granulating base in the wound would prompt the authors to cut the air knot and achieve secondary skin approximation by tying the suture. This is a bedside procedure that is accomplished without so much as local anesthesia. This pathway avoids the scenario of a primarily closed

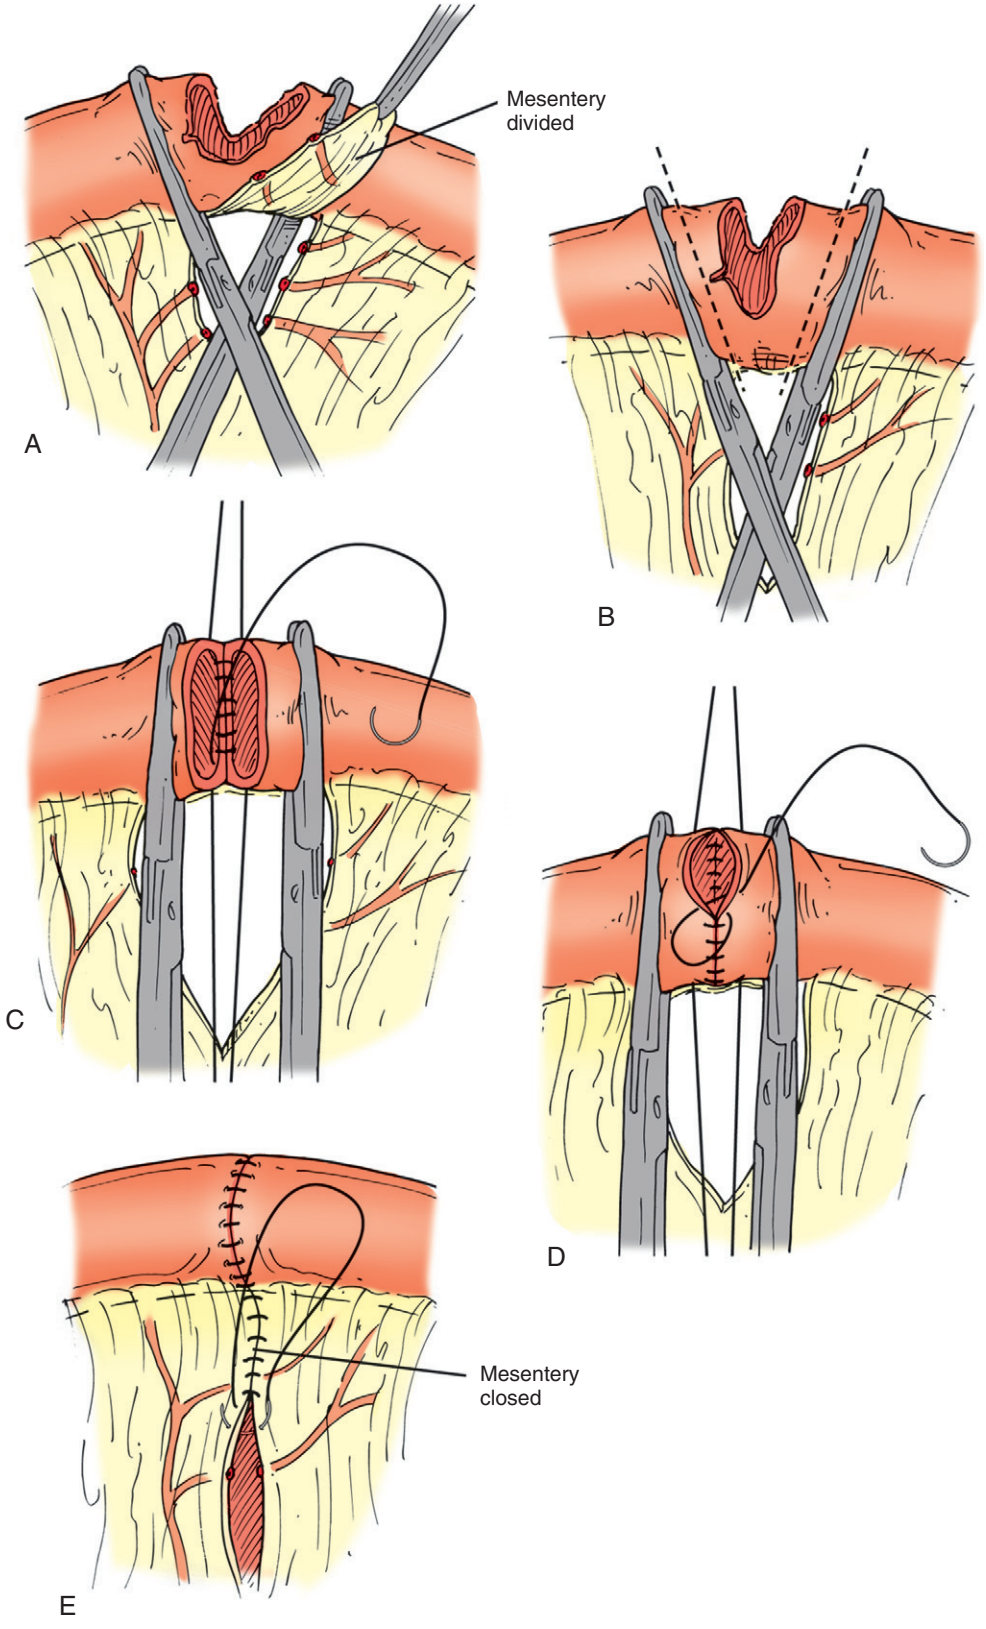

FIGURE 1 Small bowel injury necessitating resection. **A,** The bowel is clamped proximally and distally to the perforation while dividing the mesentery. **B,** The injured segment of bowel is resected. **C,** A single-layered anastomosis is performed with a running absorbable 3-0 using the Lembert suture technique, inverting the posterior wall. **D,** Then completing the suture on the anterior surface. **E,** The mesentery is then reapproximated. *(Modified from Thal ER, Weigelt JA, Carrico CJ, editors:* Operative trauma management, an atlas, *ed 2, New York, 2001, McGraw-Hill, p. 207. Reproduced with permission from the McGraw-Hill Companies.)*

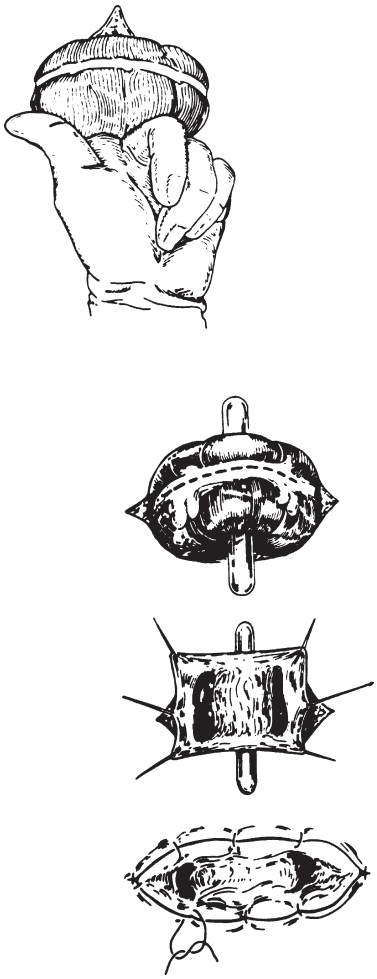

FIGURE 2 Formation of a loop colostomy. A segment of large bowel is eviscerated through a defect in the abdominal wall. The posterior wall is maintained above the level of the skin with the benefit of a red rubber catheter. Securing the catheter to the skin an angle towards the distal lumen achieves luminal occlusion and functional diversion. The colon edges are approximated to the skin by first passing the suture through the full thickness of the colon, then a more proximal seromuscular bite, and finally through the dermis.

skin incision after a case of contamination in which subcutaneous wound infection and signs of inflammation may escape early detection in an obese patient or one with a dark complexion. A delay in detection of subcutaneous space infection, combined with a running fascial closure, is a recipe for regional fascial necrosis and subsequent fascial dehiscence.

In the damage control setting, as with small bowel injuries, the authors recommend performing a primary anastomosis instead of leaving the bowel in discontinuity. At the time of the primary operation, the formation of a colostomy is not recommended.

Complications after colon repair remain an important concern. The most common complication includes anastomotic leaks or suture line failure. The rate of these complications is fortunately low (between 2% and 9% of cases). Colon leaks can result in intra-abdominal abscesses, fecal fistulas, and in some cases severe intra-abdominal sepsis that leads to death. Fistulas and abscesses can be managed nonoperatively by appropriate diet and antibiotic treatment. Intra-abdominal sepsis may necessitate reoperation and possible proximal diversion. The overall mortality rate after colonic anastomotic leaks is about 0.1%. Ostomy formation carries its own complications, including necrosis, infection, retraction, prolapse, parastomal abscesses and hernias, skin irritation, and significant emotional trauma. Severe or early minor complications have been reported in up to 22% of cases and late complications in about 3% of cases.

The Management of Rectal Injuries

David J. Ciesla, MD, and John Y. Cha, MD

OVERVIEW

Surgical management of colon and rectal injuries has evolved dramatically since World War II. Accepted treatment at that time generally consisted of resection and end colostomy based on experience with battlefield casualties. Although a difference between civilian and military injuries was recognized, the treatment by civilian trauma surgeons paralleled that of their military counterparts. In the most recent decades, treatment based on anatomic level of rectal injury has replaced mandatory colostomy as the sole approach. Similarly, adjuncts to repair, such as presacral drainage and distal rectal irrigation, have been used selectively to good effect.

Mechanisms of rectal injuries can be classified as direct penetration of the bowel wall by a foreign body, high-pressure blowout of the bowel wall as occurs in blunt trauma, and rarely, a devascularization injury from avulsion of the supporting mesentery. Approximately 80% of rectal injuries are caused by firearms, 10% by blunt trauma, 6% by transanal or impalement injuries, and 3% by transabdominal stab wounds.

DIAGNOSIS

The approach to diagnosis of rectal injuries is determined by the injury mechanism and index of suspicion. Patients with pelvic fractures, truncal gunshot and stab wounds, or impalements of the lower abdomen, buttocks, perineum, or upper thighs and any patient with a history of anal manipulation and lower abdominal or pelvic pain are at risk and should be suspected of having a rectal injury. The incidence rate of rectal injury in patients with pelvic fractures sustained during high-energy transfer mechanisms can be as high as 1%. Evaluation begins with a digital rectal examination in which the presence of gross blood should trigger further investigation. However, a negative digital rectal examination does not rule out a rectal injury. Although an organ-specific diagnosis is rarely made before surgery in the setting of an acute abdomen, free intraperitoneal air may occasionally be seen on chest x-ray or abdominal computed tomographic (CT) scan. Suspicion of enteric injury should be raised in all patients with evidence of fever, tachycardia, peritonitis, and leukocytosis.

In the preoperative setting, rigid proctosigmoidoscopy should be performed in all patients with suspected rectal injury. Transanal palpation or visualization of a perforation is diagnostic. Occasionally, intraluminal blood or submucosal hematoma is the only evidence of rectal injury. Therefore, these patients should be treated in the same manner as patients with confirmed rectal injuries. Suspicion of intraperitoneal involvement warrants abdominal exploration. Diagnostic laparoscopy has been proposed to evaluate peritoneal violation in patients with stable conditions with low-velocity transpelvic gunshot and stab wounds with conversion to celiotomy on identification of intraperitoneal injury. In any case, determination of the anatomic location of rectal injury is important because it is a key factor in choosing the appropriate therapeutic strategy.

Most rectal injuries are discovered during abdominal exploration after an abdominal gunshot wound. As such, a thorough evaluation of the pelvis during a systematic abdominal exploration is important immediately after control of life-threatening hemorrhage. Superior displacement of the small bowel exposes the structures of the pelvis. This is best accomplished with cephalad retraction of the viscera and mesentery, with only the distal colon and rectum left in the pelvis. Blood and enteric contents are then evacuated with laparotomy pads, and the peritoneal surfaces are inspected for violation or underlying hematoma. Although penetrating rectal injuries to the extraperitoneal rectum are usually obvious, missed injuries are often the result of small-caliber gunshot wounds or stab wounds to areas that are difficult to examine, such as the rectosigmoid junction and the proximal retroperitoneal rectum. Opening of the peritoneum and mobilization of the proximal retroperitoneal rectum can easily be accomplished. However, proceeding more distally simply for diagnosis is not recommended because of the potential for iatrogenic, vascular, urologic, neurologic, or additional rectal injury. When necessary for hemorrhage control, the presacral space is developed with blunt dissection posterior to the rectum in the sacral hollow. Most presacral bleeding is effectively managed with packing with laparotomy pads and can be supplemented with topical clotting adjuncts, such as a slurry of particulate gel foam suspended in activated thrombin. Patients who have undergone laparotomy for hemorrhage control with a suspicion of distal penetrating rectal injury should have the abdomen temporarily closed and be repositioned for proctoscopy.

ANATOMIC LOCATION OF INJURY AND INJURY GRADING

The rectum begins at the rectosigmoid junction and ends at the dentate line in the anal canal. Blood is supplied by the superior hemorrhoidal branch of the inferior mesenteric artery and the middle and inferior hemorrhoidal branches of the internal iliac or internal pudendal arteries. Venous drainage of the rectum follows the arteries, with the superior hemorrhoidal vein draining into the portal system and the middle and inferior hemorrhoidal veins draining via the internal iliac veins. The rectum can be further divided into intraperitoneal and extraperitoneal zones that help guide surgical decision making (Figure 1). The Organ Injury Scaling Committee of the American Association of the Surgery of Trauma (AAST) has developed a rectal injury scale (RIS) that facilitates comparison of injuries between patients and facilities and helps identify patients at high risk for postoperative complications (Table 1).

SURGICAL MANAGEMENT

The anatomic level, degree of injury, and physiologic state of the patient governs the surgical management of rectal injuries. Nondestructive injuries to the proximal intraperitoneal and extraperitoneal rectum that do not require resection based on intraoperative

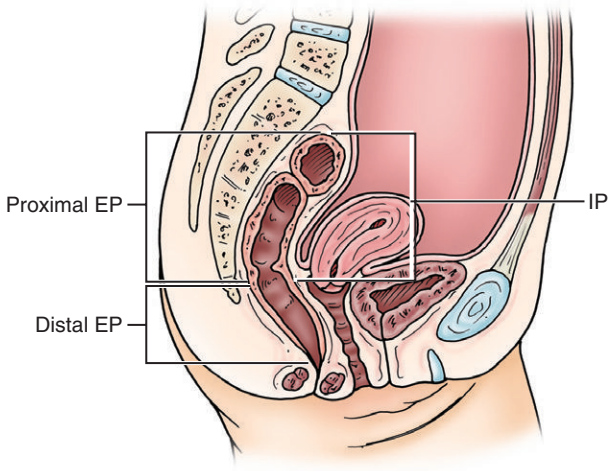

FIGURE 1 The intraperitoneal *(IP)* and extraperitoneal *(EP)* divisions of the rectum. *(From Weinberg JA, Fabian TC, Magnotti LJ, et al: Penetrating rectal trauma: management by anatomic distinction improves outcome,* J Trauma *60[3]:508-514, 2006.)*

TABLE 1: American Association of the Surgery of Trauma rectal injury grading

	Grade	Injury description
I	Hematoma	Contusion or hematoma without devascularization
	Laceration	Partial thickness, no perforation
II	Laceration	Laceration < 50% of circumference
III	Laceration	Laceration > 50% of circumference
IV	Laceration	Full-thickness laceration with extension into perineum
V	Vascular	Devascularized segment

Note: Advance one grade for multiple injuries to the same organ.
Modified from Organ Injury Scaling Committee of the American Association of the Surgery of Trauma. Moore EE, Cogbill TH, Malangoni MA, et al: Organ injury scaling II: pancreas, duodenum, small bowel, colon and rectum, J Trauma *30:1427, 1990.*

evaluation (AAST RIS I to III) are repaired primarily. These injuries are generally lacerations with minimal surrounding tissue destruction that are easily exposed after mobilization of the proximal rectum and sutured. A running single layer of 3-0 absorbable monofilament suture is used. With repair of rectal gunshot wounds, débridement of the devitalized edges of the wound back to healthy bleeding bowel wall is important before suture repair. Placement of drains in the pelvis after primary repair of proximal rectal injuries is not necessary and may increase the risk of fistula.

Proximal rectal injuries with extensive loss of the rectal wall or devascularization (AAST RIS IV and V) are generally treated with resection distal to the injury and proximal end colostomy followed by delayed reconstruction. If necessary, the rectum can be divided within a few centimeters of the anal verge with the aid of a thoracoabdominal (TA) stapler after mobilization of the distal rectum. In addition, the advent of the end-to-end circular stapling device has facilitated elective colostomy closure. This has proved to be a much safer approach to destructive colon injuries than primary repair. Select patients with minimal coincident injuries, minimal contamination, and normal physiology are candidates for resection and immediate primary colorectal anastomosis. Patients with extensive abdominal injuries, significant contamination, or persistent shock should undergo resection and proximal diversion. A damage control posture should be adopted in patients with a persistent base excess of −10 or less, a temperature less than 33°C, and refractory nonsurgical bleeding. After surgical control of hemorrhage, fecal contamination can be controlled with stapled division or resection of the injured segment of rectum followed by temporary abdominal closure, resuscitation, and return to the operating room once the acidosis, hypothermia, and coagulopathy are corrected.

Wounds to the distal extraperitoneal rectum are generally treated with proximal diverting colostomy. As mentioned previously, extensive dissection to definitively visualize distal rectal injuries offers no advantage and should be avoided because of the potential for vascular, urologic, neurologic, or iatrogenic rectal injury. Although several methods for open and laparoscopically assisted proximal diversion are described, the chosen technique must completely divert the fecal stream from the rectal injury. The authors use a loop colostomy located in the patient's left lower quadrant with the sigmoid colon (Figure 2). The critical technical elements to ensure complete diversion are creation of a longitudinal colotomy, maintenance of the common wall or spur between the afferent and efferent limbs above the level of the skin, and maturation of the stoma to the skin immediately. A loop colostomy created in this manner completely diverts the fecal stream. Same admission colostomy closure can be considered 7 to 10 days after injury in select patients with radiographic (contrast enema) evidence of rectal wound healing. Successful nonoperative management of isolated nondestructive distal rectal injuries without proximal diversion has been reported. Candidates for treatment without diversion are limited to those in whom intraperitoneal rectal injury and bladder injury have been excluded.

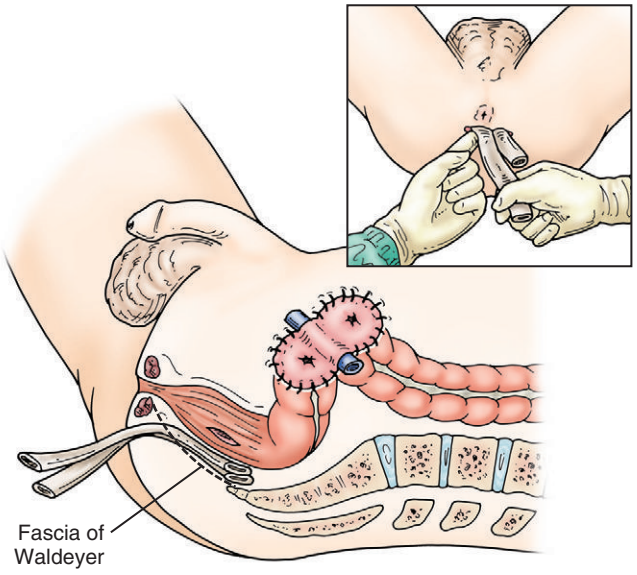

FIGURE 2 Technique for presacral drainage and proximal diversion for treatment of occult or unrepaired distal colon injuries. *(Courtesy Baylor College of Medicine.)*

Distal rectal washout has been advocated as a means to reduce the septic complications associated with rectal injuries based on military experience but has not consistently been associated with improved outcome in the civilian setting. The authors use a selective approach based on the level of injury and the chosen repair. In general, the rectal contents are removed during diagnostic proctosigmoidoscopy, either before or during the main operation. Patients with proximal nondestructive rectal injuries are generally repaired primarily without distal rectal washout unless the stool burden is large. In such cases, the injury is repaired and the washout is performed with transanal irrigation and manual expulsion of rectal contents with the aid of rigid proctosigmoidoscopy. The repair is always reinspected after expulsion of stool to ensure its integrity. Patients with destructive proximal rectal injuries undergoing resection and anastomosis or proximal diversion generally receive transanal distal rectal irrigation with the aid of rigid proctosigmoidoscopy of the rectal stump. The authors do not routinely perform distal rectal washout of patients with distal rectal injuries that are not repaired, whether or not a proximal diverting loop colostomy is created.

Presacral drainage has long been considered an integral component of treatment of distal rectal injures. The principal is to drain the presacral space of perirectal contamination resulting from violation of the bowel and avoid the potential for pelvic sepsis. Several authors have reported successful management of distal rectal injuries without presacral drainage in both the presence and the absence of proximal diversion. Nonetheless, many still advocate its use, reasoning that the minimal morbidity of presacral drainage is outweighed by the risk of pelvic sepsis and its attendant morbidity and mortality. For destructive injuries with contamination, proceeding with presacral drainage seems most prudent. A curved incision is made posterior to the anus, and the presacral space is developed bluntly to the level of the sacral hollow (see Figure 2). Ideally, Penrose drains are placed in proximity but not in contact with the injury. The drains are secured to the skin with silk sutures for better patient comfort and usually removed between 4 and 7 days after placement.

MORBIDITY AND COMPLICATIONS MANAGEMENT

Intra-abdominal abscess is the most frequent septic complication after rectal injury. Small abscesses of less than 2 cm often respond to intravenous antibiotic therapy and do not require drainage. Many intra-abdominal abscesses can be managed with image-guided percutaneous drainage. Occasionally, percutaneous drainage reveals an underlying fistula. In such cases when the patient has no evidence of sepsis, the percutaneous drain is left in place until imaging shows obliteration of the abscess cavity. Once this occurs, the drain is slowly removed. Larger intra-abdominal abscesses that are inaccessible to percutaneous drainage and those associated with sepsis require operative drainage.

Suture line failure and fecal fistula are observed in 1% to 8% of patients. Fistulas that extend to the incision are often associated with intra-abdominal abscesses and evidence of sepsis. A fistulogram should also be performed to determine whether there is

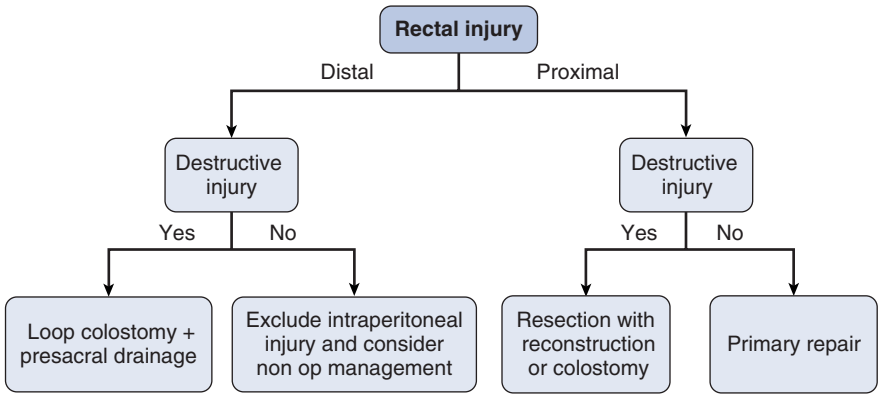

FIGURE 3 Algorithm for the management rectal injuries.

diffuse leakage throughout the abdominal cavity, and an abdominal CT scan is obtained to look for intra-abdominal abscesses. A controlled fistula can be managed nonoperatively, but the wound must be carefully inspected for evidence of necrotizing fasciitis. Uncontrolled fistulae require operative intervention and are usually treated with resection and proximal diversion with an end colostomy.

Wound infections occur in up to 50% of patients with colon or rectal injuries but should not be considered a complication of the repair. Virtually all wound infections can be avoided by leaving the wound open at the time of abdominal closure. Closure of the wound during the initial operation should be reserved for the patient with few associated injuries, minimal subcutaneous fat, and little contamination and without prolonged shock.

CONCLUSION AND ALGORITHM

As with colon injuries, the management of rectal injuries has progressed from near universal treatment with diversion to selective management according to injury characteristics and risk of complications. Prompt recognition, hemorrhage control, and control of enteric spillage are the immediate management priorities, followed by repair or diversion. Although more severe injuries in patients with compromised conditions are still best treated with repair or resection, proximal diversion, and presacral drainage, it is recognized that some patients with limited injuries can be successfully treated with a less invasive approach. With these considerations, the authors have adopted an approach to injuries outlined in Figure 3. The critical decision-making points are level of injury, the extent of tissue destruction, and the metabolic state of the patient.

The first consideration is the location of the injury. Nondestructive intraperitoneal and proximal extraperitoneal injuries are repaired primarily, and destructive injuries are resected. Reconstruction via colocolostomy is preferred for patients with minimal additional injuries and an appropriate physiologic condition. Resection and proximal diversion is performed in patients with more extensive injuries and persistent shock. Destructive distal rectal injuries are treated with proximal diversion and presacral drainage. Isolated nondestructive distal injuries are considered for nonoperative management. In cases that are unclear, a more aggressive traditional approach of diversion and drainage is favored.

Injury to the Spleen

Ho Phan, MD, and
Christine S. Cocanour, MD, FACS, FCCM

OVERVIEW

The spleen is the most commonly injured organ in blunt abdominal trauma. The management of splenic injury has fluctuated over the past century from observation and expectant management in the early twentieth century to primarily operative management for all injuries, and now to the current practice of selective nonoperative management (NOM). The shift in treatment is a result of our changing technology and understanding of the spleen's role in immunologic function.

The spleen's role in immunologic response was demonstrated in a publication by Morris and Bullock in 1919, revealing an increase in mortality in postsplenectomized rats challenged with *Bacterium enteritidis* compared to controls. The risk of postsplenectomy infection was not demonstrated in humans until 1952 in a landmark paper by King and Shumacker. In this case series, the authors described death due to sepsis in two of five infants who had undergone splenectomy for congenital hemolytic anemia. Subsequently, several authors noted this increased rate of overwhelming sepsis in adults. The reported rate of postsplenectomy overwhelming sepsis varies depending on the age at splenectomy and indications, with the highest risk in very young children and in patients undergoing splenectomy for hematologic disorders. Although the rate of sepsis after splenectomy is low, it is a lifelong risk for these patients. This knowledge led to an increased emphasis on splenic preservation.

Initially attempted in children, comfort grew with NOM of splenic injury in adults as computed tomography (CT) became more widely available and with the realization that negative laparotomies carry significant morbidity. As angioembolization techniques become more refined, it is increasingly used as an adjunct to NOM, with improvement in NOM success.

DIAGNOSIS

The initial management of all trauma patients should follow the guidelines of the American College of Surgeons Advanced Trauma Life Support. Trauma patients often have multiple confounding injuries that make physical examination unreliable. Therefore, the diagnosis of splenic injury relies on a high index of suspicion. Factors that should increase the index of suspicion include hypotension, abdominal ecchymosis, abdominal pain or tenderness, presence of lower left rib fractures, and presence of pelvic fractures. It is important to point out that the presence of acute hemoperitoneum does not always lead to abdominal pain and tenderness, especially in the absence of clot lysis. Referred left shoulder pain (Kehr sign) is not reliably present, but even if present, it is often confounded by multiple injuries.

Diagnostic and management decisions in patients with blunt splenic injury rely heavily on the presence or absence of hemodynamic stability and the response to resuscitation. The initial evaluation and management of patients with blunt splenic injury is summarized in Figure 1. During the initial assessment, blood should be drawn for laboratory testing, including hemoglobin, electrolytes, markers of metabolic stress (base deficit or lactate), coagulation profile, and blood typing. Intravenous access should be obtained for resuscitation and potential intravenous contrast administration. A hypotensive, patient who does not respond to fluid resuscitation or who only transiently responds to fluid administration should undergo a focused assessment with sonography for trauma (FAST) examination. A positive FAST examination indicates presence of peritoneal fluid and, in the case of a trauma patient, hemoperitoneum until proven otherwise. An emergent laparotomy is indicated in these patients. For patients who are unstable and have a negative FAST examination, intra-abdominal hemorrhage is not reliably excluded. FAST may be repeated in 15 to 30 minutes or a diagnostic peritoneal aspirate (DPA) or lavage (DPL) should be considered as the next step to rule out intra-abdominal hemorrhage. Other alternative causes of hemorrhagic shock, such as thoracic injuries, pelvic injuries, external blood loss, or other types of shock, should be considered. For patients without a clear source of hemorrhage and who remain unstable despite resuscitation, immediate laparotomy should be considered.

The FAST examination evaluates three areas of the abdomen for the presence of intra-abdominal fluid: the hepatorenal fossa (Morrison's pouch), the splenorenal fossa, and the area around the bladder. A fourth view evaluates the pericardium for pericardial fluid. The presence of fluid in any of these locations indicates a positive examination. Like other sonographic studies, the accuracy of FAST is operator dependent and limited by the patient's body habitus and presence of subcutaneous emphysema. FAST only allows determination of the presence of fluid within the abdominal cavity. It does not provide the source of the fluid or evaluation of the retroperitoneum. The reported sensitivity of FAST varies. Generally, FAST has a sensitivity of 80% and specificity of 96%; however, at some large trauma institutions, the sensitivity may be as low as 50%. The false negative rate for FAST is higher in the setting of pelvic trauma, thoracolumbar spine fracture, hematuria, and rib fractures.

When FAST is negative, the suspicion for intra-abdominal hemorrhage remains high, and the patient remains too unstable to be safely taken to the CT scanner, DPA may quickly provide an answer. It is the aspiration portion of the diagnostic peritoneal lavage without the lavage. When performed percutaneously, DPA is rapid and safe, and it does not have the high sensitivity of DPL. In a small prospective, observational trial, DPA had a sensitivity of 89% and a specificity of 100%.

For patients deemed hemodynamically stable, intravenous contrast-enhanced CT scan of the abdomen and pelvis is the study of choice for diagnosis of splenic injury. It allows for the grading of splenic injuries as developed by the American Association of the Surgery of Trauma (Table 1). When a single-phase CT scan identifies contrast extravasation outside the splenic parenchyma, it usually indicates active splenic hemorrhage, whereas a focal accumulation of contrast within the parenchyma is often a contained vascular injury. Contrast extravasation or "blush" has been used in the past to predict failure of NOM, guide selection for angioembolization, or even laparotomy. With the introduction of multidetector row CT systems in 1998, CT scanning is more rapid and has better spatial resolution, which has led to a greater sensitivity in detecting "blush." However, with the greater sensitivity, it is not unusual to find no active bleeding on angiography in patients identified with a contrast "blush" on CT scan. Only 5% to 7% of all patients with blunt splenic injury have been found to have extravasation of contrast requiring angioembolization.

NONOPERATIVE MANAGEMENT

Selective nonoperative management is the standard of care for the hemodynamically stable patient with a blunt splenic injury in the absence of peritonitis. NOM should only be considered in environments that have the capability of monitoring and providing serial clinical exams and that have an operating room available for emergent laparotomy. Original exclusions for NOM in adults suggested

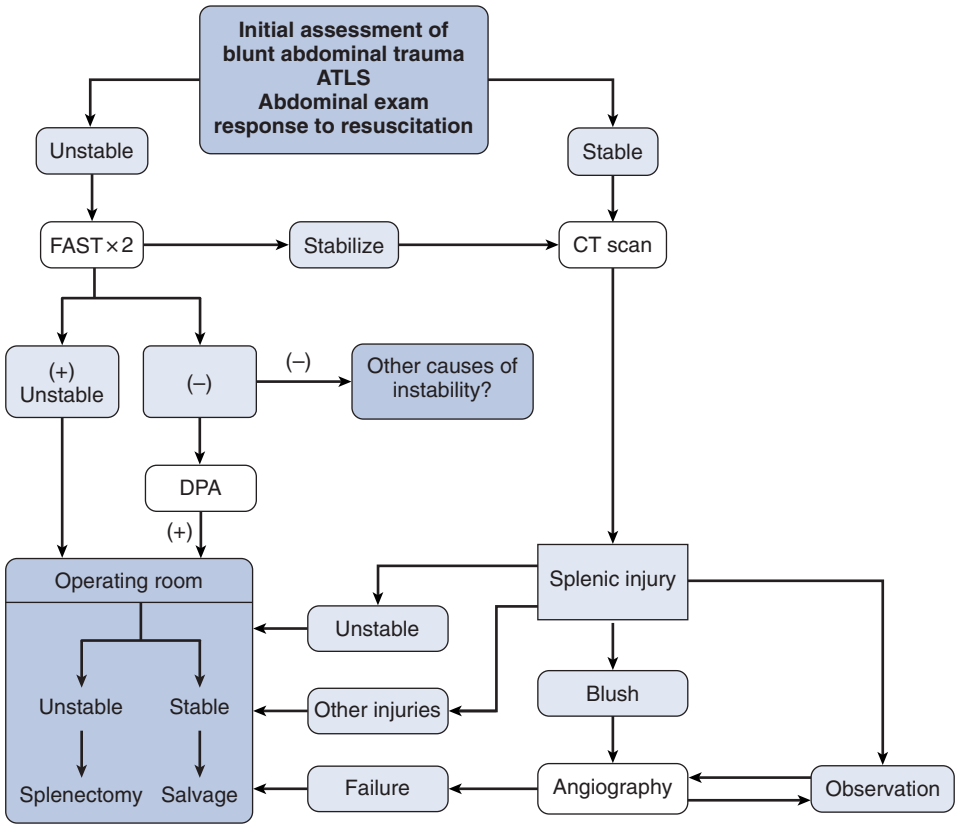

FIGURE 1 Algorithm for management of blunt splenic injury. *ATLS,* Advanced trauma life support; *CT,* computerized tomography; *DPA,* diagnostic peritoneal aspiration; *FAST,* focused abdominal sonography for trauma. *(Adapted from Moore FA, Davis JW, Moore EE, et al: Western Trauma Association (WTA) Critical decisions in trauma: management of adult blunt splenic trauma,* J Trauma *65:1007-1011, 2008.)*

TABLE 1: Spleen injury scale

Grade	Injury	Description
I	Hematoma	Subcapsular, >10% surface area
	Laceration	Capsular tear, <1 cm parenchymal depth
II	Hematoma	Subcapsular, 10% to 50% surface area, intraparenchymal, <5 cm in diameter
	Laceration	1-3 cm parenchymal depth that does not involve a trabecular vessel
III	Hematoma	Subcapsular, >50% surface area or expanding; ruptured subcapsular or parenchymal hematoma
	Laceration	>3 cm parenchymal depth or involving trabecular vessels
IV	Laceration	Laceration involving segmental or hilar vessels producing major devascularization (>25% of spleen)
V	Laceration	Completely shattered spleen
	Vascular	Hilar vascular injury that devascularizes spleen

Modified from Moore EE, Cogbill TH, Jurkovich GJ, et al: Organ injury scaling: spleen and liver (1994 revision), J Trauma *38:323-324, 1995.*

that a high grade of injury, head trauma, quantity of hemoperitoneum, age greater than 55, contrast "blush," and a large number of associated injuries precluded the ability to offer NOM. However, more recent literature has shown that the severity of splenic injury (by either grade or amount of hemoperitoneum), age greater than 55, neurologic injury, presence of contrast "blush," and associated injuries should no longer be considered as absolute contraindications to NOM. Although found in only 0.3% of all blunt trauma admissions, hollow viscous injury as suggested by peritonitis, increasing abdominal pain, or suspicion for hollow viscous injury mandates exploration.

Angiography and embolization are controversial adjuncts to NOM. First described by Sclafani in 1996, embolization allows an improved splenic salvage rate, especially for grades III to V. Its success and acceptance are most likely tempered by the availability and skill of the interventionalist. Indications for angiography with embolization in blunt splenic trauma include contrast "blush" on CT with evidence of ongoing hemorrhage, pseudoaneurysm, AAST grades IV and V, moderate hemoperitoneum, or clinical evidence of continued hemorrhage. Multiple studies have shown improved success of NOM with its use. A NOM failure rate of 13% to 15% dropped to as low as 2% with embolization.

There is concern that the small increase in splenic salvage rate is not worth the 19% risk of major complications and 23% risk of minor complications reported in early studies. Major, potentially life-threatening complications include continued hemorrhage, total splenic infarction, splenic abscess, contrast-induced nephropathy, pancreatitis, and pneumonia. Minor, non–life-threatening complications include fever, pleural effusion, partial splenic infarction, pain, coil migration, and puncture site injuries. Bleeding is the most common complication and has been reported in 5% to 24% of those undergoing embolization. Minor complications such as fever are seen in over 50% of patients undergoing embolization. Centers where angiography and embolization for splenic injury are common often report low numbers of complications.

Controversy exists over embolization techniques. In experienced hands there is no difference in outcome when main splenic coil embolization is compared to distal or combined proximal and distal embolization. Although there is concern that embolization leads to splenic necrosis and negates the advantage of splenic salvage, recent

studies have shown that splenic embolization does not impact immune function.

Roughly 85% of patients with blunt splenic injury are managed nonoperatively with over a 90% success rate. Patients with high-grade injury, large hemoperitoneum, vascular blush, pseudoaneurysm, and arteriovenous fistula are all at high risk of failure of NOM. Velmahos and colleagues found that of 40% of patients with grade IV splenic injuries treated nonoperatively, 65.5% were successful. Sixteen percent of patients with grade V injuries were treated nonoperatively, and 40% were successful. Of those patients who do fail, approximately 75% will fail within 48 hours of injury, 88% within 5 days, and 93% within 1 week of injury. In a review of a statewide discharge database, the 180-day risk of splenectomy following NOM and discharge home was 1.4%. Patients must be given specific discharge instructions about what symptoms may indicate a need for rapid return to the hospital.

Controversy continues to reign over the hospital management of a patient with blunt splenic injury treated nonoperatively. The frequency of serial hemoglobins, abdominal exams, and monitoring; determining when an oral diet should be started; deciding whether to use bed rest; determining the optimum length of stay in both the intensive care unit (ICU) and the hospital; determining the necessity of repeat imaging; and setting limitations on activities after discharge are all questions in which definitive data are lacking. As resources have become more limited, recent studies have attempted to address the optimal care of the patient with blunt splenic injury without sacrificing safety. A retrospective study found that early mobilization did not alter the risk of delayed hemorrhage and that bed rest was unnecessary. Recently published protocols suggest that grade I splenic injuries can be discharged as early as 1 to 2 days after injury if their hemoglobin is stable and vital signs remain normal. Grade II and higher injuries differ between published protocols. Most will discharge grade II injuries when the hemoglobin is stable and vital signs are normal. Grade III injuries and above are admitted to the ICU and had a minimum overall length of stay of at least 3 days. Figure 2 is a suggested management guideline for patients chosen for NOM. Each institution will need to modify this depending on its resources and patient population.

Repeat imaging in patients managed nonoperatively is controversial. Most repeat CT scans did not change patient management. An Eastern Association for the Surgery of Trauma survey found that only 14.5% of surveyed surgeons routinely obtain follow-up CT scans. Those physicians who routinely reimage splenic injuries with CT scans and angioembolize as indicated believe that their aggressive approach greatly contributes to their high NOM success rate. Currently, there is not enough evidence to recommend routine follow-up CT scans.

Clinical judgment is the predominant factor in determining a return to activity, including contact sports for patients with blunt splenic injuries treated nonoperatively. Restrictions may be recommended for less than 6 weeks for grades I and II injuries and longer than 6 months for grades IV and V injuries. The American Pediatric Surgical Association published management guidelines in 2000 for return to unrestricted activity that included "normal" age-appropriate activities that suggested 3 to 6 weeks for grades I to IV, respectively. Return to full-contact, competitive sports was left at the discretion of the pediatric surgeon.

PENETRATING SPLENIC INJURY

Penetrating abdominal injuries due to gunshot wounds are usually managed by laparotomy. Isolated stab wounds to the spleen may undergo a trial of NOM. However, splenic injuries from penetrating trauma are often accompanied by injuries to the bowel. Penetrating injuries to the spleen tend to violate intraparenchymal anatomic planes, and as a consequence, arterial injury and subsequent pseudoaneurysm formation are common. Because of the risk of delayed bleeding, splenectomy should be considered at the initial exploration. If it is an isolated splenic pole injury that can be treated by resection of the injured segment of the spleen, splenorrhaphy may be considered in the absence of accompanying bowel injury.

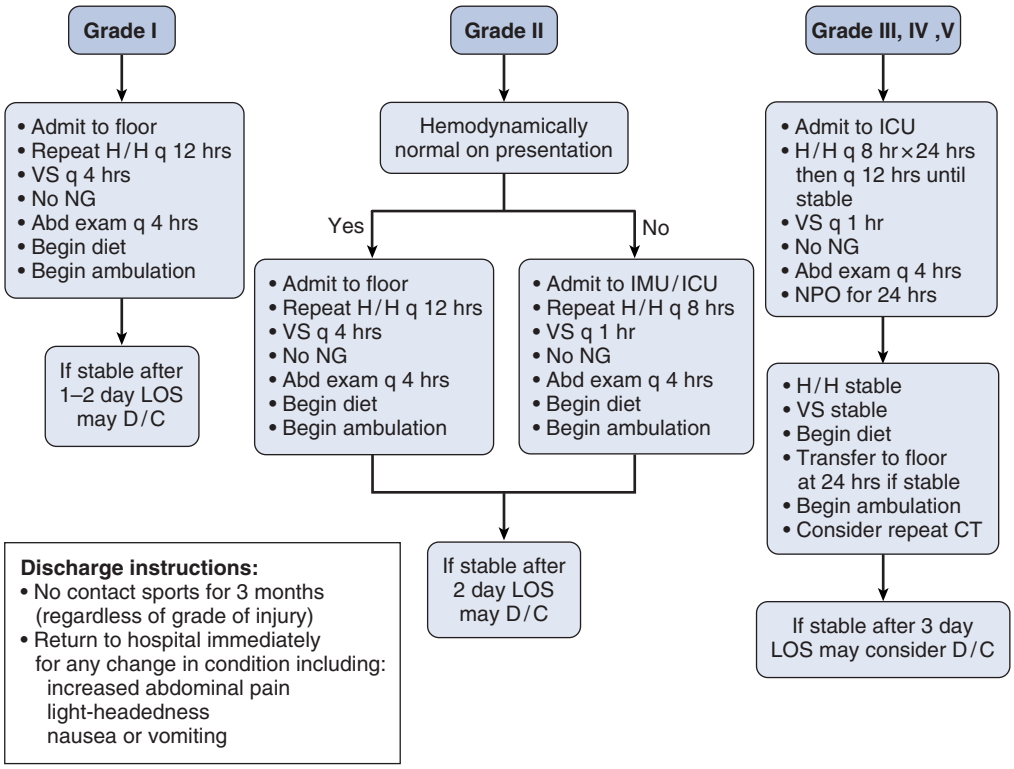

FIGURE 2 Suggested management guidelines for those patients chosen for nonoperative management (NOM). OPERATIVE MANAGEMENT

When it is determined that the patient with blunt splenic injury requires operative management, preparation for trauma laparotomy is essential. Blood is sent for crossmatch, and preoperative antibiotics are given. The patient should be placed in a supine position and is induced under general anesthesia. The patient's chest, abdomen, pelvis, and midthighs are prepped and sterilely draped. All measures to prevent hypothermia should be instituted, including using only warm intravenous (IV) fluids.

A midline incision is made that extends from the xyphoid to the pubic symphysis. Upon entering the abdomen, blood and clots are rapidly evacuated, and the abdomen is packed in all four quadrants to control hemorrhage. The priority should be given to hemorrhage control first followed by control of gastrointestinal contamination. The presence of clots in a particular quadrant should provide a clue as to where the source of hemorrhage may be. Active hemorrhage should first be controlled, and then the rest of the abdomen should be inspected systematically.

To adequately evaluate the injured spleen, it must be completely mobilized from all of its attachments and brought to the midline. Splenic attachments are shown in Figure 3. The left costal margin is retracted laterally and superiorly to facilitate exposure. The surgeon's hand is placed posterior to the spleen, and the spleen is rotated medially to expose the lienophrenic and lienorenal ligaments. By compressing the spleen against the spine medially with the surgeon's hand, bleeding from the spleen can be temporarily controlled. The lienophrenic and lienorenal ligaments are generally avascular and can be divided either with cautery or Metzenbaum scissors. Sometimes, these ligaments have to be divided by feel with scissors because exposure is not always adequate. The surgeon's index finger is inserted under the cut lienorenal ligament, and with a combination of blunt and sharp dissection, the spleen is freed from Gerota's capsule and the diaphragm. In the same plane, the surgeon's hand slides to the posterior surface of the tail of the pancreas, and both the spleen and the tail of the pancreas are elevated to the midline incision. It is helpful at this point to place a few laparotomy pads in the splenic fossa to help elevate the spleen. The lienocolic ligament is then divided, freeing the spleen from the omentum and colon. This ligament generally contains small vessels that require ligation. The short gastric vessels are then ligated and divided at this time, freeing the spleen from the stomach. Care should be taken during this step to ligate the short gastric vessels far from the stomach to prevent entrapment of the stomach wall. A nasogastric tube in the stomach can be used as traction, which helps expose the short gastric vessels for ligation.

At this point the spleen is mobile on its vascular pedicle and can be adequately inspected. If splenectomy is required, the splenic artery and vein are suture ligated close to the spleen to avoid injury to the tail of the pancreas. The splenic bed is then inspected to ensure hemostasis. Using a rolled-up laparotomy pad in the deepest part of the fossa and slowly rolling the pad anteriorly and medially allow systematic inspection of the fossa. The tail of the pancreas should be inspected for injury. If injury to the tail of the pancreas is suspected, a closed-suction drain should be placed near the tail of the pancreas. Routine use of drains after splenectomy is not recommended because it is associated with increased incidence of subphrenic abscess.

Most patients with splenic injuries are taken to the operating room for hemodynamic instability. Therefore, the most prudent operation is splenectomy. Splenic salvage should be considered only in hemodynamically stable patients who are not coagulopathic or hypothermic. Grades I and II injuries can be controlled with electrocautery, argon beam coagulation, and application of topical hemostatic agents. Sutures buttressed with omentum, Teflon, absorbable mesh, and oxidized regenerated cellulose (Surgicel; Ethicon, Inc., Somerville, NJ) have been described for higher-grade injuries. If simple hemostatic methods do not work, splenectomy should be considered. More aggressive approaches to splenorrhaphy could be considered in very young children who are hemodynamically stable.

IMMUNIZATIONS

The Surgical Infection Society guidelines recommend that patients undergoing splenectomy should receive pneumococcal vaccine and meningococcal vaccine, and for high-risk patients, *Haemophilus influenza* vaccine. The optimal time for vaccinations for patients undergoing splenectomy for trauma is 14 days postoperatively. However, due to concern for lack of follow-up, many institutions give vaccinations prior to discharge. Pneumococcal vaccination should be repeated 5 years after the first dose.

Retroperitoneal Injuries: Kidney and Ureter

Benjamin N. Breyer, MD, MAS, and Jack W. McAninch, MD, FACS

KIDNEY

Overview

The kidney is the most common genitourinary organ injured from external trauma, occurring in 1% to 5% of all injuries. The vast majority of kidney injuries can be successfully managed nonoperatively. Blunt traumas are more frequent than penetrating (around an 80:20 ratio). Penetrating trauma is more common in urban areas, is commonly caused by gunshot or stab wounds, and more commonly requires exploration. Blunt trauma results from falls from heights, motor vehicle and motorcycle crashes, or blunt assaults. An estimated 2% of blunt injuries require exploration as opposed to over 50% of penetrating injuries.

Similar to other solid organ injuries such as spleen and liver, advances in staging techniques (computed tomographic scan) have helped promote nonoperative management of renal injuries. Nevertheless, certain severely injured kidneys require exploration and reconstruction or, rarely, removal. Advances in embolization techniques have produced a useful adjunct treatment modality for renal trauma. Ultimately, the objective of managing these patients is to stem life-threatening bleeding while retaining enough nephron mass to avoid end-stage renal disease.

Initial Evaluation

The initial evaluation begins with the American College of Surgeons Acute Life Support Program algorithm of airway, breathing, circulation (external bleeding control), disability (neurologic status), and exposure (undress)/environment (temperature control). Subsequently, one should perform a history and physical examination, including blood pressure measurements to assess for shock (systolic blood pressure [SBP] <90 mm Hg) and an examination for gross or microscopic hematuria. Microhematuria is commonly defined as greater than three red blood cells per high-powered field on urine microscopy. Hematuria is a common sign of penetrating and blunt trauma, but the presence and degree of hematuria do not correlate with injury location and severity. This is particularly true for penetrating injuries where no hematuria may be present. The first void should be observed and analyzed because hematuria may clear quickly in the setting of aggressive fluid resuscitation. Hematuria helps guide whether imaging is needed.

Blunt Trauma

The suspected blunt renal trauma algorithm is shown in Figure 1. The mechanism of trauma should be documented. For motor vehicle collisions, the speed and angle of impact and whether the patient was restrained or ejected on impact are important history to gather. One should record the height from which the patient fell, whether a significant deceleration injury occurred, or where on the body a blunt assault was perpetrated.

Signs of renal injury on physical exam include flank ecchymoses, rib fractures, and transverse spinal process fractures. Minor trauma can cause significant damage to congenitally abnormal kidneys such as horseshoe or pelvic kidneys that are less protected from external trauma.

Penetrating Trauma

The suspected penetrating renal trauma algorithm is shown in Figure 2. Understanding the mechanism of injury is again important. If a knife was used, noting the size of the blade can help with determining the depth of penetration. If a firearm was used, knowledge of the type of bullet (high-velocity vs low-velocity) can provide information about injury extent. High-velocity bullets cause blast effects and will often produce delayed tissue necrosis. Low-velocity missiles are less devastating.

Stab wounds or bullet entry locations should be noted. Abdominal stab wounds anterior to the anterior axillary line (a vertical line that runs along the anterior axillary fold or armpit crease) that injured the kidney are often associated with current commitment abdominal injuries. Renal injuries posterior to this line may injure the ascending or descending colon but are less likely to injure intra-abdominal contents.

Children

Children under 16 require increased suspicion for renal injury because of anatomic and physiologic differences from adults. They have relatively large kidneys, underdeveloped Gerota's fascia and less perirenal fat, incomplete ossification of the lower ribs, and kidneys that are located in the abdomen and are less protected by the ribs. Shock is an unreliable indicator of injury extent in children because they can have a robust catecholamine response to stress that can mask severe blood loss.

Indications for Renal Imaging

Decisions regarding whether to image are predicated on mechanism (blunt/penetrating), presence of hematuria (gross/microscopic), and shock (blood pressure of less than 90 mm Hg). In adults, blunt trauma with gross hematuria should prompt imaging, as should blunt trauma with microscopic hematuria and shock. In adults with blunt trauma, microscopic hematuria without shock has not been associated with significant injury and does not call for imaging. Major acceleration or deceleration injuries such as a fall from a great height or a high-speed motor vehicle accident should prompt imaging.

In adults with penetrating injuries, any degree of hematuria or injury location suspicious for renal trauma should prompt imaging. Lower thresholds to image children exist given their anatomic differences. Any pediatric trauma (younger than 16 years) with any degree of significant hematuria (greater than 50 red blood cells per high-powered field) should be imaged.

Imaging Studies

Computed Tomography

Contrast enhanced computed tomographic (CT) scan with additional 10-minute delay scans is the gold standard imaging modality to stage the stable renal trauma patient and is both sensitive and specific for renal injuries. Expert opinion contends that no delays are required if the kidneys are uninjured and no perinephric, retroperitoneal pelvic or perivesical fluid is present. CT helps to delineate concurrent abdominal solid organ and vascular injuries. With CT imaging, one can determine the size and location of perinephric hematomas, the degree of parenchymal laceration, collecting system injuries, differential contrast uptake and excretion indicative of arterial injury or obstruction, a cortical rim sign indicating an arterial injury, and the degree of devitalized tissue. A renal vein injury can be subtle and marked by a hematoma medial to the renal artery and vein, while medial arterial contrast excretion represents a major

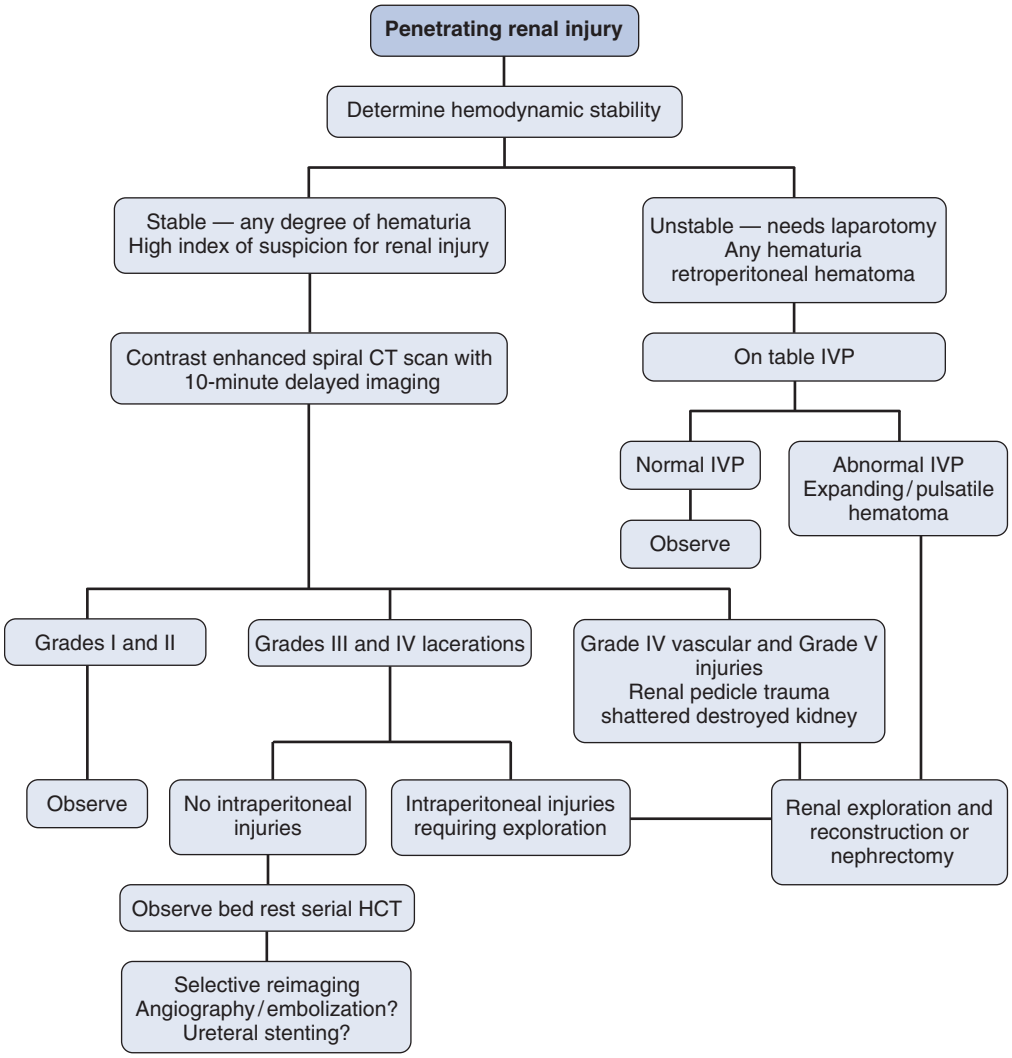

FIGURE 2 Penetrating renal trauma algorithm. *CT,* Computed tomography; *Hct,* hematocrit; *IVP,* intravenous pyelogram. *(From Santucci RA, Wessells H, Bartsch G, et al: Evaluation and management of renal injuries: consensus statement of the renal trauma subcommittee,* BJU Int *93:937, 2004.)*

arterial injury. Medial urinary contrast excretion may indicate a major tear in the ureteropelvic junction, while this finding teamed with a lack of distal contrast excretion suggests ureteropelvic junction avulsion.

Ultrasound

While ultrasound (US) is a widely used imaging tool in the assessment of the abdominal trauma patient, it is not an effective modality to image acute kidney injuries. The kidney is bound by Gerota's fascia, and unless there are tears in the fascia, retroperitoneal bleeding will not be visualized. Ultrasound cannot reliably differentiate urine and blood. US can provide rapid, inexpensive, and noninvasive imaging of the abdomen. The focused assessment with sonography for trauma (FAST) is frequently used to identify intra-abdominal fluid and abdominal injuries.

Intravenous Pyelogram

While CT scan has replaced intravenous pyelogram (IVP) as the imaging modality of choice for the traumatized urinary system, IVP still plays a role in genitourinary trauma staging. In patients directly taken to the operating suite without CT staging of their kidney or ureteral injury, a one-shot IVP can help indicate the presence of a contralateral functioning kidney and indicate possible collecting system or ureteral injury. An IVP may demonstrate an abnormal renal outline, loss of the psoas margin, or displacement of the bowel or ureter suggestive of a hematoma. Patients found to have a solitary functioning kidney require every attempt possible to save the kidney, as even a portion of a solitary kidney can keep someone off dialysis. Opponents of the one-shot IVP contend it causes unneeded delays during critical moments in the trauma suite. While opponents advocate simple palpation to verify the contralateral kidney, the surgeon can be fooled by a prominent psoas muscle. The one-shot IVP is performed by administering 2 mL/kg body weight of contrast medium followed by a plain film x-ray of the kidneys, ureters, and bladder (KUB) 10 minutes later. IVP should only be employed in normotensive patients, as the timing of imaging in hypotensive patients is difficult when the kidneys are poorly perfused.

Angiography

Angiography and subsequent super-selective embolization therapy for renal trauma have evolved and have a place in the treatment armamentarium of renal trauma patients. Super-selective coil embolization provides an effective and minimally invasive means to stop bleeding. Given that the majority of the renal injuries can be managed conservatively, care should be taken to avoid needless embolizations. The kidney is an end arterial organ that lacks significant collateral arterial blood supply, and as such, embolization will cause nephron death in addition to causing bleeding cessation.

Injury Scale for the Kidney

The American Association for the Surgery of Trauma renal organ injury scale is shown in Table 1. Grading is important clinically to help guide management and for outcomes research. The renal injury classification is one of the few classifications schemes that have been prospectively validated and found to correlate directly with the need for surgical intervention. Grades I and II injuries are minor, Grade III injuries are intermediate, and Grades IV and V injuries are severe. Grade I injuries include subcapsular nonexpanding hematomas without parenchymal laceration. Grade II injuries include lacerations in the parenchyma less than 1 cm. Grade III is a laceration greater than 1 cm that does not extend into the collecting system. Grade IV includes parenchymal lacerations extending into the collecting system and main vascular injuries with contained hemorrhage. Grade V includes shattered or avulsed kidneys.

Management

Nonoperative Management

The vast majority of renal injuries can be managed nonoperatively. Improvements in the reliability of staging imaging have resulted in increased nonoperative management. In addition, as surgeons have increasingly managed other solid organ injuries such as spleen and liver nonoperatively, there has been a rise in the nonoperative management of kidney injuries.

After appropriate staging, patients are typically managed with bed rest, hemodynamic monitoring, and serial hematocrits. Some evidence suggests that bed rest can be avoided unless hematuria increases or resumes after ambulation. Transfusions should be given as needed, but when more than 6 units are needed or hemodynamic instability develops, repeat imaging and possible embolization or surgical exploration may be needed.

Conservatively managed kidneys with collecting system injuries should be reimaged 3 to 5 days later to evaluate persistent urine leak or urinoma formation. Patients with large leaks are typically managed with indwelling stents, while large or infected urinomas are drained percutaneously. For patients with a urine leak, Foley catheter drainage is used to decompress the urinary system, and antibiotic therapy is used to prevent infected urinomas.

Indications for Embolization

Angiography and embolization are recommended for (1) patients with persistent bleeding from a segmental renal artery, (2) unstable patients with a Grade III or IV renal injury, (3) treating a pseudoaneurysm or arteriovenous malformation, (4) cases of persistent gross hematuria, and (5) a rapidly declining hematocrit requiring 2 units of blood.

Indications for Renal Exploration

Absolute indications for renal exploration include expanding, pulsatile, uncontained retroperitoneal hematomas; renal pedicle avulsion; persistent, life-threatening hemorrhage or shock; and ureteropelvic junction disruption.

Relative indications for renal exploration include urinary extravasation with nonviable tissue; concurrent colon/pancreas/trauma exploration with incomplete staging or Grade III or greater concurrent renal injury; renovascular hypertension; and failed embolization.

TABLE 1: American Association for the Surgery of Trauma: injury scale for the kidney

Grade*	Type	Description
I	Contusion	Microscopic or gross hematuria, urologic studies normal
	Hematoma	Subcapsular, nonexpanding, and without parenchymal laceration
II	Hematoma	Nonexpanding perirenal hematoma confirmed to renal retroperitoneum
	Laceration	<1 cm parenchymal depth of renal cortex without urinary extravasation
III	Laceration	<1 cm parenchymal depth of renal cortex without collecting-system rupture or urinary extravasation
IV	Laceration	Parenchymal laceration extending through renal cortex, medulla, and collecting system
	Vascular	Main renal artery or vein injury with contained hemorrhage
V	Laceration	Completely shattered kidney
	Vascular	Avulsion of renal hilum, which devascularizes kidney

*Advance one grade for bilateral injuries up to Grade III.

Surgical Management

Retroperitoneal Exploration

Controversy exists regarding whether to obtain proximal vascular control for every operative renal injury. Some advocate a lateral approach by medializing the overlying colon and approaching the vasculature after dissecting the kidney from Gerota's fascia, dissecting lateral to medial with respect to the great vessels. Manual compression or a Satinsky clamp can be used to stop bleeding, and the kidney can then be repaired. Proponents of this method argue that it takes less time, and, particularly for lateral parenchymal injuries, isolating each vessel for possible clamping is overkill.

We contend that early vascular control can decrease the nephrectomy rate. Unplanned nephrectomy in a trauma setting results from uncontrolled hemorrhage. If approached in a systematic fashion, vascular control can be done quickly and efficiently.

The approach to the injured kidney is made through a standard trauma laparotomy midline incision from the pubic symphysis to the xiphoid process. The incision should be extended to the xiphoid if not already done so to gain exposure to the renal hilum. A fixed retractor such as the Bookwalter may be employed, but more typically the surgical assistants will perform manual retraction.

The transverse colon is wrapped in a moist laparotomy sponge and placed on the chest. The small intestine can be placed in a bowel bag or protected with moist lap sponges and retracted superiorly and placed on the chest to the right. This maneuver exposes the root of the mesentery, the ligament of Treitz, and the underlying great vessels. The retroperitoneum is incised over the aorta superior to the inferior mesenteric artery, and the incision is extended to the ligament of Treitz. Occasionally, a retroperitoneal hematoma can prevent distinct palpation of the aorta. An incision can be made medial to the inferior mesenteric vein because it runs a few centimeters to the

left of the aorta and is easily identifiable. March along the anterior surface of the aorta until the left renal vein is encountered at its crossing. Rarely (less than 5% of the time), the left renal vein will be retro-aortic. A vessel loop should be placed around the left renal vein, and this vessel can be used as a guide to help find the remaining renal vasculature, each of which is then encircled with a vessel loop but not clamped. The vast majority of bleeding can be controlled during repair with manual compression of the kidney; rarely will vessel occlusion be necessary (Figure 3).

After vascular control has been achieved, the injured kidney is exposed by mobilizing the ipsilateral colon along the white line of Toldt and reflecting it medially. Gerota's fascia is then incised along its lateral aspect. A lateral incision is important because it avoids accidentally dissecting the kidney subcapsularly, avoids ureter injury, and preserves perinephric fat for reconstruction. Preserving the renal capsule is important because this fascia is a strength layer needed during reconstruction and tearing it can result in more bleeding.

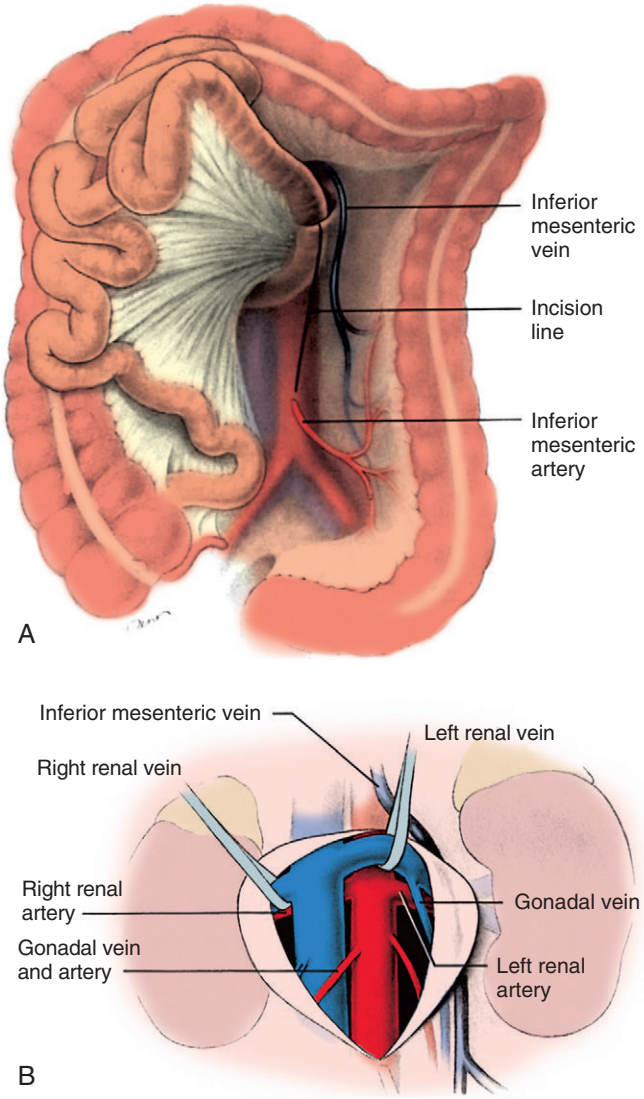

FIGURE 3 Technique to obtain vascular control. **A,** Exposure of the major vessels. **B,** Relationship of renal vasculature after incision of the posterior peritoneum over the aorta. *(From McAninch JW: Surgery for renal trauma. In Novick AC, Streem SB, Pontes JE, editors:* Stewart's operative urology, *Baltimore, 1989, Williams & Wilkins.)*

Renovascular Injuries

In contrast to parenchymal injuries, renovascular injuries are frequently irreparable and often result in nephrectomy. In cases where vascular injury is suspected, proximal vascular control is critical. Main renal vein injuries can result in significant hemorrhage and may require ligation. A partially lacerated vein may be repaired after it is controlled, clamped, and sutured with a 5-0 Prolene. Segmental and duplicated veins can be ligated given the extensive renal venous collateral circulation.

Arterial thrombosis or dissection in the setting of a normal contralateral kidney and no concurrent hemorrhage can be managed conservatively. A subset of these cases of nonperfusion of the kidney results from the spasm secondary to stretch injury. Follow-up imaging may demonstrate reperfusion of the kidney without intervention. In cases where these injuries are explored, efforts to perform a thrombectomy and débridement of the damaged arterial segment are often unsuccessful. Endovascular stents have been used to treat arterial thrombosis. Issues related to postoperative anticoagulation have limited their use. The ultimate outcome of attempted renal artery reconstruction is time dependent. Segmental arteries can be ligated safely. Partially lacerated segmental arteries can be repaired with 5-0 Prolene.

Renal Reconstruction

In a hemodynamically stable patient who is not coagulopathic, renal reconstruction should be employed. Heroic measures should be used in patients with solitary kidneys. The typical renal injury reconstruction is analogous in many ways to the repair performed during a partial nephrectomy for cancer. First, excellent exposure of the kidney should be provided. Bleeding should be limited either by manual compression or, in severe cases, vascular occlusion. Perform sharp excision of all nonviable parenchyma. Obtain meticulous hemostasis of individual bleeding vessels with stitches, cautery, or an argon beam. The collecting system should be closed in a watertight fashion. An antegrade ureteral stent can be placed for significant collecting system reconstructions. Parenchymal defects will be reconstructed by approximating capsular edges over a hemostatic dissolvable bolster such as Surgicel or thrombin-soaked Gelfoam. Omental interposition can be used to separate the injured kidney from concurrently injured abdominal organs (Figures 4 and 5).

Damage Control

In situations where the patient is unstable and the kidney is shattered or major vascular injury with hemorrhages is present, an expeditious nephrectomy can be lifesaving. Occasionally, it will be necessary after exsanguinating hemorrhage is controlled to pack the retroperitoneum, resuscitate the patient, and complete the repair later.

Complications

Complications after renal trauma are rare. They usually occur within the first month after trauma.

Early Complications

Urinoma formation and prolonged urinary extravasation are the most common complications and result from collecting system injury. When urinomas become infected, an abscess may form. Large urinomas or abscesses require percutaneous drainage. Prolonged urinary extravasation can typically be managed with a ureteral stent.

Late Complications

Late complications include delayed bleeding, abscess formation, urinary fistula, hypertension, and hydronephrosis. Delayed bleeding

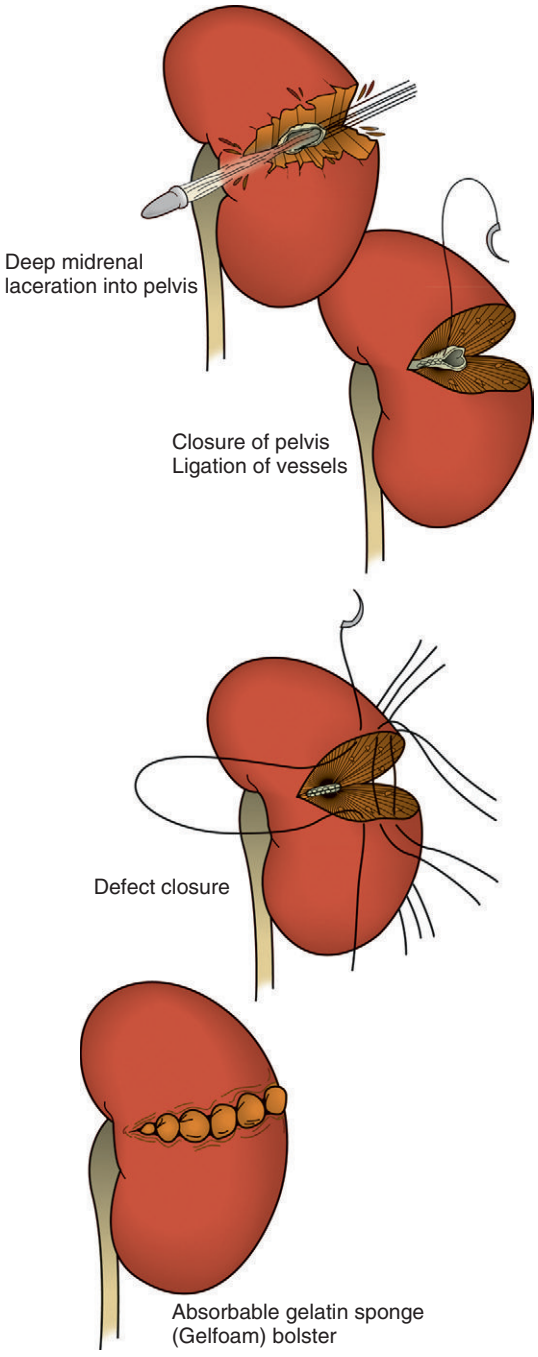

FIGURE 4 Example of renal repair after penetrating trauma. *(From Armenakas NA, McAninch JW: Genitourinary tract. In Ivatury RR, Cayten CG, editors:* The textbook of penetrating trauma, *Media, Penn, 1996, Williams & Wilkins.)*

is typically caused by a pseudoaneurysm or arteriovenous fistula, either from the initial injury or the repair, and presents 2 to 4 weeks after surgery. This can be effectively treated with coil embolization. Abscess formation is treated by percutaneous drainage and systemic antibiotics.

A delayed urinary fistula should be evaluated to determine its location. Concurrent ureteral stricture or injury may be discovered. An indwelling stent and/or percutaneous drainage of the kidney should be used with a delayed definitive repair 3 to 6 months later. Hypertension is a rare, long-term complication that results from either parenchyma compression (Page kidney) or arterial stenosis (Goldblatt kidney) and chronic upregulation of the renin/angiotensin axis. Hypertension is usually controlled medically, although severe renal compression secondary to a hematoma detected in the postoperative period may benefit from immediate surgical decompression. Hydronephrosis may develop after perinephric fibrosis that involves injuries to the ureteropelvic junction or lower pole of the kidney. Interposition of the omentum or perinephric fat between the injured kidney and the ureter is recommended to prevent such a complication.

URETER

Overview

Most ureteral injuries are iatrogenic, with the most common cause being from abdominal hysterectomy. Ureteral injuries constitute less than 1% of genitourinary trauma. The ureter is protected by the vertebral column and major muscle groups. Typically, ureteral injury caused by external trauma results in severe concurrent injuries with a high mortality, including bowel perforations and renal and bladder injuries.

Initial Evaluation

External Trauma

Penetrating injuries to the ureter are infrequent, and blunt injuries are even more rare. As such, the appropriate diagnosis and treatment of ureteral injuries require a high index of suspicion and an in-depth knowledge of ureteral anatomy and its relation to adjacent structures. High-velocity projectiles can cause direct transection and also blast injury, compromise of intramural blood supply, and subsequent delayed necrosis. Damage can extend up to 2 cm from the site of transection, which often results in underestimation of tissue destruction. Débridement should be taken to the bleeding edge of the ureter. Blunt trauma such as a significant fall from a great height or a high-speed motor vehicle collision that results in extreme force applied over the body can result in ureteral injury. Fracture of the lumbar processes and thoracolumbar spinal dislocation can cause ureteral injury. This can result from hyperextension of the back, particularly in children, who are more flexible and more limber. In addition, rapid deceleration causes ureteral injury at fixed locations such as the ureteropelvic junction or the uretero vesical junction.

Iatrogenic

The most common iatrogenic injuries occur during urologic (ureteroscopy, radical prostatectomy), gynecologic (transabdominal hysterectomy, salpingo-oophorectomy, cystocele repair), colorectal, and vascular surgeries. Risk factors include uncontrolled hemorrhage and reoperative surgery.

Diagnosis of Ureteral Injury

A high index of suspicion is required for successful management of ureteral injuries. Intraoperative direct inspection is the most effective means of injury detection, although retroperitoneal hemorrhage can make detection more difficult. When a blast injury is suspected and no clear tissue destruction is identified, a small incision can be made in the ureter to verify adequate perfusion. Simple peristalsis of the suspect segment is not sufficient. With a small butterfly needle, methylene blue or indigo carmine dye can be injected into the collecting system or ureter to look for injury. If a concurrent bladder rupture repair is being performed, an exchange catheter or feeding tube can

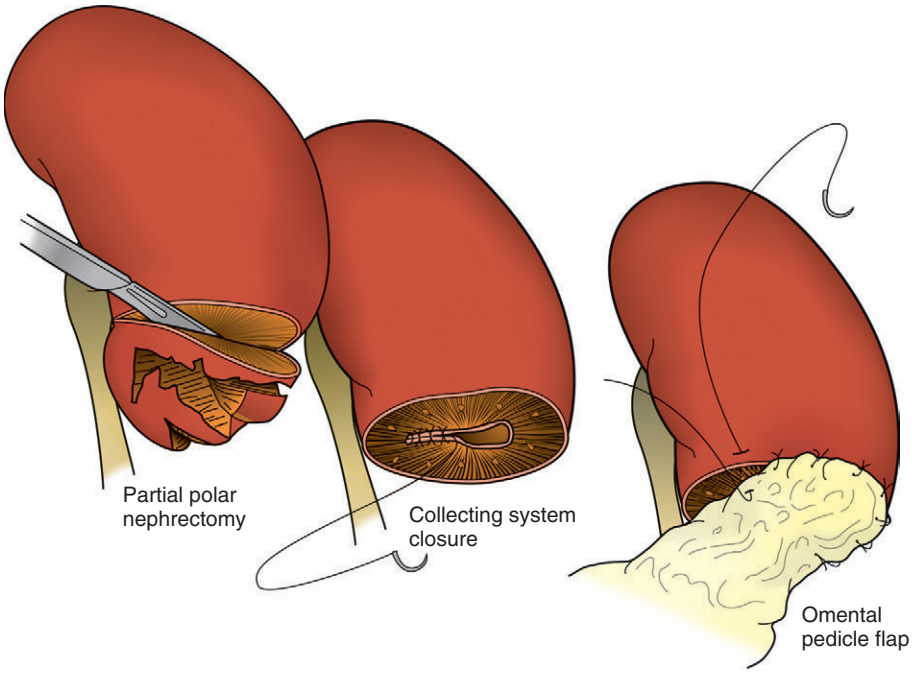

FIGURE 5 Lower pole injury requiring partial nephrectomy with omental patch. *(From Armenakas NA, McAninch JW: Genitourinary tract. In Ivatury RR, Cayten CG, editors:* The textbook of penetrating trauma, *Media, Penn, 1996, Williams & Wilkins.)*

be inserted into the ureter and dye injected in a retrograde fashion. Frank extravasation of dye or tissue staining at the injured level will aid identification.

Missed ureteral injuries may present days later with serious complications. While yellow drainage with an elevated creatinine from an abdominal drain post injury can be a telltale sign, often the signs are less clear. Prolonged ileus, a palpable abdominal or renal mass, urinary obstruction, abscess, sepsis, and flank and abdominal pain can all result from a missed ureteral injury. Depending on the time elapsed from injury to diagnosis, a nephrostomy tube should be placed to drain the kidney, as well as a drain in any fluid collection that has accumulated.

Imaging

Intravenous Urography

CT scan has replaced intravenous urography as the imaging modality of choice for appropriate staging of ureteral injuries. Occasionally in the unstaged patient in an acute trauma setting, an intravenous urogram can provide data suggestive of a ureteral injury such as incomplete visualization of the ureter, ureteral dilation, or urinary extravasation. Given the sensitivity, specificity, and variability of intravenous urography, these findings do not obviate the need for direct inspection.

Computed Tomography

High-resolution CT scan with delayed views provides excellent anatomic detail of the traumatized ureter. Medial extravasation of contrast from the hilum is the most common finding of renal ureteropelvic junction injury. In the setting of complete avulsion, the ipsilateral ureter will not fill, while a partial tear will likely show distal ureteral filling. The presence of a hematoma on axial imaging may indicate the site of ureteral injury.

Retrograde Pyelography

Given the need for time-consuming fluoroscopy, retrograde pyelography is not performed in the acute trauma setting. For delayed injuries, retrograde pyelography can help define injury location and extent.

Injury Scale for the Ureter

Table 2 shows the American Association for the Surgery of Trauma injury scale for the ureter. Injury severity is defined by degree of transection and length of devitalized tissue.

Management

When deciding how to manage a ureteral injury in the acute setting, one must take into account the location and length of the injury and the patient's stability. In the damage control setting, a temporary cutaneous ureterostomy over a single-J ureteral stent can be performed. Alternatively, the ureter can be tied off proximal to the injury and a percutaneous nephrostomy tube can be placed. Definitive repair can be made at a later time.

Bruising or contusion of the ureteral wall should prompt treatment because it could lead to necrosis and subsequent fistula or stricture formation. Minimal contusion can be treated with a ureteral stent, while severe contusion should be débrided and reanastomosed, and a drain inserted (Figure 6).

All ureteral injuries where débridement and reanastomosis are required follow the same reconstructive principles:

1. Ureteral dissection that preserves the supporting adventitia and does not skin the ureter, which can lead to vascular compromise and stricture, is required.
2. Appropriate ureteral débridement to a bleeding edge must be performed. High-velocity projectiles can result in blast injury and ischemia, which can produce occult injury up to 2 cm away from the transection.
3. The repair should be a tension-free, watertight, spatulated, mucosa-to-mucosa anastomosis.
4. A ureteral stent should be employed.
5. Wrapping the ureter with omentum or local tissue flaps helps support the ureter and isolate it from adjacent organs.
6. To prevent urinoma, a drain adjacent to the repair, but not overlaying it, should be left.

TABLE 2: American Association for the Surgery of Trauma: injury scale for the ureter

Grade*	Type	Description
I	Hematoma	Contusion or hematoma without devascularization
II	Laceration	Transection <50%
III	Laceration	Transection <50%
IV	Laceration	Complete transection with <2 cm of devascularization
V	Laceration	Avulsion with >2 cm of devascularization

Note: Injury severity is defined by degree of transection and length of devitalized tissue.

Lower Ureteral Injuries

Ureteral injuries near the bladder are the most straightforward to treat. Many can be repaired by simple débridement and creating a refluxing ureteral reimplantation into an adjacent area on the bladder, either the posterior wall or the dome. A stent should be left for 3 to 6 weeks. Tunneled nonrefluxing repairs in adults are not needed and are associated with stenosis.

Psoas Hitch and Boari Flap

When the injury is more proximal than adjacent to the bladder, the bladder can be mobilized and brought to the ureter. The psoas hitch procedure is performed by suturing the bladder to the ipsilateral psoas minor tendon. Sutures should be placed in the tendon/muscle parallel to the course of its fibers to avoid entrapment of the genitofemoral nerve, which can lead to chronic pain. The contralateral supravesical pedicle should be ligated to help mobilize the bladder. A ureteral stent and Foley catheter are left in place. Typically, a cystogram is obtained prior to removing the Foley (Figure 7). The vast majority of lower ureteral injuries can be treated this way. Rarely, for longer injuries, a Boari flap is required. Here, a flap of bladder tissue is tubularized to make up the distance. The bladder is also pexed to the psoas to relieve tension.

Midureteral Injuries

Most midureteral transections can be repaired by primary ureteroureterostomy. The repair should be tension-free, watertight, and spatulated over a double-J stent. In situations where the ureter loss is more significant, a transureteroureterostomy may be performed. This is rarely utilized during the trauma setting given its complexity.

Traditionally, a transureteroureterostomy should be avoided in patients with a history of nephrolithiasis, urothelial cancer, genitourinary tuberculosis, or retroperitoneal fibrosis. More commonly, when a large segment of ureter is not salvageable, a damage control approach should be employed by temporarily diverting the urine over a ureteral stent to the abdominal wall. Definitive reconstruction of the damaged segment can be undertaken in the future. Large-segment ureteral loss can be treated by autotransplant, ileal interposition, or some type of conduit or neobladder procedure at a later time.

Upper Ureteral Injuries

Ureteropelvic junction injuries typically occur after blunt or penetrating trauma. Complete disruptions/avulsions require acute surgical management. A primary anastomotic repair can be performed. Similar to other locations, a stent and a retroperitoneal drain should be utilized.

Complications

Over 50% of ureteral injuries are missed on initial presentation and discovered later. Patients may develop hydronephrosis, urinoma formation, fistula, abscess, and systemic infection. Unnoticed chronic obstruction can lead to kidney damage. Complication management depends on time elapsed after injury, but typically large fluid collections should be drained percutaneously and the ureteral obstruction bypassed.

Delayed Treatment

Injuries diagnosed 1 to 2 weeks after the insult should be explored and repaired. During this time, suture ligatures around the ureter can be excised and the ureter can be stented. In situations where the abdomen is hostile or the injury detected after 2 weeks, a temporizing nephrostomy tube should be placed and the reconstruction delayed for a few months.

Damage Control Operation

Caitlin W. Hicks, MD, MS, and Adil Haider, MD, MPH, FACS

BASIC PRINCIPLES

Damage control operation (DCO) refers to the strategy of limiting the initial operation to lifesaving aspects of surgery, and delaying definitive surgical management in critically ill or injured patients, until they are physiologically capable of tolerating a prolonged procedure. The primary operation consists of an abbreviated procedure that focuses on obtaining surgical control of hemorrhage, restoring blood flow to critical vessels, and eliminating intracompartmental contamination as efficiently as possible. This is followed by temporary wound closure until the patient can be stabilized enough to undergo a definitive procedure.

The concept of DCO has a military origin. The expression "damage control" was first coined by the U.S. Navy in World War II, in reference to procedures employed to maintain function of a damaged warship. On the battlefield, DCO was developed as a means to minimize hemorrhagic morbidity with the fewest resources in the least amount of time possible. It was adopted for civilian trauma in the early 1990s with a shift in focus to minimize operative time in the setting of physiologic derangement. As opposed to the traditional surgical approach of complete surgical repair immediately following injury, DCO uses a staged operative approach in an attempt to improve patient outcomes by normalizing physiology as soon as possible, optimizing perioperative physiology, and restoring homeostasis prior to definitive surgical repair. Although originally developed for major abdominal trauma, DCO has since been extended for use in thoracic, vascular, and orthopedic procedures as well.

DCO can be divided into three phases: (1) initial operation, (2) resuscitation, and (3) definitive surgical management. In the first phase, hemodynamically unstable patients are taken to the operating room (OR) for an initial, rapid lifesaving or limb-saving operation. The majority of operative repairs employ temporary stabilizing techniques; however, any major bleeding vessels must be controlled and perfusion to critical structures needs to be established. In phase 2, the patient is resuscitated in the intensive care unit (ICU) and physiologic parameters are restored. Once stabilized, the patient is then taken back to the OR for definitive procedures—reconstruction and closure of the abdomen or other cavity being operated on (phase 3). If, on return to the OR, the patient is not ready for completion of phase 3, then the patient can be returned to the ICU with a temporary closure and phase 2 and 3 are repeated.

PHYSIOLOGY AND INDICATIONS

Severely injured and critically ill patients are at risk of developing a "lethal triad" of hypothermia, acidosis, and coagulopathy. In the setting of trauma, hypothermia may be caused by hemorrhage,

evaporative and conductive heat loss, peripheral vasoconstriction, and massive transfusion of cold fluids and blood products. Acidosis occurs secondary to hypoperfusion due to hemorrhage and impaired myocardial function, as well as massive transfusion, vasopressors, and impaired oxygen use. In turn, these lead to coagulopathy, which is further worsened as a result of hemodilution and consumption of clotting factors in the setting of acute hemorrhage and inflammation. Hypoperfusion may also result in the activation of protein C and systemic hyperfibrinolysis. Each of the three factors in the cycle exacerbates the others, leading to a self-perpetuating downward spiral that becomes lethal (usually in the form of a fatal arrhythmia) if not identified and treated early in the process.

The driving concept of DCO is to break the cycle of the lethal triad early in its course, and it has been shown to improve morbidity and mortality following severe trauma. Some parameters have been developed to help identify those patients most at risk of deterioration during an acute or emergent procedure (Table 1). It must be kept in mind that the results of many of these measurements may take too long to come back in the setting of hemodynamic instability, and thus the decision to proceed with DCO is ultimately a clinical one.

PHASE 1: INITIAL OPERATION ON THE ABDOMEN OR OTHER BODY CAVITIES

Damage Control Laparotomy

The primary components of a phase 1 DCO for major abdominal injury include rapid laparotomy, hemorrhagic control, containment of gastrointestinal spillage, and temporary abdominal closure. Rather than grossly packing the abdominal cavity to prevent hemorrhage, blood and clots should be evacuated for aid in rapid exploration, the identification and containment of specific injuries, and targeted packing.

Liver

In general, liver hemorrhage should be managed with packing to pressure tamponade the injury. Packing should be placed concentrically around, but never inside, the site of the wound to reapproximate tissue edges using pressure control.

Large retrohepatic injuries should be assessed visually for active bleeding and left unexplored, if under control, to prevent the possible unroofing of a contained inferior vena cava or hepatic vein injury. Packing placed anterior to the liver should provide sufficient compression to temporarily control further retrohepatic hemorrhage, but one must be careful about impeding venous return to the heart as a result of excessive inferior vena cava compression. A couple of rolled-up towels placed on the underside of the liver can be used to prevent this occurrence, but the towels should be applied with caution to prevent dislodgement of the retrohepatic hematoma.

Penetrating liver wounds may be controlled best with an intrahepatic balloon tamponade. In the case of more shallow lacerations, including translobular injuries, a red rubber catheter can be inserted into a 1-inch Penrose drain, placed in the injury, and inflated with saline until bleeding is controlled. For deeper penetrating hepatic injuries, such as gunshot injuries, a Foley catheter with 30-mL balloon can be employed in similar fashion. Multiple inflations and repositioning may be necessary with this technique before bleeding is under sufficient control to allow for hematoma formation (Figure 1).

Simple hepatorrhaphy using 0-0 chromic catgut for deep horizontal mattress sutures and packing may also be effective for shallow penetrating liver wounds and superficial hepatic lacerations. Sutures should be placed away from the edges of the injury to prevent tearing and worsening the hemorrhage. Where indicated, finger fracture and identification of bleeding hepatic arterial vessels can be performed and vessels suture ligated. Patients should be observed for signs of hepatic necrosis, intrahepatic abscess, and hemobilia with this technique, all of which can usually be managed through secondary operations or minimally invasive techniques.

Biliary Tract

Simple bile duct injuries can be definitively repaired by primary closure during the initial operation. More complex repairs, including lacerations greater than 50% the circumference of the duct, will eventually need definitive repair with choledochojejunostomy or hepaticojejunostomy. During the initial DCO, these complex injuries should be managed temporarily by ductal ligation with T-tube or cholecystostomy placement.

Solid Organs

Injuries to solid organs such as the spleen or a single kidney should be managed with removal. Repair procedures to stem blood loss and preserve function are not indicated in DCO, as patients may not be able to tolerate the attempt at primary repair or a secondary insult in the ICU if the repair unravels.

A rapid nephrectomy can be performed by entering Gerota's fascia and manually compressing the kidney while controlling the

TABLE 1: Indications for damage control operation

Vital signs	Laboratory indications	Clinical indications
Core temperature ≤ 35°C	Arterial pH ≤ 7.2	Estimated blood loss ≥ 4 L
Systolic blood pressure persistently ≤ 80 mm Hg	Base deficit > 14 mmol/L	Blood transfusion ≥ 10 units
*Revised trauma score ≤ 5	INR > 50% of normal PTT > 50% of normal	Fluid replacement ≥ 10 L Life-threatening traumatic injury in two or more anatomic locations Vascular injuries in inaccessible locations Inability to close abdomen due to visceral edema Persistent nonsurgical bleeding

INR, International normalized ratio; *mm Hg,* millimeters of mercury; *mmol/L,* millimole per liter; *PTT,* partial thromboplastin time.

hilar vessels and the ureter. Prior to nephrectomy, the contralateral kidney should be assessed for size, location, and assessment of injury. In cases where ureteral damage is possible, an indigo carmine dye test can be used to ensure proper outflow of the undamaged kidney. If deemed normal, renal function tests are not necessary prior to removal of the damaged kidney. Ureteral injuries without kidney damage can be managed with ureterostomy, where a tube is inserted into the damaged ureter and exteriorized through the skin. If both kidneys are injured, then the lesser damaged organ should be assessed for salvage. Before removing the kidney and committing the patient to dialysis and a future kidney transplant, risks of repair must be balanced against the potential for further bleeding and hemodynamic instability.

Splenectomy should be performed for major injuries to the spleen, splenic artery, and distal pancreas. The splenic hilum can be clamped to control bleeding, and the spleen removed quickly to allow for visualization and exploration of the operative field. It should be noted that perioperative immunization and antibiotic prophylaxis are essential in the asplenic patient, especially in cases of polytrauma when the risk of infection is high. In our practice, we administer these when the patient is being discharged from the hospital or at 2 weeks after definitive repair.

Pancreas

During a DCO, pancreatic injuries should be managed with drainage and packing regardless of the location or extent of injury. Ductal exploration should be postponed until a definitive repair can be made. A distal pancreatectomy with splenectomy for severe hemorrhagic distal pancreatic injuries may be considered by an experienced surgeon, but proximal pancreatic injuries necessitating pancreaticoduodenectomy are rarely indicated during the initial operation. Once the patient has been resuscitated, reconstruction procedures are much easier.

Hollow Viscera

Aside from controlling hemorrhage, an effective DCO also limits gastrointestinal spillage. On initial identification, atraumatic clamps (e.g., Babcock clamps) can be used to control hollow visceral perforations. Following exploration for further injuries, small bowel hollow viscera perforations can be controlled through primary repair with sutures or staplers. Larger duodenal perforations (>50% circumference) can be controlled by closing the injury around a large-bore drainage tube or with a serosal patch, duodenojejunostomy, or pyloric exclusion procedure if the patient is relatively stable. Larger jejunal, ileal, and colonic injuries should be treated with resection using a gastrointestinal anastomosis (GIA) stapler. Bowel reanastomosis and stoma formation should be delayed until definitive repair. In the rare case where anastomosis is deemed most appropriate, hand sewing with two running sutures placed in opposing directions has similar outcomes to staplers. A generous amount of warm irrigation fluid should be used to wash out the abdomen in all four quadrants prior to temporary closure.

Abdominal Closure

In damage control laparotomies, the abdomen is left open following the initial operation to facilitate reoperation and obviate the risk of abdominal compartment syndrome. Although temporary abdominal closure techniques vary, the most effective are those that employ negative-pressure therapy (NPT). NPT allows for the removal of reperfusion-related ascites, including associated bacteria, toxins, and/or inflammatory cytokines. It also allows for easy access during reoperation and is associated with a high rate of definitive closure with minimal morbidity.

The three-layer vacuum-packed technique is the general NPT standard for temporary closure of the abdomen. If a commercially available device is unavailable, a fenestrated drape is placed in the

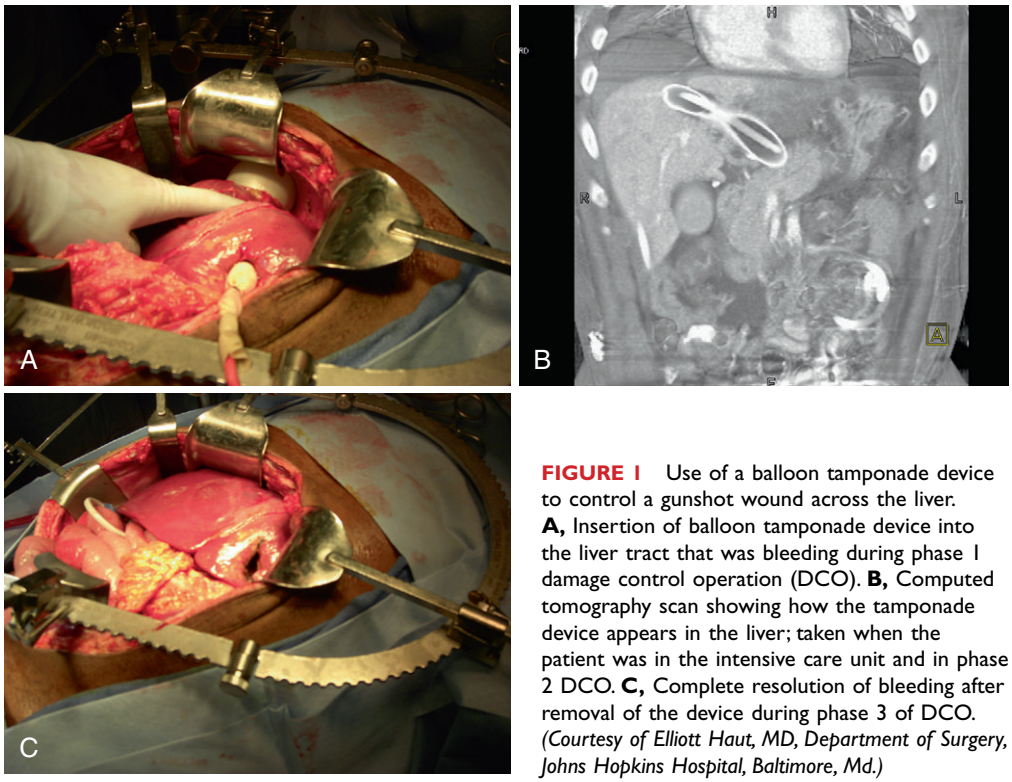

FIGURE 1 Use of a balloon tamponade device to control a gunshot wound across the liver. **A,** Insertion of balloon tamponade device into the liver tract that was bleeding during phase 1 damage control operation (DCO). **B,** Computed tomography scan showing how the tamponade device appears in the liver; taken when the patient was in the intensive care unit and in phase 2 DCO. **C,** Complete resolution of bleeding after removal of the device during phase 3 of DCO. *(Courtesy of Elliott Haut, MD, Department of Surgery, Johns Hopkins Hospital, Baltimore, Md.)*

subfascial space and covered with moist towels or gauze. Two large drains are placed along the fascial edges, and an antimicrobial iodophor-impregnated surgical incise drape is laid on top. The drains are placed to a closed suction canister at 100 to 150 mm Hg to remove and quantify developing ascites. The vacuum-assisted closure system (V.A.C. Abdominal Dressing System, KCI Inc, San Antonio, Tex) and other commercial NPT systems have similar setups that use a polyurethane foam dressing and tubing connected to a computerized suction pump to generate negative pressure.

Abdominal closure using skin approximation with towel clips or running suture should be avoided because of the high risk of abdominal compartment syndrome. Other methods of closure, such as Bogota bags, silo closure, and synthetic mesh, are not recommended because they do not allow for monitoring and removal of reperfusion-related ascites and, in the case of nonabsorbable mesh, are associated with a high risk of enteric fistula.

Damage Control Thoracotomy

DCO for chest injuries should focus on controlling hemorrhage and identifying and containing any air leaks. Patients should be placed in the supine position, as lateral positioning may waste time and provides only limited access. If necessary, a clamshell extension of an anterior thoracotomy may be performed to gain access to all structures. Patients should be intubated using a simple single-lumen endotracheal tube, and the chest is commonly entered through a left anterolateral incision, unless it is clear that the major hemorrhage is emanating from the right thorax. Whatever side is entered first, a chest tube should also be placed in the contralateral hemithorax to assess hemorrhage. If necessary, the incision can be extended to the other side to allow adequate exposure. If the patient is able to tolerate a bronchial blocker, one may be used as needed to exclude a single lung.

Heart

Assessment of cardiac injury should be achieved by anteriorly opening the pericardium parallel to the phrenic nerve. Superficial injuries to the heart may be repaired with skin staples or a running suture with 3-0 nonabsorbable polypropylene. Larger penetrating injuries can be controlled by a Foley catheter tamponade or direct, simple, finger occlusion to allow for visualization and simple suture repair with 2-0 nonabsorbable suture on a large needle (such as a V26) with pledgets. If finger compression is used, the suture bites need to be wide enough to come around the width of the surgeon's finger. During this procedure, one must be cognizant of the location of cardiac vessels, as incorporating these in the repair may cause irreparable cardiac ischemia. In cases of severe cardiac hemorrhage, injury visualization and repair may be possible only by stopping the heart from actively beating. Temporary cardiac arrest can be achieved through compression of the superior and inferior venae cavae. This approach should be used with caution and only for short periods of time. The heart can be restarted, following repair, through manual compression or electric shock.

Hemodynamically unstable patients with difficult venous access and an open thorax can be infused fluids through an intraatrial Foley catheter. The catheter should be secured with a purse-string suture and can be used for fluid resuscitation until alternate venous access is achieved.

Lungs

Acute pulmonary hemorrhage can be controlled to allow for exploration by clamping the lung parenchyma or hilum with a Satinsky clamp, or by twisting the lung 180 degrees in a "hilar twist" to occlude blood flow.

Pulmonary injuries involving the apices or costophrenic angles can often be managed with packing. When packing fails, or for blunt pulmonary injuries in other locations, a nonanatomic wedge resection using a GIA or thoracoabdominal stapler is the procedure of choice. In the case of continued uncontrollable parenchymal bleeding, a complete lobectomy can be performed by firing a stapler twice along the hilar structures en masse.

Penetrating pulmonary injuries should be approached with pulmonary tractotomy. The lung parenchyma is divided with a GIA stapler or a transaction/anastomosis stapler applied through the injury, which allows for visualization and access of injured bronchi or vessels. Bronchial and small vessel injuries should be controlled and repaired with individual ligation using 3-0 nonabsorbable or slow-absorbing suture. The access tract should be left open until definitive repair can be completed to allow for reexploration and ease of further pulmonary resection.

Tracheobronchial and Esophageal Injuries

All tracheal and most bronchial injuries should be initially treated with débridement and primary repair if the patient is stable enough. An endotracheal tube may be used to stent across an injured trachea until a formal repair is possible. Larger bronchial injuries may require a quick, stapled lobectomy to ensure air leak control.

Esophageal injuries should be diverted with wide drainage during the initial operation. Early antibiotic therapy is essential to minimize infectious morbidity.

Thoracic Wall Injury and Closure

Thoracic wall injuries should be treated with packing to control hemorrhage, although it is often difficult to achieve effective compression against the bony structure of the ribs. Obvious vessel injuries can be repaired with simple ligation followed by packing to improve control.

Similar to a DCO laparotomy, the thorax should be left open following phase 1 of a DCO thoracotomy. Although it is unclear whether the benefits of this practice prevent thoracic compartment syndrome, an open thorax allows for expedited reoperation and access during definitive surgical management. Temporary closure can be accomplished by placing a blue towel above the ribs, followed by an occlusive plastic dressing over the wound to seal it closed. Alternatively, the wound can be closed using a simple mass closure of the skin and muscle. In both cases, the chest must be drained with thoracostomy tubes to prevent development of a pneumothorax and to remove hemorrhage or monitor further acute hemorrhage. NPT and vacuum closure devices are not indicated.

Damage Control Vascular Surgery

The primary goal of DCO is to control hemorrhage without causing end-organ ischemia. Vasculature injuries should be managed with simple repairs whenever possible, including lateral repair, ligation, and temporary shunts. Destructive injury to the celiac artery can be managed with ligation. In extreme circumstances, the portal vein can be ligated as well. Injuries to the superior mesenteric artery, external iliac arteries, and infrainguinal arteries should be managed with a temporary intravascular shunt to maintain blood flow. With the exception of the suprarenal inferior vena cava, and popliteal veins, which also require shunt repair to maintain blood flow, most venous injuries can be ligated to achieve hemorrhagic control. Severe aortic injuries should be repaired with a polytetrafluoroethylene graft. Heparinization is probably unnecessary in patients with shunts and grafts because of the temporary nature of the implant and the patients' presumed coagulopathic state.

Fasciotomy with delayed closure is advised in patients with severe traumatic vascular injuries to prevent compartment syndrome.

When ligated, the infrarenal inferior vena cava and iliac veins are particularly prone to temporary edema and may require fasciotomy with eventual in situ reconstruction or extraanatomic bypass. Fasciotomy closure should be delayed even beyond the definitive repair of vascular injuries to prevent the formation of late compartment syndrome and limb ischemia.

Damage Control Orthopedics

Although open fractures are traditionally treated in urgent fashion, orthopedic injuries associated with severe head wounds or pulmonary contusions are often cited as an indication to perform a DCO rather than definitive repair. DCO can be used to prevent exsanguination from vascular injuries in the chest, abdomen, pelvis, or long bones, and to explore and control potential multicavity injuries. Hemodynamically unstable patients with severe orthopedic injuries should be treated with splinting or traction early to control hemorrhage and reduce the risk of fat embolism before transfer to the OR. Patients who are more stable may be candidates for angioembolization, either before or after the initial DCO procedure.

Long Bones

Long bone fractures can be treated temporarily with external fixation and traction in patients with severe associated traumatic injuries. During the DCO, open fractures should be carefully inspected for the presence of foreign material and fully débrided to remove all particulate matter and dead tissue. Wound washout and débridement within 6 hours of injury are recommended to prevent infection and potential osteomyelitis, which can have devastating long-term consequences. Open reduction and internal fixation should be delayed until the patient is stable enough to withstand the physiologic stress of a definitive procedure. The use of external fixators allows optimization of definitive repair with minimal long-term functional consequences.

With all severe extremity injuries, one must be particularly vigilant about monitoring the patient for compartment syndrome. A lack of pulses, change in color, and/or change in temperature necessitates immediate fasciotomy to prevent limb ischemia and death.

Pelvis

Patients with unstable pelvic fractures, particularly those presenting after high energy injuries, are at extremely high risk of mortality. Along with the use of a pelvic binder, angiography is an excellent mode to stem hemorrhage associated with open book or other severe pelvic fractures. The main stems of both internal iliac arteries can be embolized using gelatin sponge particle injections. Compared with selective coil embolization, this method is much faster, promotes clotting, and allows for some continued blood to ensure distal organ perfusion. Alternatively, pelvic hemorrhage can be controlled with extraperitoneal packing through a lower midline or Pfannenstiel incision. Intraperitoneal packing is less effective because the vasculature compression is difficult against the bony prominences of the pelvis.

Following packing, a damage control laparotomy is commonly indicated to assess associated intraabdominal injuries. The laparotomy incision should be made discontinuously from the pelvic incision to keep the retroperitoneal space separate from the intraperitoneal cavity. It is important that the pelvic binder be left in place at all times, as extraperitoneal packing is only effective in the setting of external stabilization. Once major hemorrhage has been controlled in all body parts, an external fixator can be placed on the pelvis during DCO, as this will help with restoring physiologic normalcy in phase 2 of damage control.

PHASE 2: RESUSCITATION

Following the first stage of a DCO, the patient is brought to the ICU for resuscitative management and prevention or correction of the lethal triad of acidosis, coagulopathy, and hypothermia (Figure 2). Low body temperature should be managed with active rewarming (including use of warm ambient temperatures, warm blankets, infusion of warm fluids, and forced warm-air devices) to a core temperature of 37°C. Coagulopathy should be treated with fresh frozen plasma, platelets, cryoprecipitate, vitamin K, and calcium to achieve the following values: international normalized ratio (INR) <1.2, prothrombin time (PT) <15 seconds, fibrinogen >100 mg/dL, and platelets >100,000/mm^3. Acidosis is managed best through reversal of hypothermia and coagulopathy and continued fluid resuscitation.

Damage control resuscitation (DCR) as described by the military should be continued throughout this phase as well as during the initial DCO. The principles of DCR include (1) use of permissive hypotension until hemorrhage control has been achieved (this should be achieved prior to entering the phase 2 resuscitative phase), (2) judicious use of crystalloid resuscitation, and (3) early and increased transfusion of plasma and platelets. The rationale behind DCR is that aggressive preoperative crystalloid resuscitation may be detrimental to the severely injured patient by causing a dilutional coagulopathy, dislodging unstable clots to worsen hemorrhage, exacerbating hypothermia (in the case of unwarmed fluids), worsening acidosis as a result of the high chloride content, and increasing the intraabdominal pressure. Patients requiring massive blood transfusions are particularly appropriate candidates for this approach and should be transfused with a ratio of fresh frozen plasma to platelets to packed red blood cells of 1:1:1. DCR is credited with significant improvements in mortality rates and is thought to be one of the most important lessons learned in the resuscitation of causalities of the recent Iraq and Afghanistan conflicts. Adjunct studies can also be employed in phase 2 of DCO. Computed tomographic scans may be useful for planning definitive procedures, and radiographic studies should be obtained to evaluate for missed indolent orthopedic injuries. Hemodynamically stable patients with continued postoperative bleeding may be appropriate for angiographic intervention (e.g., those with a liver laceration that may benefit from unilateral hepatic arterial embolization), either as a temporary reprieve to delay returning to the OR or as definitive vascular management. Most patients will continue to have some amount of bleeding following the initial DCO procedure, so a balance between when to intervene and when to maintain the patient's hemodynamic status through the transfusion of blood products must be achieved. If a patient truly has developed a disseminated intravascular coagulopathy, he or she will not benefit from a return to the OR and will require resuscitation and correction of coagulopathy. On the other hand, if postoperative bleeding is severe, patients may need a second abbreviated laparotomy to gain surgical control of the hemorrhage and allow for continued resuscitation before definitive operative management is attempted.

PHASE 3: DEFINITIVE SURGICAL MANAGEMENT

Definitive management of DCO patients' injuries should wait until their physiologic parameters return to normal, meaning that hypothermia is corrected, acidosis is reversed, and coagulopathy is resolved. In many patients, definitive surgical management may require multiple reoperations. The staging and timing of these return trips to the OR should be planned according to patient stability and clinical condition, the extent of surgical repair required, and surgeon experience.

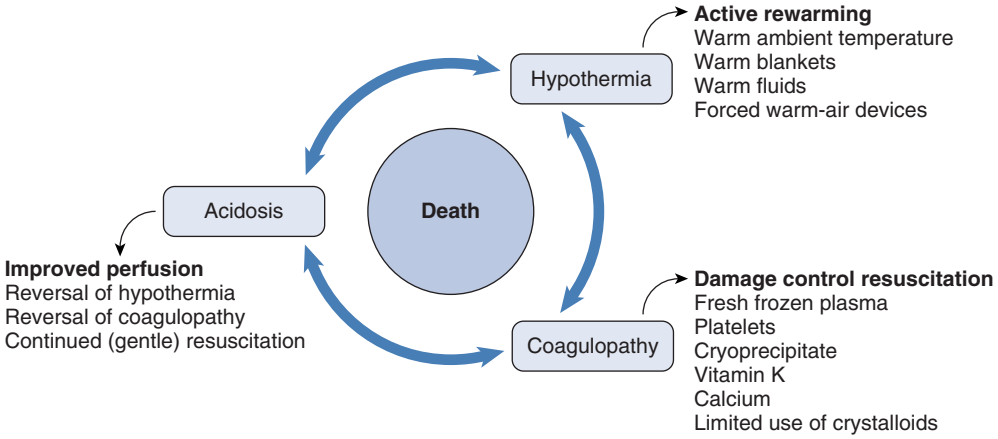

FIGURE 2 The lethal triad. Severely injured and critically ill patients are at risk of developing a "lethal triad" of hypothermia, acidosis, and coagulopathy, which is associated with a high rate of mortality. Phase 2 of a damage control operation is aimed at halting the progression of the triad, and should be approached using the strategies outlined in section on Phase 2.

In most cases, reoperation and definitive surgical care can be attempted within 24 to 48 hours of the initial operation. Definitive management following thoracic DCO procedures should be as early as possible (ideally less than 12 hours) because of the high risk of decreasing pulmonary compliance that can lead to difficulties with patient ventilation. In contrast, there is some evidence to suggest that definitive orthopedic repairs should occur within 24 hours or up to 5 days following injury to prevent pulmonary complications.

During phase 3, all packing should be removed, and the patient should be thoroughly reexplored for any injuries that may have been missed during the initial operation. Once exploration is complete, definitive surgical repair can proceed as necessary depending on the patient's specific injuries (e.g., bowel reanastomosis with diversion for hollow viscous injuries, definitive thoracic closure for thoracic injuries, reconstruction or extraanatomic bypass with insertion of permanent graft for vascular injuries, etc). Following completion of definitive repair, if the patient is stable and not at risk for abdominal compartment syndrome, the abdomen can be closed. However, if there is any potential for its development, or if definitive repairs cannot be completed, then the abdomen should be left open (using one of the mechanisms described previously) and the patient should be returned to phase 2 of DCO.

EVIDENCE FOR EFFECTIVENESS OF DCO

DCO in patients with major abdominal trauma has been shown to reduce rates of morbidity and mortality compared with immediate definitive surgery in a number of descriptive and retrospective series. By reducing operative time and allowing for focused perioperative resuscitation in physiologically unstable patients, the potential insults of a complex definitive repair are thought to be decreased. However, there is limited prospective evidence from randomized clinical trials on the subject and minimal data of any kind versus immediate definitive surgery in the setting of severe nonabdominal injuries. In addition, a DCO approach tends to be more costly than immediate surgical repair, and multiple return trips to the OR may increase the risk of some surgical morbidities, including intraabdominal abscess, bile leak, enteric fistula, and wound infection (Table 2). As a result, there is some controversy among experts regarding its appropriate use in trauma, and concerns regarding its overuse are now arising.

Currently, the general consensus is that DCO should be employed when a longer procedure may cause risk of clinical deterioration, particularly in the setting of multiple and/or complex organ injuries.

TABLE 2: Estimated incidence of morbidity and mortality following abdominal damage control operation versus traditional single-stage procedure

Measured outcome		Damage control operation	Single-stage procedure
Prevalence of procedure in trauma*		30%	70%
Mortality†		44%	63%
Morbidity‡	Sepsis	42%	3%
	Intraabdominal abscess	18%	4%
	Enteric fistula	18%	2%
	Recurrent hemorrhage	6%	0%
	Wound infection	6%	2%

‡Nicholas JM, Rix EP, Easley KA, et al: Changing patterns in the management of penetrating abdominal trauma: the more things change, the more they stay the same. *J Trauma* 55(6):1095-1108; discussion 1108-1110, 2003.

Recent estimates demonstrate that DCO is used in as many as 30% of trauma patients undergoing emergent laparotomy, which may suggest an overuse of the technique. There is some evidence that, particularly in older patients, certain characteristics such as chronic congestive heart failure or acute renal insufficiency may be correlated with an increased risk of death following DCO. Thus, individual patient history, both chronic and acute, must be considered when making the decision to proceed with DCO. Future studies will help differentiate those patients most likely to benefit from a staged operative approach and help delineate specific indications for abdominal, thoracic, vascular, and orthopedic injuries.

Urologic Complications of Pelvic Fracture

Hunter Wessells, MD, FACS

It is the urologist who will have to share with the patient, the burden of any residual disability when thoracic, abdominal, and even the orthopedic aspects are long forgotten.

– Richard Turner Warwick

Pelvic injuries cause a significant disease burden in the United States, representing 7.5% of all traumatic injuries. It is estimated that more than 110,000 pelvic injuries occur every year with direct costs exceeding $1.1 billion. Patients with pelvic trauma are severely injured, the majority having injury severity scores exceeding 16. There is significant mortality due to associated head injury, but the genitourinary and gastrointestinal complications can be morbid and life threatening as well.

Pelvic trauma has a male preponderance, with approximately two thirds of injuries occurring in men and one third in women. Conventional wisdom states that 5% of patients with a pelvic fracture will have an associated bladder injury and that a subset of these will have urethral injury. More recent data suggest that the proportion of patients with a urethral injury will be higher, with 3% of males with pelvic fracture demonstrating a urethral disruption, and many will not have bladder injury. Urethral and bladder neck injuries occurred in 6.8% of female pelvic fractures. Notably, these figures represent rates of injury at large trauma centers and may not be representative of the experience in community hospitals or centers without trauma designation.

BLADDER INJURY

Identification of pelvic fracture–associated bladder injury requires a detailed history, physical examination, urinalysis, and appropriate imaging. Ninety-five percent of patients with a bladder rupture will have gross hematuria, and the remaining few with microhematuria can be detected, with appropriate algorithms, during the initial trauma evaluation. There is no clinical prediction rule to identify patients requiring cystography after pelvic fracture other than the degree of hematuria. Recent studies suggest that patients with microscopic hematuria are unlikely to suffer bladder injury. Thus, criteria for imaging the bladder include any blunt trauma with gross hematuria; blunt trauma with a pelvic fracture and greater than 30 red blood cells per high-power field; and penetrating trauma with any degree of hematuria and an injury to the pelvis. Fracture patterns associated with bladder and urethral injuries are similar, namely, diastasis of the pubis and obturator ring fractures. The greater the displacement of these fractures is, the more likely a genitourinary injury will happen.

Imaging is important because failure to recognize a bladder injury can lead to significant complications, including urinary ascites, infection of pelvic hematoma, chronic bladder dysfunction, and sepsis. A spiral computed tomographic (CT) scan with 5-mm cuts obtained after complete filling of the bladder will delineate all intra- and extraperitoneal bladder injuries. The degree of bladder filling is important and, in responsive patients, should be as much as they can tolerate. In unresponsive patients, the contrast is hung at 40 cm of water and a volume of 350 mL infused. With a CT cystogram, there is no need for scout or postevacuation imaging because the cross-sectional nature of the imaging identifies both anterior and posterior leaks. Conversely, with plain film cystography, scout and postevacuation films are required. Because of these differences, CT cystogram is more expedient and is now the standard in most trauma centers.

The classic intraperitoneal bladder rupture, whether identified by CT or plain film cystography, will outline loops of bowel consistent with intraperitoneal location. Extraperitoneal bladder ruptures lead to extravasation of contrast in the retroperitoneum, including the space of Retzius, the lateral colic region, and into the groin and thigh. Typically, the direct defect in the bladder wall can be visualized with a CT cystogram (Figure 1). Combined intra- and extraperitoneal bladder ruptures can be missed when a large injury in one location makes it difficult to distend the bladder.

The sensitivity and specificity of computed tomography and cystography has been determined for blunt trauma and is 95% and 100%, respectively, based on operative findings as a gold standard. Intraperitoneal rupture has a lesser degree of sensitivity, possibly because of the aforementioned confounding that is due to multiple sites of rupture. Importantly, no such data exist for penetrating injuries, and although these may be delineated with a CT scan, caution must be exercised when considering a nonoperative approach. In cases of penetrating injury, additional imaging to delineate vascular and gastrointestinal injuries should be coordinated.

Management of bladder injuries can be nonoperative with catheter drainage as long as the rupture is extraperitoneal and does not involve open pelvic fractures, urinary infection, bony fragments, or foreign body in the bladder. Use of an appropriate-sized catheter is essential to avoid obstruction by clots and poor bladder drainage. Absolute indications for bladder repair include a bladder neck injury (Figure 2), concomitant rectal injury, major vaginal laceration, and the previously mentioned caveats.

Operative management of bladder rupture requires differing exposure depending on whether the lesion is felt to be intra- or extraperitoneal. With extraperitoneal bladder rupture, a lower midline or transverse Pfannenstiel-type incision provides access to the bladder and allows primary closure of injuries. For intraperitoneal bladder ruptures, which tend to be stellate in nature, and large,

FIGURE 1 Computed tomographic cystogram showing extraperitoneal bladder rupture with two defects in the anterior bladder wall.

FIGURE 2 Computed tomographic cystogram showing extravasation at level of catheter balloon consistent with a bladder neck injury.

a midline incision slightly higher on the abdominal wall gives good access to the dome of the bladder.

In performing bladder exploration, it is important to identify associated injuries to the genitourinary tract. Although ureteral injury is very uncommon in pelvic fractures, when the bladder is open, as long as visualization is adequate, assessment of the ureteral orifices is mandatory. This can be performed by observing a jet of clear urine out of each orifice, intubation of the orifice with a feeding tube or other small 5F catheter, or by the administration of intravenous indigo carmine and observation of blue dye excreted in the urine. The bladder neck should also be assessed, by visual inspection, palpation, or endoscopic evaluation.

Bladder lacerations should be repaired in a standard two-layer closure with running slowly absorbable suture such as 2-0 polyglycolic acid. The first layer incorporates the mucosa and the muscularis. The second layer incorporates the muscularis and overlying serosa. In the region of the bladder neck, where access to the urinary tract behind the pubic bone may be difficult, a single layer of well-placed interrupted absorbable sutures is sufficient to allow appropriate healing. In patients with multiple bladder lacerations, smaller lacerations can be fixed from within the bladder with a single layer of slowly absorbable suture. A closed suction drain is placed adjacent to the bladder to prevent collections. Urinary drainage after bladder repair may be carried out either with suprapubic cystostomy or, in most cases, with urethral catheter drainage alone. There is no evidence that

FIGURE 3 Computed tomographic cystogram showing bony spicule in bladder lumen in a patient with unrecognized bladder injury treated nonoperatively.

suprapubic cystostomy leads to improved outcomes compared with urethral catheterization alone.

Follow-up imaging is required after nonoperative management by catheter drainage is selected, and after operative repair. Cystography should be carried out 10 to 14 days after injury in order to assess the healing process for nonoperative management (Figure 3) or to confirm appropriate healing after operative repair. Once bladder integrity has been confirmed, the catheter can then be removed based on the patient's other injury status and mobility. If extravasation persists, repeat cystography is recommended at appropriate intervals until healing occurs. Overall, only a very small subset of patients with bladder injury will require reoperation or delayed closure.

URETHRAL INJURY

Pelvic fracture urethral injury is a rare but significant injury and is associated with potential genitourinary morbidity, including urethral stricture, urinary incontinence, sexual dysfunction, and chronic pain. The signs and symptoms of these injuries are nonspecific and include blood at the urethral meatus, difficulty or inability to void, a palpable bladder, butterfly perineal hematoma, high-riding prostate on digital prostate examination, fracture of the pubic symphysis, pelvic hematoma, or associated bladder injury.

These injuries are suspected in cases of pubic diastasis or fracture of the inferior pubic ramus. Such "straddle fractures" lead to significantly greater odds of injury. Urethral injuries are classified according to American Association for the Surgery of Trauma (AAST) grades I through V. Grades I and II injuries (contusions and stretch injuries, respectively) need only urethral catheter drainage until the patient recovers from other injuries. Grade III injuries (partial disruptions) are best managed with realignment, whereas grades IV and V (complete disruptions with or without extensive separation or involvement of the prostate or vagina) may be treated with early endoscopic realignment or suprapubic cystostomy. There is debate as to the benefit of early endoscopic realignment, and suprapubic cystostomy remains the most commonly elected treatment nationwide.

Male urethral injuries after pelvic fracture are best delineated with retrograde urethrogram (Figure 4). However, when patients have blood at the urethral meatus and immediate catheter drainage is required, a single attempt at urethral catheterization may be

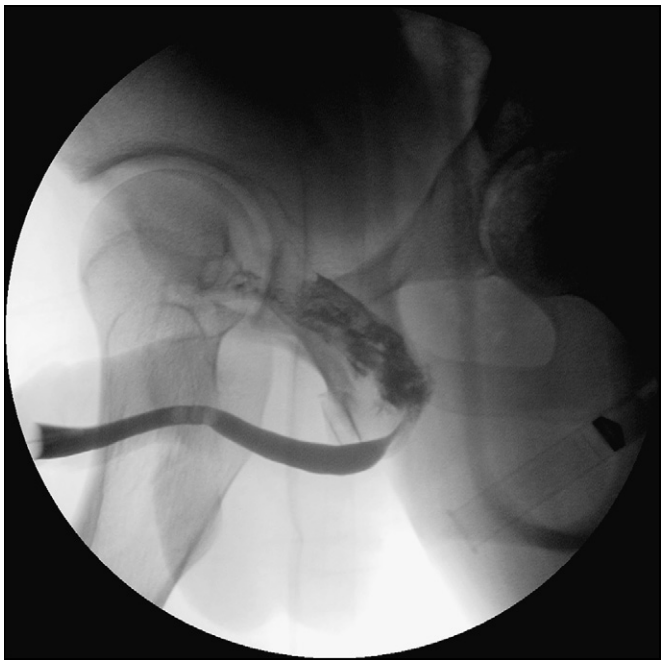

FIGURE 4 Retrograde urethrogram showing complete urethral disruption with extravasation of contrast and no filling of the proximal urethra or bladder (grade IV injury).

considered. There is no strong evidence to suggest that this maneuver will convert a partial urethral injury to a complete injury. Nevertheless, in stable patients without immediate need for catheter drainage, retrograde urethrogram is still the primary diagnostic modality. Cystoscopy can provide additional information and may be performed in the emergency department, but overall it is not favored as a primary diagnostic modality. Female urethral and bladder neck injuries are more difficult to identify and diagnose when compared with male injuries. These injuries may only be identified with intraoperative physical examination or incidentally in the intraoperative setting (40% of injuries). Thus, with all such patients, a thorough history and physical examination, laboratory studies, and imaging as indicated remain important. The decision whether to perform suprapubic cystostomy or urethral realignment depends on the patient's stability and associated injury status. When patients are unstable, suprapubic cystostomy urinary diversion is appropriate as the initial step in the emergency department. Indications for realignment include a stable patient with complete or partial urethral disruption. Other rare but considerable factors include a concomitant bladder rupture, rectal and vaginal laceration, bladder neck injury, severe bladder displacement ("pie in the sky"), and open reduction and internal fixation with the placement of orthopedic hardware.

Stricture rates will be higher after suprapubic cystostomy compared with primary urethral realignment; realignment allows healing without strictures in 40% to 50% of patients versus less than 5% with suprapubic diversion. The standard approach for realignment uses flexible endoscopes inserted per urethra and per suprapubic tract. This can be performed when the patient is stable. Typically, this requires two urologists skilled in flexible endoscopy, fluoroscopy, and, in many cases, coordination with orthopedic procedures. As long as suprapubic cystostomy can temporize urinary drainage, realignment can be performed in an elective or semi-elective fashion when appropriate resources can be brought to bear, up to a week after injury.

After urethral realignment, pericatheter retrograde urethrogram is recommended at 6 weeks after injury to assess for persisting leak. If leaks persist, repeat imaging is required until healing. Aggressive treatment of the complications of these injuries requires close vigilance to detect urethral strictures and urinary incontinence.

CONCLUSIONS

Immediate identification of acute genitourinary injuries and appropriate urinary drainage is essential to prevent early septic complications and to ensure subsequent normal organ function. Coordination with the trauma team allows appropriate operative repair or nonoperative management based on the injury severity and presence of associated injuries. Close follow-up is required to identify fistulae, strictures, urinary incontinence, and sexual dysfunction resulting from injury to the bladder, urethra, and pelvic vascular structures. Even in the absence of overt genitourinary organ injury, soft tissue and vascular damage may lead to delayed complications, including urinary and sexual dysfunction, and cause significant impairment of quality of life.

Facial Trauma: Evaluation and Management

John J. Chi, MD, and Daniel S. Alam, MD, FACS

OVERVIEW

Facial trauma evaluation and management remains an unfortunate necessity in our contemporary society. Although most patients who present with facial trauma can be safely assessed and stabilized by the trauma surgery and emergency department teams, complex injuries often result in consultation with a facial plastic surgeon, plastic surgeon, otolaryngologist, or oral maxillofacial surgeon for definitive management. The complex interplay between the aesthetics and the function of the maxillofacial region requires a consideration for anatomy and mechanics that is generally not necessary in traumatic injuries outside of the head and neck. This chapter provides a general overview of the critical aspects of the evaluation and management of facial trauma.

EMERGENT TREATMENT AND EVALUATION

Emergent Treatment of Facial Trauma

The evaluation of any patient who presents with a traumatic injury begins with the Advanced Trauma Life Support (ATLS) protocol. An assessment of the ABCs (airway, breathing, and circulation) must be made judiciously before evaluation of the facial injuries. Airway evaluation is of particular importance because of the myriad head and neck injuries that can cause airway compromise (i.e., larynx trauma, mandible fractures, neck hematoma, etc.). Acute airway management may require direct laryngoscopy with intubation, fiberoptic intubation, or a surgical airway (cricothyrotomy or emergent tracheotomy). Because of the vascular nature of the head and neck region, traumatic injuries may present with hemorrhage that needs to be urgently addressed. The acute management of hemorrhage in the head and neck is vital as a result of the potential for airway compromise, from extraluminal compression (neck hematoma, bilateral mandible fracture), intraluminal obstruction (epistaxis, oral cavity/oropharyngeal bleeding), or airway luminal separation (laryngotracheal injury). Hemorrhage from most branches of the external carotid artery can be addressed with pressure, surgical ligation, or embolization. For example, severe epistaxis can be managed with nasal packing, endoscopic blood vessel ligation, or angiography with embolization. Hemorrhage from the internal carotid, subclavian, or vertebral arteries, however, usually requires endovascular management because of the difficulty with open surgical control of the proximal and distal ends of these vessels (Burgess, 2012; Kesser, 2009). The management of penetrating neck trauma is dictated by patient presentation, symptomatology, and the location of the injury within the neck. A diagram of the zones of the neck is shown in Figure 1. Zone 1 and 3 injuries are initially managed with angiography (computed tomographic [CT] or conventional). Definitive treatment with endovascular management or neck exploration is contingent on patient presentation and imaging studies. These injuries are usually treated with an endovascular approach because of the difficulty with surgical access to the blood vessels in these regions. Zone 2 injuries are initially treated with neck exploration or angiography based on patient presentation. Although historically these injuries were all treated with neck exploration, recent studies suggest that neck exploration may be reserved for selected cases (Tisherman, 2008; Burgess, 2012; Kesser, 2009). In general, neck exploration is recommended for patients with unstable or symptomatic conditions. Contrast gastrointestinal studies and aerodigestive endoscopy should also be performed on a selective basis depending on the level of concern for airway or gastrointestinal injury. On completion of the primary survey, attention can then be placed on specific body systems and injuries during the secondary survey.

Evaluation of Facial Trauma

After immediate life-threatening conditions are ruled out or stabilized, attention can be focused on a comprehensive assessment of facial injuries. The physical examination of the head and neck is a critical aspect of the evaluation of patients with facial trauma. This examination should begin by carefully cleaning the head and neck of debris and blood to allow a thorough visual inspection. These patients are often intubated and present for evaluation with a cervical collar placed by first responders in the field. Without confirmation of cervical spine stability, the trauma patient must be maintained in inline stabilization. Radiographic evaluation should be a precursor to removal of the immobilizer.

The examination of the face should proceed in thirds: upper face, mid face, and lower face. Evaluate each third of the face for neurovascular integrity, bony factures, and lacerations. A systematic assessment of sensation and voluntary facial movement should be performed in each third of the face. Unique structures in each region require special assessment. For example, in the upper face, integrity of the frontal bone overlying the frontal sinuses should be assessed. The midface assessment should include a thorough assessment of the eyes, including pupillary light reflex, extraocular movements, globe position, and visual acuity. An evaluation of the bony structures should include palpation of the inferior and lateral orbital rim, bony nasal dorsum, zygomatic arch, palate, and maxillary dentition. An intranasal examination should also be performed to rule out a septal hematoma. The lower face assessment should include palpation of the mandible and mandibular dentition as well as assessment of the floor of mouth, tongue, and oral airway. Special attention should also be given to the patient's occlusion, bite abnormalities (open bite, cross bite, early contact) and dental wear facets.

Once the facial examination is complete, the examination of the scalp, ears, and neck completes the head and neck examination. The hair-bearing scalp should be carefully assessed for lacerations and foreign bodies. The ears are assessed for lacerations, auricular hematoma, otorrhea, and hemotympanum. The neck is assessed for crepitus, lacerations, foreign bodies, and hematomas. Special attention should be given to the palpation of the larynx to assess for occult injuries and fractures.

Several imaging modalities are useful in the evaluation of facial trauma. The selection of the imaging modality depends on the primary survey, the mechanism of injury (blunt versus blast versus penetrating), and the suspected injuries. CT scan is the primary radiographic study used for the evaluation of facial fractures. Intravenous contrast is usually not necessary for this evaluation. Three-dimensional reconstruction of axial and coronal CT scan images can also be obtained and may provide the additional advantage of helping in the planning of any surgical repair. In the absence of three-dimensional reconstruction, a panoramic tomographic view, or panorex, of the mandible may allow improved characterization of fractures, specifically, ramus and subcondylar fractures. An example is show in Figure 2. If embedded foreign bodies are suspected, then

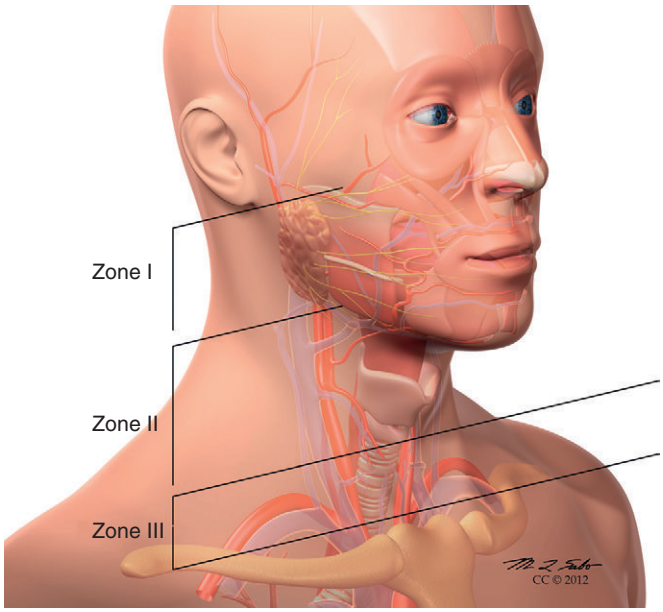

FIGURE 1 The zones of the neck. Zone 1 extends from the clavicle to cricoid cartilage. Zone 2 extends from the cricoid cartilage to the angle of the mandible. Zone 3 extends from the angle of the mandible to the skull base. *(Reprinted with permission from Cleveland Clinic Center for Medical Art & Photography, 2012. All rights reserved.)*

FIGURE 2 Panorex of a nondisplaced left mandibular ramus fracture.

imaging should be tailored to the investigation. CT scans and plain film x-rays can be used for the detection of glass and metal. Magnetic resonance imaging (MRI) can be used for the detection of wood and organic foreign bodies. If a vascular injury is suspected, as is the case with penetrating injuries to zone 1 and zone 3 of the neck, then CT angiography or conventional angiography is recommended.

SOFT TISSUE INJURIES AND MANAGEMENT

Lacerations and Avulsions

The initial assessment of soft tissue injuries of the head and neck begins with cleaning of the area of interest. Blood, clot, and debris should be cleared to allow for a thorough inspection of all lacerations. The wounds should be irrigated liberally with copious amounts of sterile saline solution with gentle pressure to remove debris. Failure to remove debris, especially dark foreign matter, can lead to traumatic dermal tattooing. When possible, documentation of the size, depth, and extent (skin/mucosa, subcutaneous tissue, muscle, bone, nerve) of any wound is appropriate. Clean wounds should be closed primarily either in the trauma bay or, if necessary, in the operating room. Débridement of frayed, tattered, and nonviable skin and tissues may be necessary for effective wound closure. Deeper injuries and injuries communicating with a mucosal surface may require a multilayered closure or a passive drain. Large soft tissue defects that are not amenable to early primary closure should be dressed with saline solution–soaked gauze or a wound vacuum-assisted closure (VAC) dressing to promote wound closure with secondary intent healing. Avulsed soft tissue may be returned to its native site. If the tissue is viable, then it provides the best functional and aesthetic outcome. If the avulsed tissue is not viable, then it at least serves as a temporary biologic dressing. After closure, the wounds should be maintained with a thin moisture layer, such as petroleum jelly or water-based ointment, applied twice daily for 1 to 2 weeks. Sutures should be removed within approximately 5 to 7 days. Aesthetically unacceptable scars can be revised in 6 to 9 months.

The Facial Nerve and Parotid Duct

The assessment of facial nerve function is critical. The decision to explore, decompress, or repair the facial nerve is based on the level of function, the mechanism of trauma, and the temporal onset of the paralysis in relation to the injury. A quick assessment of facial nerve function should document normal movement, incomplete paralysis (paresis), or complete paralysis in the tasks of eyebrow raising, eye closure, smile and snarl, and lower lip depression. Attention should be paid to any asymmetry and its location. An anatomic diagram of the facial nerve branches is shown in Figure 3. However, even in the awake patient, assessment may be difficult and limited to the observation of facial expressions in response to the pain of the injuries, as in the obtunded patient. In addition, time should be allowed for the clearance of any local or general anesthetic before a facial nerve examination.

The mechanism of trauma (blunt versus blast versus penetrating) is an important factor in determination of clinical intervention in facial nerve paralysis. Most penetrating injuries in the distribution of the facial nerve with incomplete facial paralysis can be managed conservatively with observation. The presence of some function implies some neuronal and axonal integrity. In contrast, lateral penetrating injuries with complete facial paralysis are generally explored for possible repair of the facial nerve. The location of the facial injury influences the decision to explore. Exploration is necessary for penetrating trauma lateral to the lateral canthus of the eye. If the injury is medial to the lateral canthus, the facial nerve has been shown to have significant arborization, which allows for greater recovery potential, particularly in the midface region. These medial injuries may be observed. Blunt and blast injuries with associated facial paralysis should also involve an investigation of the temporal bones as a possible etiology of the facial paralysis.

Facial lacerations with facial nerve paralysis that warrant exploration should be explored within 72 hours of injury. During this clinical window, the distal nerve can be identified with probing with electrical stimulation. Once this period has temporally passed, wallerian degeneration prevents this clinical evaluation, and the identification of the nerve endings, which are often less than a millimeter in diameter, becomes much more difficult.

If a transection is identified, the proximal and distal ends of the nerves should be minimally mobilized to allow for a tension-free epineural repair. This should ideally be performed with magnification to avoid inadvertent axonal injury and align the epineurium optimally. Nerve interposition grafts should be placed wherever there is a missing segment of facial nerve. In addition, care must be taken to maintain separate and distinct branches of the facial nerve when facial nerve repair is performed to avoid synkinesis.

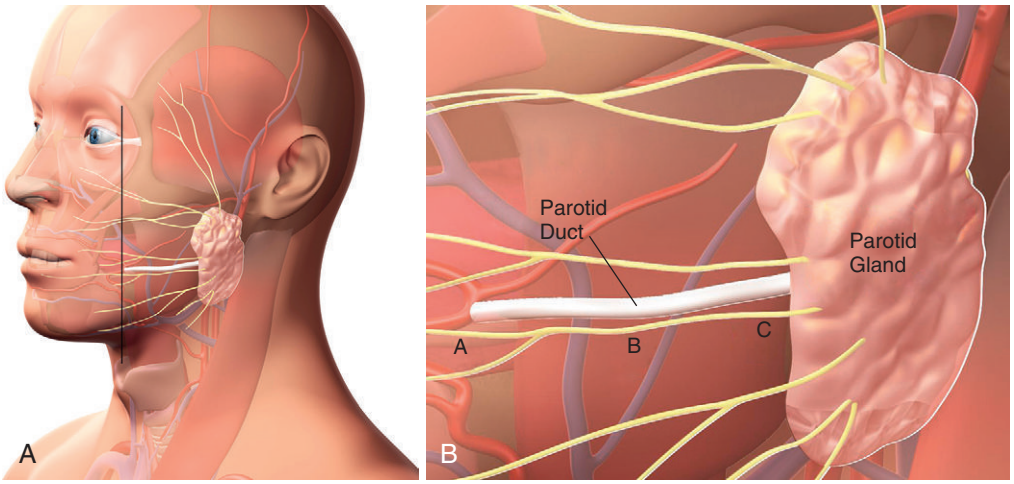

FIGURE 3 **A,** Facial nerve branches with vertical line demarcating lateral canthus and region for nerve exploration. **B,** Inset of parotid gland and duct: *point A,* distal near papilla; *point B,* midparotid duct; *point C,* proximal near parotid gland. *(Reprinted with permission from Cleveland Clinic Center for Medical Art & Photography, 2012. All rights reserved.)*

Facial lacerations in the vicinity of the parotid duct (Stenson's duct) or blood at the orifice of the parotid duct warrant evaluation with cannulation with a lacrimal probe to identify injuries to the duct. A diagram of the parotid gland and duct is shown in Figure 3, *B*. Injuries to the parotid duct should be repaired primarily whenever possible and ideally in the operating room. The cannulation of the duct can aid in performing this repair. A silicone elastomer stent is cannulated into the orifice of the parotid duct intraorally and passed proximally across the transected segment of the parotid duct and then into the proximal parotid duct segment. The transected parotid duct is then closed over the silicone elastomer stent. The stent may be left in place for several weeks to divert saliva and prevent stenosis of the parotid duct during its healing. Injuries to the more distal aspect of the duct with a reasonable length of viable parotid duct present should be reimplanted either into the papilla (Figure 3, *point A)* or into the buccal mucosa at a more posterior location in the oral cavity (Figure 3, *point B)*. Injuries to the very proximal aspect of the parotid duct near the parotid gland without hope for primary repair are usually best treated with parotid duct ligation (Figure 3, *point C)*. A drain should be placed in the wound bed to evacuate residual blood and saliva and prevent sialocele formation.

Bites: Human and Canine

Approximately 44,000 facial dog bite injuries occur annually according to the Centers for Disease Control (Karlson, 1984). Traditionally, the approach to management of a dog bite injury was washout, débridement, and then delayed closure or healing with secondary intention (Callahan, 1980). However, some studies suggest that primary repair of a facial injury carries no greater risk of infection and allows the best chance for a superior functional and aesthetic outcome (Javaid, 1998). Consideration should be given to a primary closure, if the wound has not suffered a significant loss of soft tissue. In addition, antibiotics should be administered for coverage against the flora present in a dog's mouth, *Staphylococcus aureus, Streptococci, Pasteurella multocida*, and anaerobes. Finally, the rabies status of the animal should be determined early in the evaluation to allow for appropriate treatment.

Human bite injuries are the third most common bite injury of the face, after dogs and cats. The basic tenets of initial wound care are similar to those described previously for dog bite injuries. Additional consideration should be given to the increased pathogenicity and potential for transmission of infection with human bites. Hepatitis B and C, herpes simplex virus, syphilis, tuberculosis, tetanus, and human immunodeficiency virus (HIV) are transmissible through human bite injuries (Harrison, 2009). In addition, antibiotic coverage for human bites should include coverage for *Eikenella corrodens* and *Corynebacterium* species, both known causes of delayed abscesses after human bites. In contrast to human bites outside of the head and neck, bites to the face that are not grossly infected at the time of presentation should be closed primarily to achieve the best functional and aesthetic outcome. Human bites to the face are less likely to result in infection because of the vascularity of the facial region. Consideration for a delayed repair should be made with infected wounds and ear injuries with exposed cartilage (Ambro, 2010).

Most facial soft tissue injuries from canine or human bites can be addressed primarily at the bedside with local anesthesia with or without intravenous sedation. Antibiotics and continued local wound care, especially for delayed healing wounds, are critical to the achievement of satisfactory functional and aesthetic outcomes.

BONY INJURIES AND MANAGEMENT

Overview

The facial skeleton can be divided into two major structural components: the vertical and the horizontal buttresses. The vertical buttresses include the vertical portion of the mandible, nasomaxillary buttress, zygomaticomaxillary buttress, and the pterygomaxillary buttress. Their primary functional role is with mastication, so they are strong and well developed to withstand these compressive forces. The horizontal buttresses include the frontal bar, inferior orbital rim, and hard palate. These support structures act as an interconnected framework to stabilize the vertical buttresses. A diagram of the facial skeleton is shown in Figure 4.

Mandibular Fractures

Types

Mandibular fractures are the second most common facial fracture (Allareddy, 2011). Mandibular fractures are classified according to the location of the fracture: symphysis/parasymphysis, body, angle, ramus, coronoid process, and condyle. Figure 5 illustrates common fracture locations along with relative frequency. The most common sites of fracture are the angle and body, followed by the symphysis/parasymphysis (Ogundare, 2003). Assessment should include palpation of the mandible, inspection of the quality of the mandibular dentition, inspection of dental wear facets, and mental nerve

function. CT scan of the facial bones and mandible is necessary to evaluate the extent of injury. An example is shown in Figure 6. When possible, evaluation of the patient's occlusion and mouth opening should be made. Presenting signs and symptoms include trismus, malocclusion, numbness, and loose or missing teeth. A discussion of the patient's preinjury occlusion can also be helpful.

Treatment

The ultimate goals of mandibular fracture management are restoration of the preinjury occlusion, bony union after reduction of fracture segments, and preservation of facial contour and facial height. The location and type of mandibular fracture (greenstick, displaced/nondisplaced, comminuted/noncomminuted) dictate the surgical approach, the hardware used, and the nature of postoperative rehabilitation. Greenstick fractures can be treated with closed reduction

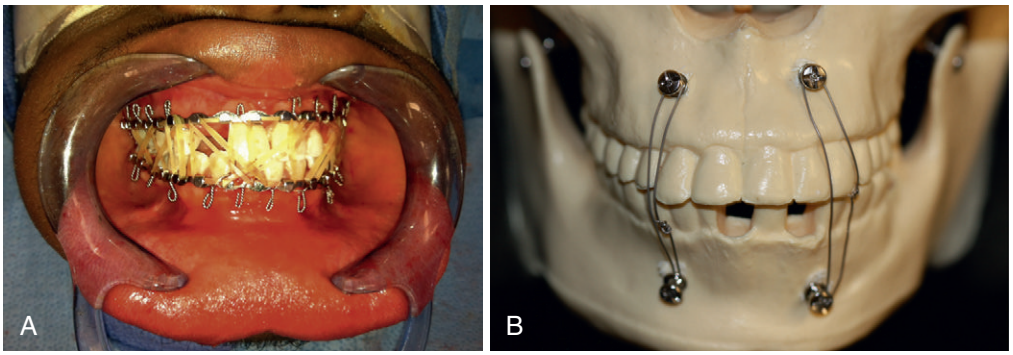

FIGURE 7 **A,** Maxillomandibular fixation with arch bars and elastic rubber bands. **B,** Maxillomandibular fixation with intermaxillary fixation screws and wires.

without fixation and maintenance of a soft diet. Maxillomandibular fixation (MMF) can be used to achieve closed reduction in patients who cannot spontaneously bring their teeth to their preinjury occlusion. Steel arch bars are applied to the maxillary and mandibular gingiva and tightly secured to the underlying dentition with loops of 24-gauge wire. The maxillary arch bar is then fastened to the mandibular arch bar, locking the patient into rigid fixation and ideally the preinjury occlusion. Examples are illustrated in Figure 7. If MMF is chosen as the definitive treatment for a mandibular fracture, then it should be maintained for approximately 6 weeks. MMF should be used with caution in patients with questionable mental status, mental retardation, seizure history, or substance abuse history. These patients may not be capable of removing their MMF in the event of emesis, which can lead to aspiration and potentially life-threatening airway compromise. Beyond the airway risks, MMF has significant morbidity associated with its use. Poor dental hygiene and enamel loss, discomfort, and speech and articulation difficulties are common reports of patients in intermaxillary fixation. The inability to chew and the lack of solid food consumption for 6 weeks can result in difficulty maintaining nutritional balance, with resultant weight loss during the fixation. Adult patients may lose up to 20 lbs during this period. These prolonged and significant morbidities have led to the increased use of open approaches with permanent rigid internal fixation as the primary mode of treatment for the vast majority of operative mandibular fractures.

Advances in plating systems have improved outcomes over the last few decades. Displaced fractures of the angle, body, and symphysis/parasymphysis can be managed with open reduction and rigid internal fixation with plates and screws via a transoral or transcervical approach. Figure 8 shows a compression plate and tension band. The use of dynamic compression plates allows a force vector to be created across the fracture line to optimize bone healing and reduce callus formation. The incorporation of lower profile hardware, superiorly based tension bands, and occlusal splints has reduced the morbidity of rigid fixation and improved outcomes.

Condylar fractures are unique because of the complexities with surgical approach and the difficulties with plating at this location. They can be managed closed (with or without MMF) or open (Zide, 1983; Palmieri, 1999; De Riu, 2001). The closed approach without MMF can be used in patients with good spontaneous occlusion. These patients are encouraged to exercise a full range of motion while maintaining a soft diet. The closed approach with MMF can also be used, but a greater concern exists for subsequent temporomandibular joint (TMJ) dysfunction because of the inflammatory response at the TMJ in condylar fractures. The open approach, either transoral or transcervical, involves plating across the fractured condylar segments with or without the assistance of endoscopic instrumentation. The indications for open repair of condylar fractures are displacement into the middle cranial fossa, poor occlusion with closed reduction, lateral extracapsular displacement of the condyle, presence of a foreign body, and open fracture with potential for fibrosis (Zide, 1989).

FIGURE 8 Compression plate and tension band at the symphysis.

Most high ramus and nondisplaced angle fractures do not warrant the morbidity of an open approach and can be treated with a closed approach with or without MMF. Isolated coronoid process fractures are rare and usually do not require treatment.

Complications

The major complications of mandibular fractures are infection, malunion, nonunion, malocclusion, and TMJ dysfunction. Antibiotics in the perioperative period have not been associated with a decrease in infection risk (Furr, 2006). The risk of TMJ ankylosis can be reduced with shorter periods of MMF (<3 weeks) and physiotherapy, such as range of motion exercises.

Special Considerations

Patients often present with more than one site of fracture (Allareddy, 2011; Ogundare, 2003). Unstable bilateral mandible fractures can lead to airway compromise through hemorrhage or edema followed by prolapse of the base of the tongue or fractured segments of mandible. Urgent airway intervention may be necessary in these cases. Edentulous mandibles present additional challenges in their management because of the atrophic nature of the mandible. The patient's dentures may need to be used for MMF, and a more aggressive open reduction internal fixation approach with load-bearing plates may be considered to minimize postoperative complications. Comminuted fractures can be difficult because of the mobility of the small mandible fragments. These patients should be placed into MMF; the smaller fracture segments are realigned with miniplates, and then the larger fracture segments are spanned by a more durable load-bearing plate.

Nasal Fractures

Types

Nasal bone fractures are the most common facial fracture (Allareddy, 2011). Nasal bone fractures can be unilateral, bilateral, nondisplaced, and displaced and with variable involvement of the septum. Assessment should include palpation of the nasal bones, nasal dorsum, and intranasal examination for septal hematoma or fracture. Radiographic imaging is usually not necessary in isolated nasal bone fractures but may be warranted depending on the comorbid injuries. Figure 9 illustrates a nasal bone fracture. Presenting signs and symptoms include epistaxis, nasal airway obstruction, alterations in smell, and cosmetic deformity. A review of the patient's preinjury nasal breathing and appearance can be helpful.

Treatment

The goals of nasal fracture management are to reestablish the preinjury nasal airway and restore the nasal contour. Nasal fractures can be treated with closed reduction or open reduction with osteotomy of the nasal bones. Closed reduction involves the mobilization of displaced nasal bones and cartilages with or without the use of a blunt elevating instrument inserted into the nose. Rapid spontaneous healing of these fractures requires acute intervention within 10 days of the injury. Even with early intervention, however, unsatisfactory cosmesis may still necessitate an open reduction procedure in the future. If the fractures are not managed within the acute time frame, then it is generally advisable to wait at least 3 months for adequate bone healing and overall nasal structural stabilization before performing an open reduction with osteotomy of the nasal bones. After reduction of the nasal fracture, external fixation should be applied with a nasal splint. If necessary for nasal breathing, a septoplasty may be performed in the operating room to correct any septal deviation or fracture. A septal hematoma should be drained as soon as possible to prevent septal cartilage necrosis, septal perforation, and potential saddle nose deformity.

Special Considerations

Although most cases of traumatic epistaxis can be managed conservatively with topical nasal decongestants, digital pressure, or blood pressure control, severe epistaxis may necessitate nasal packing, endoscopic blood vessel ligation, or angiography with embolization. Clear nasal drainage in the patient with facial trauma may also warrant an investigation for cerebrospinal fluid (CSF) rhinorrhea from a skull base fracture. Patients often note a salty or metallic taste if a CSF leak is present. The halo sign, from differential capillary action of CSF and blood on a white cloth or tissue can also suggest the diagnosis. Collection of adequate sample volume to do this test is often not possible. It is primarily of historical significance. The advent of beta 2 transferrin testing allows accurate diagnosis with minimal sample collection and has become the standard of care to confirm the diagnosis.

FIGURE 9 Axial computed tomographic scan image without contrast showing bilateral nasal bone fractures.

Complications

The major complications of nasal fractures include nasal airway obstruction, unsatisfactory cosmesis, epistaxis, and septal perforation from septal hematoma.

Nasoorbitoethmoidal Fractures

Types

Nasoorbitoethmoidal (NOE) fractures are usually the result of a high-impact blunt trauma to the mid face. They can occur in isolation but usually present as part of a panfacial fracture. NOE fractures are classified according to the extent of bony fracture and condition of the medial canthal tendon. Figure 10 illustrates the classification scheme for NOE fractures. Assessment should include palpation of the nasal bones, visual acuity check, evaluation of eyelid and globe condition and position, and intranasal examination. CT scan of the facial bones is necessary to evaluate the extent of injury. Presenting signs and symptoms include telecanthus, enophthalmos, epiphora, nasal airway obstruction, and epistaxis.

Treatment

The goals of NOE fracture management are to restore nasal contour and intercanthal and interpupillary distance by reestablishing the medial orbital rim and attachment of the medial canthal tendon to the frontal process of the maxilla. An open approach through an existing laceration or a facial incision, such as coronal, Lynch, midface degloving, or gull wing, is necessary to ensure adequate reduction and fixation. NOE fractures are often severely comminuted. Fractured segments of bone can be sutured, wired, or screwed with miniplates into fixation. The complex comminuted nature of these fractures often precludes plate fixation of the bone with medial canthal tendon attachment. In these cases, the detached medial canthal tendon must be secured to the frontal process of the maxilla via a transnasal canthopexy to restore the preinjury intercanthal distance. Type 2 and 3 NOE fractures may require bone grafts to reconstruct the medial orbit and the nasal dorsum.

Special Considerations

NOE fractures may have concomitant injury to the nasolacrimal system. However, routine exploration of the lacrimal apparatus or a dacryocystorhinostomy in the acute settings is not indicated unless obvious injury is noted.

Complications

The major complications of NOE fractures include epiphora, telecanthus, enophthalmos, midface retrusion, and saddle nose.

Frontal Fractures

Types

The frontal bone is the strongest of the facial bones, but its superior anatomic location also makes the area prone to traumatic injury in

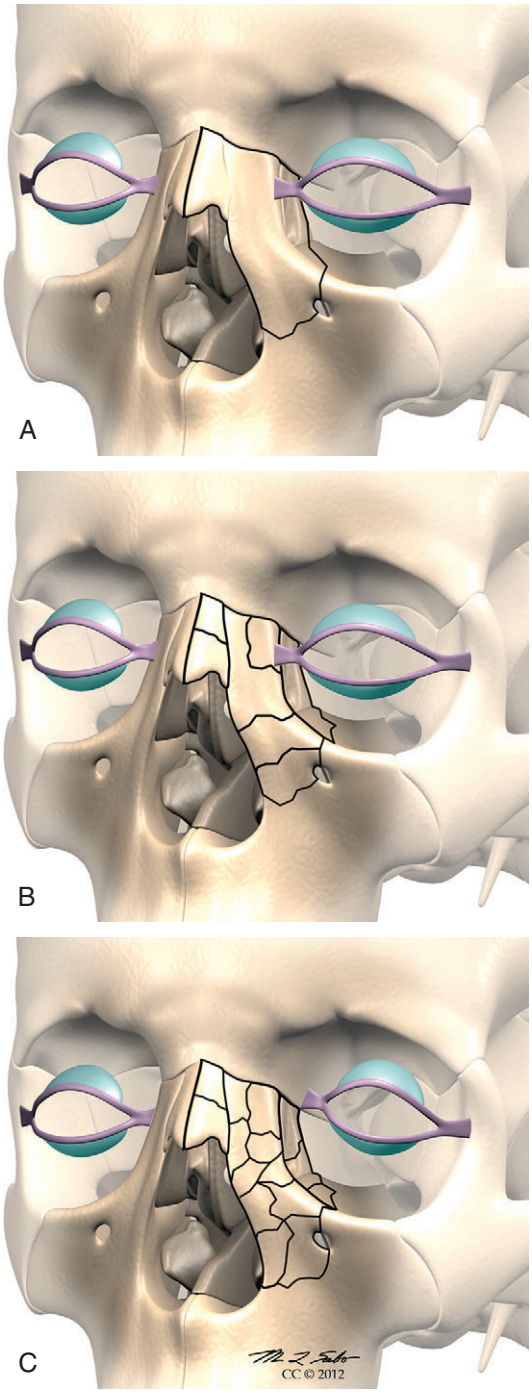

FIGURE 10 Nasoorbitoethmoidal (NOE) fracture classification scheme: **A,** type 1 NOE; **B,** type 2 NOE; **C,** type 3 NOE. *(Reprinted with permission from Cleveland Clinic Center for Medical Art & Photography, 2012. All rights reserved.)*

vehicular injuries and falls. Fractures in the region are therefore not uncommon. Frontal sinus fractures can be displaced, nondisplaced, comminuted, and noncomminuted. Figure 11 illustrates a frontal sinus fracture. Assessment should include palpation of the frontal bar, evaluation of forehead sensation, visual acuity check, and intranasal examination. CT scan of the facial bones and sinuses is a critical portion of the assessment of frontal sinus fractures. Presenting signs and symptoms include forehead lacerations and numbness, epistaxis, and rhinorrhea. Any posterior table fracture should be examined with a high suspicion for possible CSF leak.

FIGURE 11 Axial computed tomographic scan image without contrast showing nondisplaced anterior and posterior table frontal sinus fractures.

Treatment

The goals of frontal sinus fracture management are to restore the aesthetic appearance of the frontal region and maintain the drainage and aeration of the frontal sinus system. The management of frontal sinus fractures is dependent on the condition of the anterior and posterior tables of the frontal sinus, the nasofrontal duct, and the anterior cranial fossa. Nondisplaced anterior table fractures do not require intervention. Displaced anterior table fractures require intervention if there are cosmetic concerns or if the fracture interferes with the frontal sinus drainage via the nasofrontal duct. Frontal sinus obliteration is used for fractures that involve the nasofrontal duct. Posterior table fractures that are nondisplaced do not require immediate intervention but should be followed with serial CT scans to evaluate the sinus. Posterior table fractures that are displaced or comminuted or present with pneumocephalus should be explored. Frontal sinus obliteration should be reserved for cases where the frontal sinus floor is not comminuted and the posterior table bone is largely intact. Frontal sinus cranialization is the treatment of choice for posterior table fractures with severe comminution or displacement of bone.

Special Considerations

Intracranial morbidity is a primary short-term concern with frontal sinus fractures. CSF leak through an anterior skull base injury can be both an early and a late complication. Delayed mucocele formation is another complication that warrants long-term follow-up with serial CT scans of the sinuses and anterior skull base.

Complications

The major complications of frontal sinus fractures include obstruction of the frontal sinus drainage pathway with resultant sinusitis, mucocele, or intracranial extension of infection.

Zygomaticomaxillary Complex Fractures

Types

Anatomically, zygomaticomaxillary complex (ZMC) fractures involve four suture lines: zygomaticofrontal, zygomaticomaxillary, zygomaticotemporal, and zygomaticosphenoid. Figure 12 illustrates a ZMC

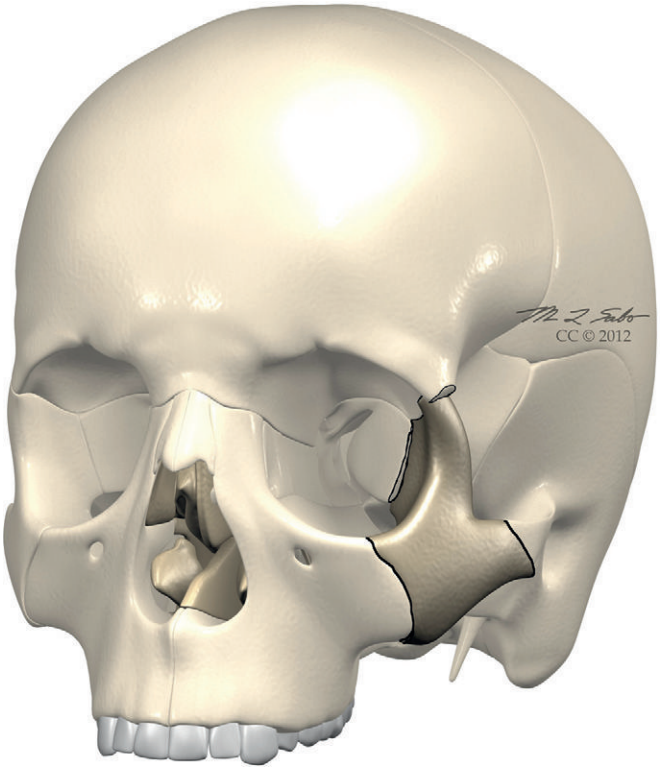

FIGURE 12 A typical displaced zygomaticomaxillary complex fracture. *(Reprinted with permission from Cleveland Clinic Center for Medical Art & Photography, 2012. All rights reserved.)*

fracture. Radiographically, ZMC fractures usually involve fractures of the lateral orbital wall, orbital floor/inferior orbital rim, anterior maxillary sinus wall, lateral maxillary sinus wall, and zygomatic arch. ZMC fractures can lead to significant aesthetic disturbances because the malar eminence of the zygoma is the most anterior projection of the lateral mid face and the zygomatic arch is the most lateral projection of the mid face. Assessment should include palpation of the zygoma, intraoral and intranasal examination, mouth opening, visual acuity check with extraocular muscle function, and midface sensation. Ophthalmologic consultation should be considered for any vision symptoms or significant orbital injury. CT scan of the facial bones and sinuses is a critical portion of the assessment of ZMC fractures. Presenting signs and symptoms include epistaxis, vision changes, midface and dental numbness, malar depression, enophthalmos, trismus, and malocclusion.

Treatment

The goals of ZMC fracture management are restoration of the height, width, and projection of the malar eminence; reestablishment of the buttresses of the mid face; restoration of orbital volume; and adequate reduction of the fractures. Fractures can be approached with a combination of surgical incisions: upper gingivobuccal (sublabial), lateral upper blepharoplasty, transconjunctival, subciliary, or Gilles. After exposure and adequate reduction of the fractures, forced duction testing should be performed to rule out extraocular muscle entrapment during fracture reduction. Confirmation of continuity of the orbital floor after fracture reduction should also be considered. Fixation should be done at a minimum of two fracture points with plates and screws. Isolated zygomatic arch fractures may need to be reduced if the fracture produces a depression over the lateral face or if the fracture segments impinge on the temporalis muscle, leading to trismus or masticatory dysfunction. Maxillary sinus fractures in isolation without other associated ZMC fractures rarely require intervention. Patient counseling regarding the risks of facial and orbital cellulitis and swelling with future episodes of sinusitis is advisable when appropriate.

Special Considerations

Given the intimate relationship between the ZMC and the orbit, preoperative and postoperative ophthalmologic evaluation may be warranted in certain circumstances.

Complications

The major complications of zygomaticomaxillary complex fractures include maxillary nerve anesthesia, trismus, globe malposition, vision changes, ectropion, and malar depression.

Le Fort Fractures

Types

The Le Fort fracture classification scheme is used to describe midface fracture patterns with separation of the tooth-bearing bone and cranium. Figure 13 illustrates the Le Fort fracture classification scheme. All Le Fort fractures have bilateral pterygoid plate fractures. Le Fort type 1 is a horizontal fracture through the maxilla superior to the maxillary dentition. Type 2 is a pyramidal fracture through the maxilla and orbit, outlining the nose. Type 3 is a fracture of the facial bones from the skull, a complete craniofacial separation. These fracture patterns are suggestive of a high-impact trauma.

Assessment should include manipulation of the hard palate relative to the skull, facial sensation, visual acuity check with extraocular muscle function, and intraoral and intranasal examination. CT scan of the facial bones and sinuses is a critical portion of the assessment of Le Fort fractures. Presenting signs and symptoms include facial anesthesia, epistaxis, vision changes, and malocclusion.

Treatment

The goals of Le Fort fracture management are restoration of the continuity of the facial bones with the cranium and reduction of fractures with the goal of returning the patient to the preinjury occlusion. Putting the patient into MMF ensures satisfactory occlusion and provides a stable foundation for the remainder of the repair. Type 1 injuries can be approached through an upper gingivobuccal (sublabial) incision. Type 2 and 3 injuries usually require the addition of eyelid incisions or a coronal approach. The details of the management of Le Fort fractures are analogous to the management of ZMC fractures discussed previously.

Special Considerations

Multiple Le Fort fracture patterns can be present in the same patient. For example, a complex type 3 fracture may have a concomitant fracture at the Le Fort 1 level (horizontal fracture through the maxilla superior to the maxillary dentition). For complex Le Fort fractures, a top-down approach is used to reduce the complexity of the overall fracture pattern as the fractures are sequentially reduced.

Complications

The major complications of Le Fort fractures include facial anesthesia, malocclusion, trismus, globe malposition, vision changes, ectropion, midfacial distortion, and nasal obstruction.

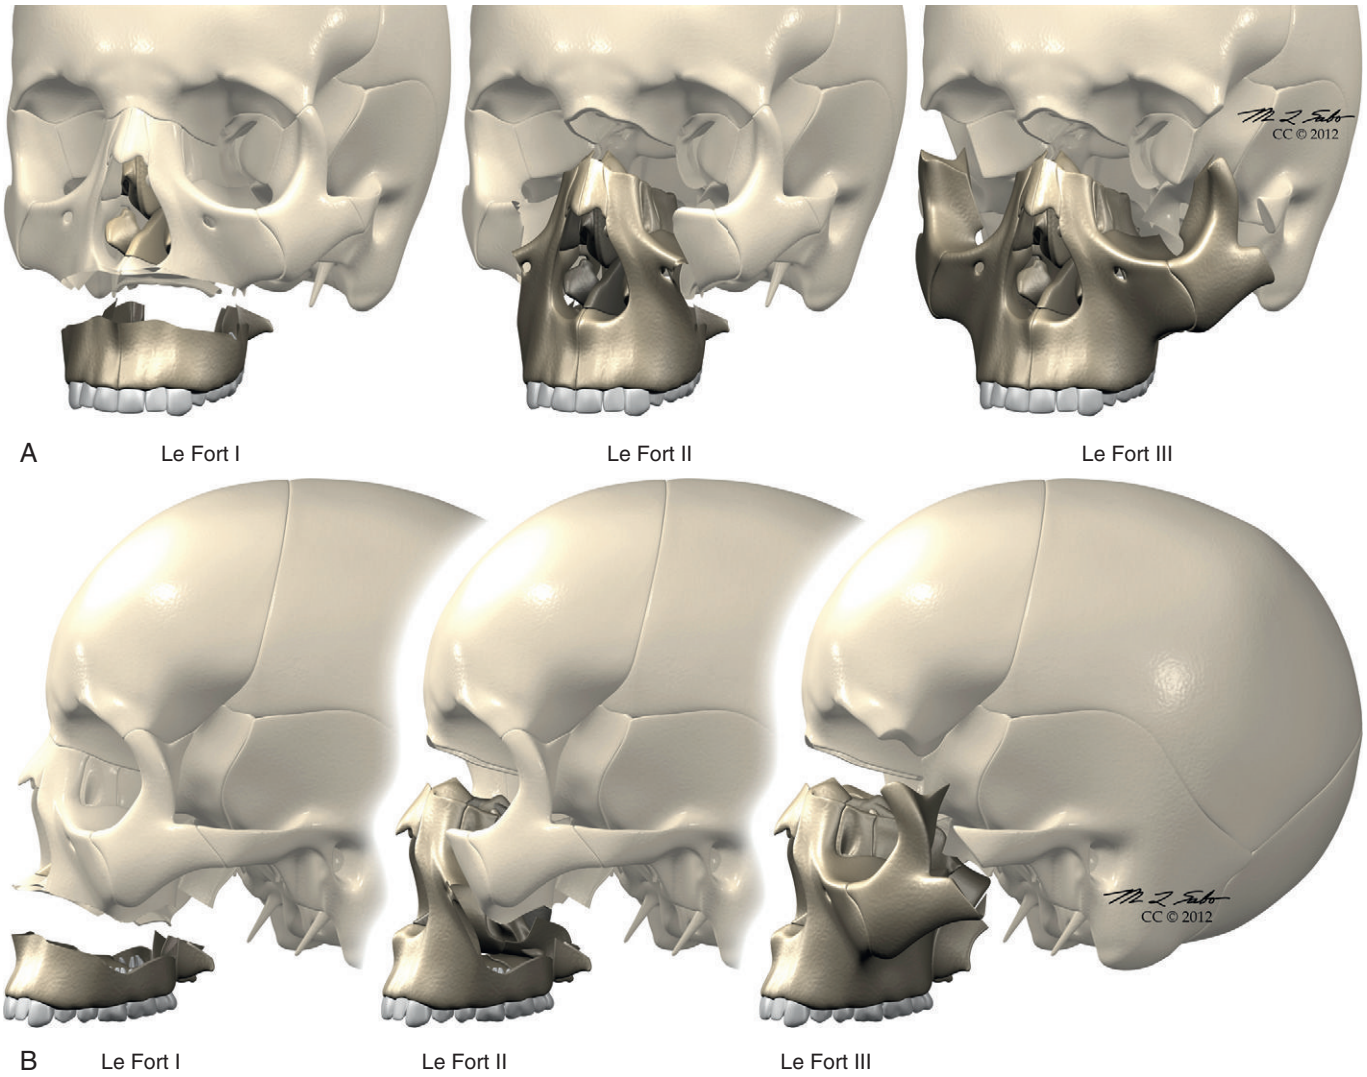

FIGURE 13 Le Fort fracture classification. **A,** Anterior view. **B,** Lateral view. *(Reprinted with permission from Cleveland Clinic Center for Medical Art & Photography, 2012. All rights reserved.)*

Panfacial Fractures

Types

Panfacial fractures involve fractures of the mandible, mid face, and frontal bones. These complex fractures may present with any of the signs and symptoms of the aforementioned facial fractures. For the purposes of panfacial fractures, the Le Fort type 1 fracture is used to delineate the facial skeleton into an upper and lower segment (Manson, 1999). CT scan of the facial bones and sinuses is imperative to the correct diagnosis and treatment of these injuries.

Treatment

The goals of panfacial fracture management are to restore the upper and lower facial skeleton in continuity with the cranium. Both the upper and the lower facial fractures should be secured to adjacent nonfractured bony landmarks. The upper facial skeleton (superior to the Le Fort type 1 fracture line) should be reduced and fixated to the frontal bone and cranium. The lower facial skeleton (inferior to the Le Fort type 1 fracture line) should be reduced and fixated to the mandible, which via the TMJ is secured in continuity with the cranium. Although the sequence of fracture reduction and fixation is not critical, it should allow for flexibility in the management of the multiplicity of fractures. Manson and colleagues suggest the following: for the upper facial skeleton, reduce the frontal bones, then the NOE complex, followed by the ZMC; and for the lower facial skeleton, reduce the palate, then the vertical mandible (condyle, ramus, proximal angle), followed by the horizontal mandible (distal angle, body, symphysis/parasymphysis; Manson, 1999). The lower facial skeleton should be put into MMF to ensure proper occlusion and allow another point of fixation. After both the upper and the lower face are reconstructed in their proper alignment relative to the cranium, the two units are then fixated at the Le Fort 1 fracture line.

Special Considerations

Although initially a daunting task, the reconstruction of panfacial fractures can be simplified to smaller component fractures. In addition, the best chance for satisfactory functional and aesthetic outcome is with early reconstruction of soft tissue and bony injuries.

Complications

These complex fractures may present with any of the complications of the aforementioned facial fractures.

Orbital Fractures

Types

Orbital fractures can involve the inferior orbital rim, the lateral orbital rim, the medial orbital wall, the orbital floor, and rarely, the superior orbital rim. The isolated orbital floor fracture is commonly known as an orbital blowout fracture. These fractures can present with a trapdoor pattern with associated extraocular muscle entrapment seemingly outside of the orbital confines, especially in children. Assessment should include palpation of the orbital rims, evaluation of eyelid and globe condition and position, visual acuity check with extraocular muscle function, and evaluation of forehead and midface sensation. Ophthalmologic consultation should be considered for any vision symptoms or for significant orbital injury. CT scan of the facial bones and sinuses is a critical portion of the assessment of orbital fractures. Figures 14 and 15 illustrate orbital floor fractures. Presenting signs and symptoms include vision changes, forehead and midface numbness, enophthalmos, dystopia, chemosis, hyphema, and subconjunctival hemorrhage.

Treatment

The goals of orbital fracture management are restoration of orbital structure and volume. Orbital fractures are unique from other facial fractures in that the goal of treatment is not the healing of fractured bone but the reconstruction of violated orbital walls to restore volume. For correction and prevention of enophthalmos, dystopia, and diplopia, the orbital volume and globe position of the injured eye must be comparable with that of the uninjured eye. For reconstruction of the injured orbit, the surgeon must have an understanding of the complex anatomy of the orbit. Critically important is recognition of the S shape of the orbital floor as it extends posteriorly toward the orbital apex. Reconstruction of this complex floor is critical to achieving a satisfactory outcome. Orbital fractures can usually be approached through upper and lower eyelid, upper gingivobuccal, and coronal incisions. Isolated orbital floor fractures medial to the infraorbital nerve may be amenable to transmaxillary endoscopic repair. Isolated medial orbital wall fractures without extraocular muscle entrapment or significant orbital volume distortion do not require intervention. After adequate exposure of the orbital fracture is gained, the primary focus becomes restoration of the orbital volume. First, the orbital contents (extraocular muscles, fat, periorbita) are deposited back into the confines of the orbit. Next, the orbital wall defects are reconstructed with autogenous grafts (split calvarial bone, septal cartilage), absorbable alloplastic implants (polydioxanone, polyglycolide), or nonabsorbable alloplastic implants (titanium, silicone, polytetrafluoroethylene [PTFE], porous polyethylene).

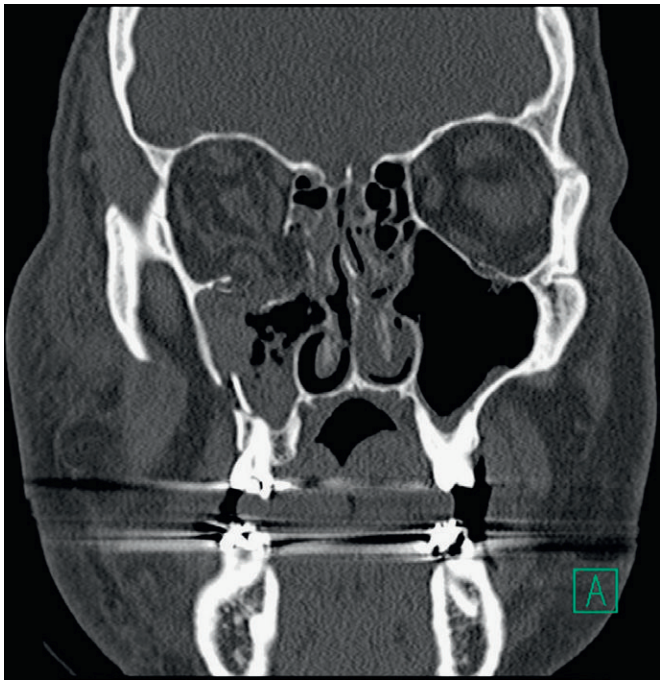

FIGURE 14 Coronal computed tomographic scan image without contrast showing displaced right orbital floor fracture with associated right lateral maxillary sinus wall fracture

Special Considerations

Appropriate consultation with ophthalmology and oculoplastic surgery should be initiated with significant globe or eyelid injuries or vision symptoms.

Complications

The major complications of orbital fractures include vision loss and changes, forehead and midface anesthesia, and eyelid and globe malposition.

EXTENSIVE INJURIES AND MANAGEMENT

Gunshot Wounds and Blast Injuries

Gunshot wounds cause tissue injury through three mechanisms: direct tissue injury, cavitation, and blast injury after entry. The management of gunshot wounds requires knowledge of the weapon used.

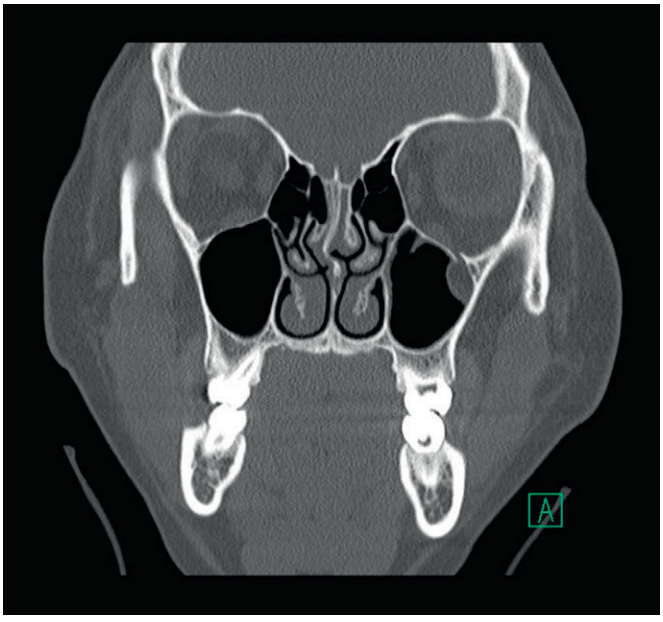

FIGURE 15 Coronal computed tomographic scan image without contrast showing minimally displaced left orbital floor fracture.

The weapon's muzzle velocity and ballistics of the penetrating missile dictate the survivability and extent of injury. The tissue damage caused by a gunshot wound depends on four characteristics of the projectile: kinetic energy, yaw, deformation, and fragmentation. The kinetic energy that is transferred from the missile to the body in a gunshot wound is dependent on the velocity and mass of the projectile (kinetic energy = ½ mass × velocity^2). Yaw is the amount of movement about the axis with which the projectile is traveling. Deformation is the change in shape or size of the projectile during its flight. Fragmentation is the separation of the missile into multiple smaller projectiles.

Handguns generally fire smaller caliber missiles at a lower muzzle velocity, and hunting and military rifles fire larger caliber missiles at higher muzzle velocity. Rifles also often implement missiles that deform in flight or fragment on entry, creating greater tissue damage. Shotgun missiles tend to have high velocity at close range but decrease rapidly as they travel through the air.

Blast injuries are commonly classified into four categories: primary, secondary, tertiary, and quaternary. Primary blast injuries result from the direct interaction of the blast wave with the body. Secondary blast injuries are caused by objects propelled by the blast. Tertiary blast injuries are the result of displacement of the body by the blast wind. Quaternary blast injuries encompass all other injuries (psychologic, thermal, crush, respiratory, etc.) related to exposure to the blast.

Management

The initial assessment and management of ballistic trauma to the head and neck follow the same algorithm for treatment outlined previously in Emergent Treatment and Evaluation. After initial treatment and stabilization, the patient should be taken to the operating room for a thorough examination of the extent of injuries, washout, and débridement of nonviable tissues. An attempt should be made to preserve and stent the facial soft tissue envelope and all orifices. Fractures that can be reduced and fixated should be repaired. Tracheotomy may need to be performed. Planning for a staged definitive repair should be done at this time.

Facial injuries from ballistic trauma differ from other types of traumatic facial injuries. The restoration of bony landmarks and closure of soft tissue wounds are often not possible because of the loss of viable soft tissue and bone. In addition, the inherently poor vascularity of the severely traumatized tissues that remain and the associated evolving tissue necrosis and infection make a challenging situation worse. Primary repair of the injured tissues is rarely feasible because adequate viable tissue is no longer present locally. The paradigm must shift from the classic conceptions of injury repair to rebuilding. Successful restoration of form and function can only be achieved by recruiting tissues to rebuild the deficient structures of the face.

The treatment approach for extensive traumatic head and neck injuries has shifted away from delayed repair to early repair with local tissue and free tissue transfer reconstructions. Staged early definitive reconstruction allows for fewer surgeries and shorter hospitalizations (Doctor, 2007). The initial repair may involve some elements of healing with secondary intention or primary closure but usually requires early recruitment of healthy tissue into the face via local tissue rearrangement, pedicled regional flap, or free tissue transfer (anterolateral thigh flap, osteocutaneous fibula flap). Local tissue advancement with a cervicofacial flap can be used to reduce the soft tissue deficit and provide skin coverage. Although this flap brings healthier adjacent tissue into the defect, it is a randomly based flap and susceptible to vascular compromise and distal flap necrosis. Pedicled regional flaps (paramedian forehead flap, deltopectoral flap, latissimus dorsi flap) are supplied by a vascular pedicle, allowing for greater tissue viability and versatility. The paramedian forehead flap can be used for nasal reconstruction. The deltopectoral flap and latissimus dorsi flap can be used to reconstruct large skin defects of the neck, lateral face, and scalp.

The evolving success and reliability of microvascular surgery has led to the early use of healthy vascularized free tissue transfer for trauma reconstruction. The advantages of recruiting nontraumatized naive tissue for the reconstruction include a more physiologic restoration of function and a reduction in scar contracture. Free tissue transfer also allows for the reconstruction of varying tissue defects (mucosa, bone, skin) with comparable vascularized tissue. The anterolateral thigh flap can be used to reconstruct large skin and soft tissue defects. The osteocutaneous fibula flap can be used to reconstruct orbitomaxillary and mandibular defects. The ultimate evolution of this concept is the use of allograft flaps. Face transplants have been used to reconstruct severe facial trauma injuries where massive loss of facial structures exist (Alam, 2009). Figure 16 illustrates the skeletal deficit from a face transplant recipient. Although technically more challenging than the typical free tissue transfer and requiring lifelong immunosuppression for the recipient, face transplants allow a composite transfer of varying soft tissue and bone that replaces the lost tissue with an exact anatomic match. With the development and success of face transplant programs, this once implausible surgery may soon become just another tool in the facial trauma surgeon's toolbox.

CONCLUSION

The importance of the face goes beyond its function, form, or aesthetics. An individual's membership and participation in society is contingent on the face. Although the trauma patient may present with many life-threatening and severe injuries, few are more damaging to an individual's existence than a significant trauma to a person's face.

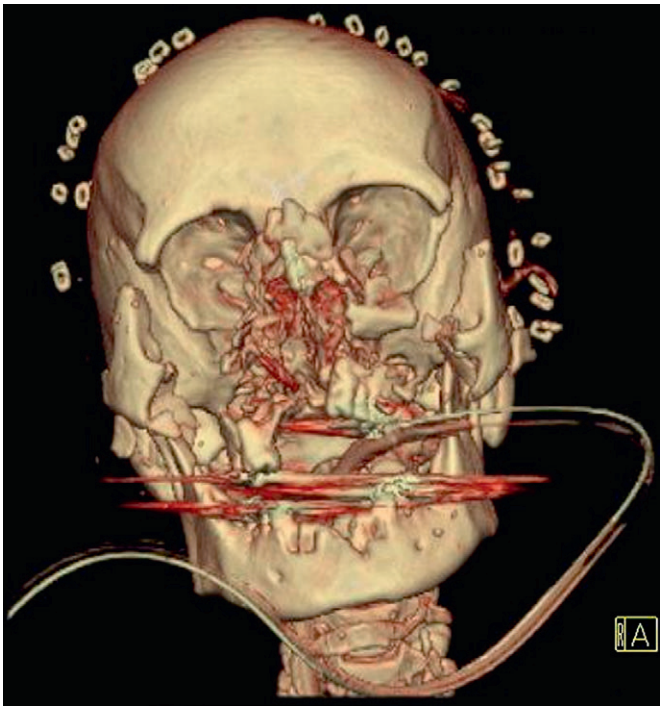

FIGURE 16 Three-dimensional reconstruction of the skeletal deficit in a face transplant recipient.

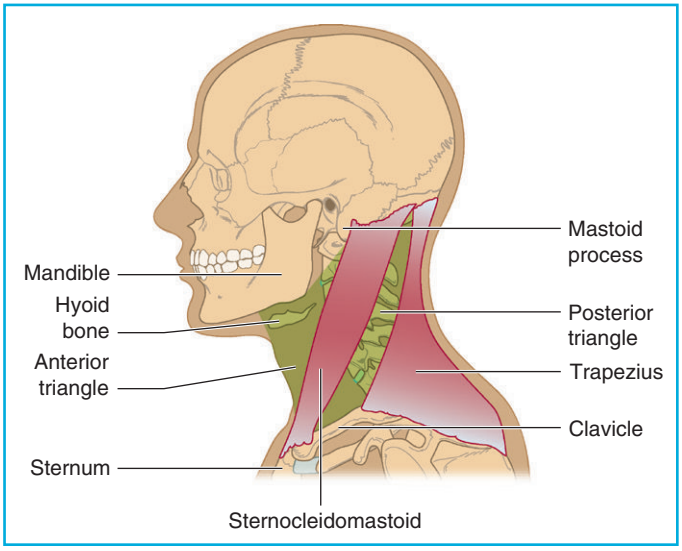
Penetrating Neck Trauma

Ronald V. Maier, MD, FACS, and Deborah Lane Marquardt, MD

INTRODUCTION

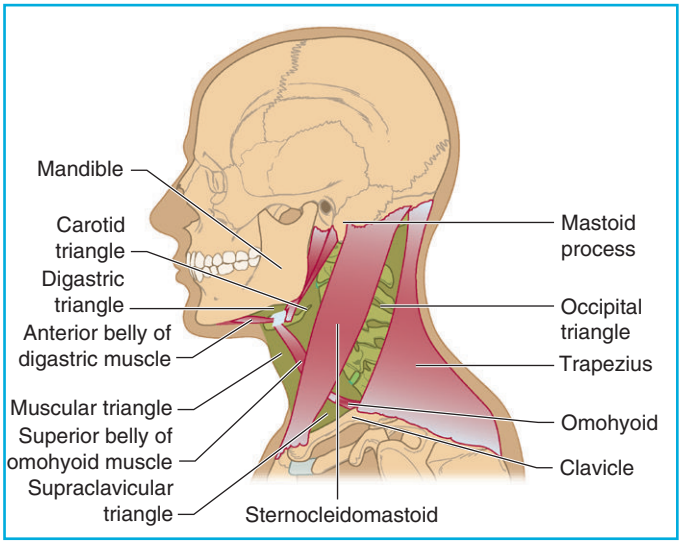
Penetrating neck injuries represent approximately 5% to 10% of traumatic incidents in adults. Though this is a small portion of the total traumatic events nationally, it is a particularly important topic given the number of significant structures located within the small space of the neck. It is critical to understand the anatomic relationships of the neck and to have a clear approach to the evaluation and management of penetrating neck injuries.

ANATOMY



The neck has classically been divided into both triangles and zones. The borders of the posterior triangle are the sternocleidomastoid muscle anteriorly, the trapezius muscle posteriorly, and the clavicle inferiorly. Within this triangle lie the spine and the vertebral arteries. The borders of the anterior triangle are the midline anteriorly, the sternocleidomastoid posteriorly, and the lower edge of the mandible superiorly. It contains many vital structures, including the carotid artery, jugular vein, trachea, esophagus, and recurrent laryngeal nerve (Figure 1). From inferior to superior, the neck is divided into zones that help direct investigation. Zone I refers to the thoracic inlet and the structures lying below the level of the cricoid cartilage. Zone II lies between the cricoid cartilage and the angle of the mandible, and Zone III includes structures above the angle of the mandible to the base of the skull (Figure 2). In considering the evaluation and management of penetrating trauma to the neck, the zones are the most useful because they divide the anterior triangles where the vast majority of critical structures reside and can help direct the pathway for evaluation and management (see Figures 1 and 2).

INITIAL EVALUATION/MANAGEMENT



As with all traumatic injuries, the first step in the evaluation and management of penetrating neck trauma is addressing the ABCs. Ensuring a secure airway is paramount. However, even in the setting of tracheal injury, the vast majority of patients may be managed either without an artificial airway or via standard endotracheal intubation. Only rarely will emergent cricothyrotomy or tracheostomy be necessary. Once a secure airway is in place, a chest x-ray and lateral c-spine films are recommended. It is critical to evaluate for the presence of a pneumothorax or hemothorax, which can come from an injury to Zone I or if more than one zone is involved. A lateral c-spine film can be useful to outline the presence of foreign bodies and subcutaneous air and to further evaluate the anatomy of the airway. C-spine immobilization is an area of some controversy. Though significant vertebral injuries or ligamentous disruption is uncommon in the vast majority of penetrating neck injuries, it is judicious to proceed with immobilization if there are any signs of neurologic deficits, if the patient cannot be examined, or if the mechanism of injury is from a high energy source such as a gunshot wound.

Zone I and III Injuries

The thoracic inlet and submandibular regions of Zones I and III, respectively, represent areas less easily managed operatively due to limited access due to restrictive anatomy. In Zone I, this consists of the sternum, rib cage, and clavicle. One or more of these must be divided for full visualization of the underlying structures. In Zone III, surgical access is particularly limited due to the proximity to the skull base and relatively fixed mandible and the narrow space between them. In patients without signs of life-threatening hemorrhage, the

A

B

FIGURE 1 Anatomic triangles of the neck. **A,** The sternocleidomastoid muscle divides the main anterior and posterior triangles. **B,** Subdivision of the triangles further defines the structures at risk of injury. *(From Bogart BI: Elsevier's* Integrated anatomy and embryology, *Philadelphia, 2007, Elsevier, pp 10-26.)*

initial approach to both of these zones is to proceed with imaging studies to evaluate for significant injury. Computed tomographic (CT) angiography is the most commonly used imaging modality for penetrating neck trauma. It provides high-resolution images that can outline the path of the penetrating injury, which may help to identify injuries to pertinent structures, identify that key structures are distant from any signs of injury, and assist in planning the operative approach. Angiography remains the gold standard for evaluation of the vasculature, though it is infrequently utilized as the initial diagnostic modality today. It is most appropriate for use in a confirmatory diagnostic manner when debris or a foreign body causes artifact that distorts CT images, and it may also be used therapeutically for definitive intervention such as embolization, balloon occlusion, or endovascular stent placement to control vascular injury.

With signs of life-threatening hemorrhage and penetrating injury to Zone I of the neck, the most versatile surgical approach is a median sternotomy. This will provide access to the origin of the right subclavian, innominate, and left carotid arteries. This incision may be extended into the neck along the anterior boarder of the sternocleidomastoid muscle if more distal vascular control is necessary. To expose and manage distal subclavian vascular injuries, a supraclavicular extension of the median sternotomy may be performed on the ipsilateral side. In the process of accessing the subclavian vessels in this manner, initial control for hemorrhage from a supraclavicular wound can often be obtained using a finger or inflating a urinary catheter balloon within the tract behind the clavicle to tamponade bleeding. For proximal left subclavian injuries, a left anterolateral thoracotomy in the third interspace is the preferred additional incision for operative exposure. However, creation of the classic "open book" exposure is time-consuming, difficult, and highly morbid, and is thus rarely utilized (Figure 3). If a subclavian artery injury is noted during angiography, a proximal occlusion balloon may be placed to control hemorrhage prior to definitive surgical repair. Additionally, consideration should be given to endovascular stent placement to bridge an injury in the midportion of the vessel as definitive therapy (see Figure 3).

Zone III injuries are particularly difficult in that they offer limited operative accessibility due to the hardened structures of the mandible and the base of the skull. Superior posterior extension of an anterior sternocleidomastoid incision across the origin of the sternocleidomastoid with dislocation of the temporal mandibular joint and forward mobilization of the mandible has been described but rarely utilized. More commonly, division of the omohyoid will assist with exposure. Care must be taken to avoid injury to the glossopharyngeal (CN IX) nerve in this process because it lies just below the angle of the mandible parallel to the omohyoid muscle. Currently, injuries to the internal carotid artery in this location are frequently managed via angiography and endovascular stent placement or via ligation dependent on the extent and duration of any neurologic deficit.

Zone II

The definition of a penetrating neck injury is that which extends deep to the platysma muscle fascia. Zone II penetrating injuries that present with hard signs of significant injury mandate surgical exploration (Box 1). The most common surgical approach is via an incision along the ipsilateral anterior border of the sternocleidomastoid muscle. This will provide excellent exposure of the internal and external carotid arteries, internal jugular vein, trachea, esophagus, and larynx. If bilateral injury is encountered, this incision may be extended to include a transverse collar incision above the sternal notch, as well as a contralateral anterior sternocleidomastoid incision.

Treatment of Zone II injuries that penetrate the platysma but are not associated with any hard signs of significant injury is an area of ongoing debate and local tradition. The most definitive approach is to proceed with mandatory surgical exploration for all such injuries. Advocates of this approach cite overall low morbidity and early discharge after surgical neck exploration and high morbidity and potential mortality associated with missed injuries, particularly to the esophagus. However, in multiple series it has been noted that there is a 40% to 60% negative exploration rate with this approach. The least invasive approach is to utilize physical exam alone in patients with no signs or symptoms of deep injury. This may be appropriate in some cases, but it mandates that the patient be admitted for a minimum of 24 hours for observation and having the local resources available to manage injuries operatively or with angiography should they become apparent during the period of observation. Between these two extremes of approach is perhaps the most common approach to management of patients with either soft signs of injury or who are asymptomatic, which includes a hybrid of physical

examination, imaging, laryngobronchoscopy, and esophagography/esophagoscopy (Box 2). It is important to remember that vascular and aerodigestive injuries may be present in the absence of any significant symptoms on initial presentation, so a high index of suspicion is always warranted with any penetrating neck injury (see Boxes 1 and 2).

BOX 2: Soft signs of significant injury

Dysphonia or voice change
Cough
Hoarseness
Dysphagia or odynophagia

As with Zone I and III injuries, Zone II penetrating injuries without hard signs mandating immediate operative intervention are most commonly initially evaluated with CT angiography. This technology is readily available in most hospitals and provides for an expeditious means to evaluate key structures for injury. As noted above, formal angiography or operative intervention will be necessary if artifact from foreign bodies obscures the carotid vessels on CT angiography. Additionally, laryngobronchoscopy can be utilized to further evaluate the upper and lower airways when injury is suspected on CT imaging. There is debate over the use of esophagography versus esophagoscopy to further evaluate for esophageal injury. Though neither study has proved 100% successful alone at identifying all injuries, in combination they are nearly 100% successful. In most circumstances, local resources and the degree of clinical indications should dictate the use of such modalities or need for transfer to a higher-level facility.

Operative Exposure

As noted above, most injuries to structures in Zone II may be managed via an incision anterior to the sternocleidomastoid muscle. Dissection is carried through the platysma. Bridging veins are ligated to facilitate exposure. The trachea and thyroid may be retracted medially and anteriorally to better expose the carotid sheath and its contents, as well as the tracheoesophageal groove. If esophageal injury is suspected, further dissection can be undertaken both anterior and posterior to the esophagus. For tracheal injuries at the level of the thyroid, the injury may provide the dissection needed for exposure. Additionally the thyroid isthmus may be divided to further facilitate visualization and repair. The proximal vertebral artery may be accessed by retracting the carotid sheath anterosuperiorly or posteroinferiorly to expose the prevertebral space and beginning of the intravertebral canal.

MANAGEMENT OF SPECIFIC INJURIES

Venous Injuries

Venous injuries are the most common cause of non–life-threatening bleeding in penetrating neck injuries. Small veins can and should be ligated without concern for significant sequelae. The internal jugular vein may be repaired with fine monofilament suture for unilateral injuries involving less than 50% of the circumference of the vessel. For larger or through-and-through injuries, ligation may be performed. Unilateral ligation of the internal jugular vein is very well tolerated. Bilateral ligation should be avoided because this significantly limits venous drainage of the brain and can predispose to intracerebral hypertension and significant facial swelling.

Arterial Injuries

Obtaining proximal and distal control is the key step in managing any major arterial injury. This may be done bluntly with a finger, particularly in areas adjacent to major nerve trunks, while dissection proceeds to allow proper clamp placement proximal and distal to the area of injury. Isolated arterial injuries without significant contusion or vessel loss may be primarily repaired with 5-0 or 6-0 permanent monofilament suture. For larger or through-and-through injuries, segmental resection should be considered. For resection or vessel loss of less than or equal to 1 cm in length, mobilization and potential repair can be undertaken by a primary anastomosis. When this is not possible, the use of reversed saphenous vein autograft is recommended. If no vein is available, prosthetic graft or a bovine patch graft may be used, but they carry higher risks for infection and graft failure. Additionally, the distal external carotid artery may be ligated and the proximal limb used as an in-continuity bypass graft for injury to the proximal internal carotid artery. The injured external carotid artery may be ligated if successful repair or reimplantation is not possible or if the patient is otherwise too systemically ill to tolerate the time required for such a repair. For the injured internal carotid artery, a shunt may be used as a temporizing measure in the setting of systemic extremis and higher treatment priorities overall. Additionally, a carotid shunt should be considered intraoperatively at the time of internal carotid repair if there is minimal backbleeding from the distal segment. Systemic heparinization is not necessary. Instead, instillation of a heparin solution proximal and distal into the vessels is recommended in the setting of acute traumatic injury.

In patients with a neurologic deficit and concomitant carotid injury, there is debate as to whether the internal carotid should be repaired or ligated due to fear of converting an ischemic stroke into a hemorrhagic one. Despite this concern, the best data to date suggest that repair of the artery provides for the best chances of a favorable outcome unless the neurologic deficit has been present for a prolonged period of time. Strict postoperative blood pressure control is indicated in all such circumstances.

Vertebral arterial injury is very uncommon in penetrating neck trauma due to its protected location within the vertebral column. Injury is most commonly identified during imaging via CT or formal angiography and less commonly via hemorrhage originating posteriorly during neck exploration. Acute hemorrhage, pseudoaneurysm, and arteriovenous fistula formation of the vertebral vessels warrant intervention. This is most commonly managed via angiographic embolization or permanent balloon occlusion. Operative ligation at the time of neck exploration may be accomplished via exposure of the prevertebral fascia as described above followed by blind hemoclip or bone wax placement between the transverse processes, behind the longus colli muscle at the level of C6 to C7. Proximal ligation may also be accomplished at the vertebral artery origin off of the subclavian artery via a supraclavicular approach with transection of the sternal head of the sternocleidomastoid muscle.

Tracheal Injuries

The trachea is easily visualized via the anterior sternocleidomastoid incision. Blunt dissection posterior to the trachea will allow for mobilization and visualization of its posterior aspect. As above, the thyroid may be divided along the isthmus to facilitate anterior visualization. For injuries to the trachea through significant portions of the thyroid gland, resection of the affected thyroid tissue is recommended.

The trachea is best repaired with a single-layer 3-0 absorbable suture, being sure to tie all knots on the outside. Sutures may need to be placed in the innerspace above and below the adjacent tracheal rings to provide stability. If necessary, up to one or two cartilaginous rings may be resected while still maintaining the ability to perform a primary anastomosis. For significant injuries that involve near to full loss of a ring level, placement of a tracheostomy is indicated to ensure a secure airway. Locating the tracheostomy at the level of the second cartilaginous ring is still preferred, even if this is above the level of the injury. For injury to the arytenoids, reattachment and mucosal repair with absorbable suture are required.

When concomitant esophageal and tracheal injuries are present, a vascularized muscle flap from the omohyoid or sternocleidomastoid should be placed between the repairs to promote healing and decrease the chance of fistulization or leak.

Esophageal Injuries

The esophagus may be bluntly dissected free anteriorly in the tracheoesophageal groove and posterior from the prevertebral fascia. Having a nasogastric tube placed facilitates identification and dissection of the esophagus. Once the injuries are fully visualized and evaluated, repair should be performed in two layers. The first is a full-thickness closure using 4-0 absorbable suture, taking care to include the inner mucosal layer with the outer muscular layer. The outer layer of sutures should be interrupted through the muscular layer using 4-0 permanent suture. Because of the high rate of temporary leakage from esophageal repairs, a drain should be left in place after esophageal repair, and a contrast swallow study is recommended a week after repair prior to oral feeding. Maintaining an nasogastric tube (NGT) post repair can allow for prompt feeding into the stomach or upper small bowel. Devastating injuries involving large-volume tissue loss may necessitate distal ligation and creating a proximal esophagostomy by bringing the proximal limb out via the left side of the neck. In this setting, a jejunal feeding tube should be placed to facilitate feeding.

Thoracic Duct Injury

Thoracic duct injuries can occur with penetrating injury to Zone I or II on the left side. They are rare and represent less than 1% of all penetrating neck injuries. If identified at the time of surgical exploration by visualizing leaking or welling of milky fluid, ligation is recommended to prevent progression to chylothorax. Most injuries that present later in the form of a chylothorax may be managed with a chest tube and a low-fat diet without the need for surgical ligation.

Blunt Cardiac Injury

Ashish Shah, MD, and Keki R. Balsara, MD

INTRODUCTION

Blunt cardiac injury (BCI) is the general term for injury resulting from blunt trauma to the heart. The spectrum of injury that can result is broad and ranges from asymptomatic to sudden death from ventricular wall rupture. Cardiac injury is subclassified based on the nature of the injury and the resultant symptoms; these symptoms include (1) complex arrhythmia, (2) minor electrocardiogram (ECG) or enzyme abnormalities, (3) pump failure, (4) coronary artery thrombosis or dissection, and (5) septal or free wall rupture.

INCIDENCE

Because BCI includes a wide spectrum of injury, the true incidence of BCI in those who have sustained chest or abdominal trauma remains unknown. Many patients with BCI die in the field from either their cardiac or other traumatic injuries; thus, the total number of individuals affected may be underestimated. Moreover, there is little consensus on the appropriate workup for patients with suspected BCI, and this influences the reported incidence in the literature. A review of the current literature suggests an incidence between 8% and 71% for all individuals who sustain blunt thoracoabdominal trauma.

Schultz and colleagues found that the most common BCI identified in clinical studies is myocardial contusion (60% to 100%), followed by right ventricular injury (17% to 32%) and right atrial injury (8% to 65%) because of the anatomic positioning in the chest.

The left heart is less commonly involved with left ventricular injury (8% to15%) and left atrial injury (0 to 31%) being somewhat less common. Injuries to the coronary arteries and valves as the result of blunt trauma are found only as a series of case reports in the literature suggesting that their incidence is quite low. Autopsy series have demonstrated an incidence of 3% to 5% of such injuries in patients following blunt trauma.

The largest autopsy series, published by Parmley and colleagues, reviewed nearly 208,000 cases from the Armed Forces Institute of Pathology. The study showed a 0.1% incidence of BCI. The most common chamber injured was the right ventricle (66 cases), followed by the left ventricle (59 cases), right atrium (41 cases), and left atrium (26 cases). Of these, 106 cases had combined chamber rupture and 80 had an associated aortic injury.

MECHANISM OF INJURY

The heart is well protected by the bony thoracic cavity. A significant amount of force, usually associated with polytrauma, is necessary to impart serious injury to the heart. Historically, motor vehicle accidents had the greatest incidence of BCI. Increasingly, blast injuries, assault, and sports-related injuries are recognized as causative agents. Due to its varied presentation, blunt cardiac trauma requires a high degree of clinical suspicion before it is properly diagnosed. Physical exam findings, including thoracic bruising, fractured sternum, murmur, jugular venous distention, and hemodynamic shock, should all raise the possibility of cardiac injury.

Myocardial contusion is the most common injury in those patients who arrive in the emergency room following blunt thoracic trauma. Although myocardial contusion remains a poorly defined entity, the presentation is typically one with stable cardiac arrhythmias. Additional problems include valvular rupture, thromboembolism, ventricular aneurysm, and constrictive pericarditis. The initial workup includes an ECG. There is little use for serial cardiac enzymes. Patients with persistent rhythm disturbances, ECG changes, or hemodynamic lability should undergo a transthoracic echocardiogram to exclude functional or structural abnormalities. Traditionally, the prognosis of patients with myocardial contusion is excellent.

Valvular injuries, while rare, most commonly involve the aortic valve, followed by the tricuspid and mitral valves. This usually presents with a new systolic murmur. Most patients present with a tear of the noncoronary leaflet. These injuries can usually be managed conservatively and present for elective repair. Symptoms suggesting acute aortic insufficiency, including dyspnea, arrhythmia, and heart failure, mandate urgent surgical intervention. Rarely can the valve be salvaged, and most patients undergo valve replacement.

Cardiac rupture is perhaps the most dramatic presentation of BCI. Free rupture at the time of initial trauma is usually not survivable, and many of those patients die in the field. Those who survive to the emergency room often show evidence of pericardial tamponade and, less commonly, of hemothorax. In decreasing order of frequency, survivors sustain injury to the right atrium, left atrium, right ventricle, and left ventricle. The key to survival is rapid diagnosis and resuscitation. Operative repair is mandated and most effectively achieved via median sternotomy. Cardiopulmonary bypass can be used, but this is rarely needed for most injuries. Most injuries can be repaired primarily.

Ventricular aneurysms most commonly occur along the anterolateral wall of the left ventricle. They usually occur in a delayed fashion and are the result of myocardial injury with resultant necrosis and scarring. Findings of recurrent arrhythmias, heart failure, or embolic events may occur months to years after initial injury. Treatment includes surgical resection and/or plication of the aneurismal segment of the ventricular wall.

Coronary artery injury from blunt chest trauma is exceedingly rare. The vessel most commonly injured is the left anterior descending artery. Most commonly, intimal disruption and dissection results in a thrombosed vessel with distal ischemia. Laceration or rupture of the coronaries with resultant tamponade has also been reported. Asymptomatic patients can be managed conservatively. Many proximal injuries can be managed in the catheterization lab with balloon angioplasty or stent deployment; those that cannot often proceed to coronary artery bypass grafting.

More than 75% of patients with BCI will have associated thoracic injuries, including rib and sternal fractures, pulmonary contusions, pneumothorax, hemothorax, and great vessel injury. Moreover,

extrathoracic injury is commonly encountered in patients with BCI, including closed head injury (20% to 73%), extremity injury (20% to 66%), solid abdominal organ injury (5% to 43%), and spinal injury (10% to 20%).

The American Association for the Surgery of Trauma (AAST) Organ Injury Scale for cardiac injuries describes six injury grades, from minor ECG abnormalities to avulsion of the heart (Table 1).

TABLE 1: American Association for the Surgery of Trauma organ injury scale: cardiac injuries

Grade*	Cardiac injury
I	Blunt cardiac injury with minor ECG abnormality (nonspecific ST-wave or T-wave changes, premature atrial or ventricular contraction, or persistent sinus tachycardia) Blunt or penetrating pericardial wound without cardiac injury, cardiac tamponade, or cardiac herniation
II	Blunt cardiac injury with heart block or ischemic changes without cardiac failure Penetrating tangential cardiac wound, up to but not extending through endocardium, without tamponade
III	Blunt cardiac injury with sustained or multifocal ventricular contractions Blunt or penetrating cardiac injury with septal rupture, pulmonary or tricuspid incompetence, papillary muscle dysfunction, or distal coronary artery occlusion without cardiac failure Blunt pericardial laceration with cardiac herniation Blunt cardiac injury with cardiac failure Penetrating tangential myocardial wound, up to but not through endocardium, with tamponade
IV	Blunt or penetrating cardiac injury with septal rupture, pulmonary or tricuspid incompetence, papillary muscle dysfunction, or distal coronary artery occlusion producing cardiac failure Blunt or penetrating cardiac injury with aortic or mitral incompetence Blunt or penetrating cardiac injury of the right ventricle, right or left atrium
V	Blunt or penetrating cardiac injury with proximal coronary artery occlusion Blunt or penetrating left ventricular perforation Stellate injuries, less than 50% tissue loss of the right ventricle, right or left atrium
VI	Blunt avulsion of the heart Penetrating wound producing more than 50% tissue loss of a chamber

ECG, Electrocardiogram.

DIAGNOSIS

There is no gold standard test to diagnose BCI. Initial evaluation should include a thorough physical examination and trauma resuscitation as defined by the American College of Surgeons Advanced Trauma Life Support (ATLS) program. ECG should be the first screening tool to rule out evidence of arrhythmia or ischemia. In the resuscitation bay in experienced hands, focused assessment with sonography for trauma (FAST) can aid in diagnosis and risk stratification for patients. It can quickly aid in the diagnosis of tamponade and give some idea about ventricular function. If an abnormality is suspected, a formal transthoracic echocardiogram should be obtained.

The Eastern Association for the Surgery of Trauma established practice guidelines for blunt cardiac trauma after an extensive literature review (Box 1). It encourages the use of ECG as an initial screening tool for suspected BCI. Further workup, including transthoracic echocardiogram and admission with continuous cardiac monitoring, should be reserved for those individuals with demonstrated ECG abnormalities. Their recommendations also argue against serial cardiac enzymes, nuclear medicine studies, and the like, as they have never been shown to alter management or change outcomes.

BOX 1: EAST practice management guidelines for blunt cardiac injury workup

Recommendation Level I

1. An admission ECG should be performed on all patients in whom a BCI is suspected.

Recommendation Level II

1. If the admission ECG is abnormal (arrhythmia, ST changes, ischemia, heart block, unexplained ST changes), the patient should be admitted for continuous ECG monitoring for 24 to 48 hours. Conversely, if the admission ECG is normal, the risk of having a BCI that requires treatment is insignificant, and the pursuit of diagnosis should be terminated.
2. If the patient is hemodynamically unstable, an imaging study (echocardiogram) should be obtained. If an optimal transthoracic echocardiogram cannot be performed, the patient should have a transesophageal ECG.
3. Nuclear medicine studies add little when compared with ECG; thus, they are not useful if an ECG has been performed.

Recommendation Level III

1. Elderly patients with known cardiac disease, unstable patients, and those with an abnormal admission ECG can be safely operated on provided they are appropriately monitored. Consideration should be given to placement of a pulmonary artery catheter in such cases.
2. The presence of a sternal fracture does not predict the presence of BCI and thus does not necessarily indicate that monitoring should be performed.
3. Neither creatinine phosphokinase with isoenzyme analysis nor measurement of circulating cardiac troponin T is useful in predicting which patients have or will have complications related to BCI.

TREATMENT

The treatment of BCI is dictated by the presumptive injury and the hemodynamic status of the patient (Figure 1). Unstable patients need immediate resuscitation with treatment of the underlying problem, whether it is shock, pneumothorax, tamponade, or other. In cases of hemodynamic stability with evidence of pericardial effusion, pericardiocentesis should be attempted until definitive management with operative window/sternotomy can be undertaken. For patients who are hemodynamically unstable and undergo witnessed cardiac arrest, some centers advocate resuscitative thoracotomy with a left anterolateral approach. The goal is to evacuate pericardial fluid, clamp the aorta, and temporize any injury until definitive surgical intervention can be undertaken. Survival is rare. In cases of prehospital cardiac arrest, resuscitative thoracotomy has never been shown to improve outcomes and thus is strongly discouraged. Complex valvular or coronary injuries should be repaired in the operating room through median sternotomy with the assistance of cardiopulmonary bypass.

Patients who are hemodynamically stable and present only with ECG changes or dysrhythmias should be monitored with continuous telemetry for at least 24 hours. A small subset of this population is at risk for lethal ventricular arrhythmias, usually in the form of ventricular fibrillation. Immediate defibrillation is the treatment of choice and has been shown to be lifesaving in nearly 25% of patients if performed expeditiously.

The long-term outcome of BCI has not been adequately studied, and longitudinal studies do not exist. In the acute setting, patients with isolated rhythm problems usually recover fully with no residual long-term effects. Those who undergo surgical intervention, provided their other injuries are non–life-threatening, enjoy good long-term survival anecdotally. Ultimately, it appears, patient survival and discharge to home are directly related to accuracy of diagnosis and rapid, definitive intervention.

Abdominal Compartment Syndrome and Management of the Open Abdomen

Nathan T. Mowery, MD, FACS, Preston R. Miller, MD, FACS, Michael C. Chang, MD, FACS, and J. Wayne Meredith, MD, FACS

Understanding the pathophysiology of abdominal compartment syndrome (ACS) and the management of the subsequent open abdomen has proven to be a lifesaving advance in acute care surgery. Patients with a variety of abdominal and nonabdominal pathology are at risk for the development of ACS. The syndrome produces significant cardiopulmonary and renal derangements. The bleeding or edema that mandates decompressive laparotomy in the face of ACS may also make abdominal closure untenable for days to weeks. The care of patients with ACS requires three critical judgments: early recognition and intervention for ACS, timing and location of subsequent operations, and techniques to be used in closure of the patient. The formulation of a plan to address these branch points ultimately determines the mortality of the patient and can significantly impact the morbidity associated with the ACS. From the moment the surgeon decides to pursue decompressive laparotomy, a plan must be formulated that includes definitive repair and closure of the patient.

PATHOPHYSIOLOGY OF ABDOMINAL HYPERTENSION

Abdominal hypertension develops on a scale with increasing extraabdominal manifestations as the pressure increases. The detrimental effects of increased intraabdominal pressure (IAP) have been well described in several populations of surgical patients. The relationship between oliguria, acute renal failure, and increased IAP has also been well characterized. Increased IAP has been shown to compromise blood flow to both the portal and the splanchnic circulatory systems. The development of increased IAP in surgical patients thus has profound detrimental effects on virtually all important organ systems and therefore dramatic effects on outcome. This syndrome of the adverse physiologic consequences that occur as a result of acute increases in IAP has been called the abdominal compartment syndrome.

It is important to recognize that intraabdominal hypertension (IAH) and ultimately ACS come from visceral and retroperitoneal edema from poor or late source control of bleeding, dead or injured tissue, or infection. Overadministration of any type fluid, in the absence of poor source control, does not result in ACS (Box 1).

RECOGNITION OF ABDOMINAL COMPARTMENT SYNDROME

The early recognition and treatment of ACS is the most critical step in the dealing with this pathology. Early identification of ACS can avoid many of the late complications that result from avoiding the perfusion/reperfusion injuries. Abdominal hypertension decreases venous return, increases systemic vascular resistance and intrathoracic pressure, and therefore reduces cardiac output. These physiologic responses to increased intraabdominal pressure lead to some of the earliest signs of ACS.

Physical examination is the first hallmark of abdominal hypertension. Patients with large resuscitations with development of significant abdominal girth or tightness must be considered for ACS. Conversely patients who have a pliable abdomen do not have ACS and should be evaluated for alternative causes of clinical deterioration. ACS was initially described as a cause of respiratory failure. Patients with rising ventilator peak airway pressures (or falling volumes on pressure-control ventilation) should be considered for ACS. Unexpected response to resuscitation is another indication of ACS. Because there is restriction of cardiac output, patients with ACS are often misdiagnosed as hypovolemic and given more fluid. This has the possibility of worsening the abdominal hypertension. Unfortunately, intraabdominal hypertension has a profound effect on measured values of preload, such as right ventricular end-diastolic volume, pulmonary artery wedge pressure, and central venous pressure. Also, blood flow to the liver and kidney may be reduced, resulting in functional impairment of both organs. Identification of abdominal hypertension from low urine output means warning signs that have been present for some time have been missed.

Another important facet of the treatment of ACS is the recognition for the potential for development. Surgical intervention can often mark the beginning of patient's resuscitation with the potential for bowel and retroperitoneal edema to follow. Surgeons must consider the tension created by definitive closure and anticipate the potential resuscitation that follows. Patients with hypotensive conditions that require vasopressors at the end of the initial laparotomy must be carefully considered for staged surgery. The best treatment for ACS is avoidance.

MEASUREMENT OF INTRAABDOMINAL PRESSURE

IAP can be measured with direct and indirect methods. Direct measurements are relegated to laboratory studies currently. Multiple means for indirect measurement have been used, but the most common is urinary bladder pressure. This simple minimally invasive method can be easily performed at the bedside because the bladder behaves as a passive diaphragm when its volume is between 50 and 100 mL. Pressure measurements in animals recorded simultaneously through a urinary bladder catheter and directly via peritoneal catheters were equal for pressures ranging from 5 to 70 mm Hg. Evidence has shown that instilling the bladder with 50 mL of sterile water creates pressures where intraabdominal pressure is closest to intravesicular pressure. The Foley catheter is then clamped, and the pressure is transduced via the port of the Foley catheter. The manner with which abdominal pressure is measured can be either intermittent or continuous. Some evidence shows that continuous, or at least more frequent intervals (every 1 hour) of, monitoring in high-risk groups can lead to earlier recognition of abdominal hypertension. The effect that this earlier recognition has on outcome is still being determined. Consideration should be given to prophylactic bladder pressures in a group of patients at high risk (Box 2).

TREATMENT OF ABDOMINAL COMPARTMENT SYNDROME

The surgeon must take in the entire clinical picture before deciding when to intervene for abdominal hypertension. In general, 20 mm Hg is used as a number where physiologic changes occur that require consideration for decompression. If patients have exceeded that number and are beginning to manifest other symptoms of ACS, then

BOX 1: Grades of severity

Mild abdominal hypertension: Acute sustained elevation of intraabdominal pressure above 10 to 20 mm Hg. Physiologic effects are generally well compensated and usually clinically nonsignificant. Nonoperative therapy may be required.
Moderate hypertension: Sustained elevation of 21 to 35 mm Hg. Therapy is generally necessary. Surgical abdominal decompression may be critical.
Severe hypertension or *abdominal compartment syndrome:* Sustained elevation above 35 mm Hg. Operative decompression is almost always indicated.

BOX 2: Factors that put patients at high risk for development of abdominal compartment syndrome

1. More than 10 units of blood products or 10 L of crystalloid resuscitation needed.
2. Pelvic fracture with retroperitoneal hematoma.
3. More than 30% burns.
4. Pancreatitis.

decompression should be strongly considered. This number is not an absolute though. There is no role for mandatory decompression in patients with otherwise stable conditions that reach the 20 mm Hg threshold. One must examine all the data available, such as physical examination, respiratory status, vital signs, and fluid responsiveness. If all those data point toward ACS, then decompression should follow.

Although the recognition of ACS can have subtle variances, the treatment is straightforward. Decompression laparotomy is the gold standard for patients with ACS. Decompression has been shown to improve preload, pulmonary function, and visceral perfusion in patients with ACS. The lack of a recent laparotomy should not influence the decision to proceed with decompression. It is well documented that patients without primary abdominal pathology can have ACS develop. Decompression should follow the diagnosis of ACS with or without recent surgery.

Less invasive means have been described, such as paralysis, percutaneous drainage of ascites, and diuresis. These interventions should only be used in low-grade abdominal hypertension or when extreme circumstances exist. Such circumstances might be in patients whose conditions are so frail that the family does not wish to pursue more aggressive interventions.

Decompression requires a full-length midline laparotomy incision. Lesser incisions may not adequately decompress the abdomen, leaving the question of persistent compression lingering. Unfortunately, the decompression surgery is usually the least technically challenging portion of operative interventions for this population. The sequential interventions that follow in an attempt to close the patient can test a surgeon's operative and clinical skills.

UNPLANNED REOPERATION

When the goals of the first phase of ACS treatment (recognition and decompression) fail, the surgeon must consider reexploration. Attending surgeons and house staff can be given a false sense of security with an open abdomen that the risk of ACS is not present. Often after decompression, patients require significant ongoing resuscitation that puts them at risk for tertiary compartment syndrome. If a patient's clinical picture remains consistent with compartment syndrome, then the surgeon must consider the decompression inadequate or the means of temporary abdominal closure too effective.

TEMPORARY ABDOMINAL WALL CLOSURES

Once the patient has undergone adequate decompression, an immediate plan for the eventual closure must begin to be formulated. A variety of temporary closure techniques have been advocated over time. Some simply contain the abdominal viscera and protect them from further injury. Other techniques have the advantage of preserving abdominal domain while still allowing room for expansion if required. Finally, some techniques allow for the recruitment of domain as the patient's physiology allows. The authors use the abdominal vacuum dressing for that very reason. Not only does it protect the viscera, but as the edema resolves, the vacuum can shrink to continually recover lost abdominal domain. Other dressings (Whitman's patch, Bogata bag) can also be adjusted to regain domain but necessitate physician intervention on a regular basis. Whatever dressing is chosen, it must not recreate the abdominal hypertension that was just released.

ABDOMINAL WALL RECONSTRUCTION

During reoperation, the surgeon should consider each time whether the patient can be safely closed. This is predicated on the determination of the amount of tension on the abdominal wall. A variety of ways can be used to determine whether the amount of tension created will be excessive and lead to complications. The key is to make use of all information that is readily available in the operating room or at the bedside. Although no technique has been validated with research, many surgeons use the change in the patients peak airway pressure (PAP) as a means of determining tension. Most anesthesia machines and bedside ventilators report a constant PAP, and if the change is greater than 10 mm Hg in approximation of the fascia, too much tension exists to proceed with closure. If undue tension is created with approximation, then a temporary method of closure must be applied again.

Planned Reexploration

The timing of reexploration is important. Traditional thinking was usually that a time period of 3 to 5 days should elapse before reexploration, with the thought that correction of physiology was not possible in less time. The timing can be tailored for each individual patient. Patients whose conditions are still physiologically altered may benefit from space between interventions and the minimized stress on the patient. Other patients who recover quickly do not have to wait for 3 days to pass before going back to the operating room (OR). Recognition of these patients should be based on the patient's current clinical picture. The degree of initial injury is not always predictive of a patient's physiologic derangement.

Control of contamination is another cornerstone of open abdomen management. Each time the abdomen is explored, an attempt to irrigate to decrease bacterial counts should be made. The surgeon should use these windows into the abdomen to evaluate contamination, hemostasis, and degree of inflammation, all of which play key roles in determining progression to the next stage of the plan, reconstruction.

Surgeons should balance the desire to see all portions of the bowel with avoidance of injury to the bowel at the time of surgery. Once the bowel becomes adherent to itself, there should be an effort to minimize disruption of these new adhesions. This is especially true when anastomosis is present. Serosal injuries and traction injuries can occur at anastomosis and have the potential to lead to fistula, which significantly complicates any open abdomen.

Where Should Abdominal Washouts Occur?

The location chosen to perform bedside washout is highly dependent on the resources available to the surgeon. In patients in whom definitive closure is clearly not possible, a bedside washout can be faster, place less stress on the patient, and protect vital OR time. These benefits must be weighed with the intensive care unit (ICU) resources and the fact that each intervention should provide the patient with the best opportunity to work toward definitive closure. If the bedside intervention will inhibit the ability to adequately place a partial closure or adequate dressing, then it should not be considered. Bedside intervention can only be done if bedside laparotomy protocols have been developed and practiced in advance. Issues that may necessitate bedside reexploration include high ventilatory requirements, hemodynamic instability that precludes transport, and unstable intracranial hypertension. Bedside surgery has the following limitations: inadequate lighting, a substerile environment, absence of trained personnel, and limited surgical instruments. In the end there lacks a defined criteria which preclude patient transport the decision falls on clinical judgment to guide the surgeon, but they should feel confident that bedside laparotomy is proven technique that is commonly practiced at a variety of centers.

When to Abandon Attempts at Definitive Closure?

Patients should undergo assessment at the time of each abdominal exploration, with the goal of working toward expedited primary facial closure. Miller and associates were able to show a marked increase in the risk of associated complications if the abdomen was unable to be closed within 8 days. Twenty-two of 185 patients (12%) in whom the fascia closed in 8 days or less had a complication develop, whereas 47 of 91 patients (52%) with closure after 8 days had a complication develop.

A variety of factors impacts this 8-day goal and affects the long-term success of the closure. Early recognition of ACS can lead to better long-term outcomes. Addressing abdominal hypertension before physiologic exhaustion helps to avoid the perfusion-reperfusion injuries that lead to bowel edema that inhibits definitive abdominal wall closure during the hospital stay.

Preservation of the integrity of the fascia is important leading up to the time of closure. In the evolution of damage control surgery, a variety of techniques have been used for temporary closure of the abdomen. Many of these techniques involved direct suturing or fastening of material to the patient's fascia. Although these techniques met the short-term needs of maintaining abdominal domain, the repeated manipulation of the fascia led to decreased strength and increased morbidity.

Some authors have used this increase in complications in late closure to advocate that attempts at definitive closure should be abandoned at that time and closure with a planned hernia proceed. Although an increase in complications may be seen after 8 days, the authors advocate that one should still continue trying to work toward abdominal closure after that time has passed. With the use of negative-pressure vacuum dressings, success has occurred with late closure, up to 49 days. Complications usually associated with late closure, such as hernia and fistula development, are low, and the complications with a second intervention are avoided. At the authors' institution, an adaptation of the negative-pressure dressing described by Barker and colleagues is used. A sponge vacuum is substituted for the towels, and the skin is closed over top of it. The system preserves the abdominal domain. The authors' own institutional experience has shown an abdominal closure rate in patients undergoing vacuum-assisted closure of 88%, with a mean time to closure of 9.5 days.

Vacuum-Assisted Closure Technique

With this method, the polyethylene sheet is perforated, placed over the viscera, and tucked under the wound edges (Figure 1). The surgeon should make every attempt to place the sheet into the gutters of the abdomen to allow the anterior abdominal wall complete mobility to "slide" to the midline. The polyurethane sponge is then placed over the plastic sheet, pushing the viscera down, and tightly laced into place with 1-0 nylon suture on the skin edges (Figure 2). The surgeon should pass the needle from the inside out, rather than use a normal baseball stitch, to avoid sewing toward the bowel. After the sponge is assured to be in contact with the full thickness of the wound edges, the surrounding skin is coated with benzoin, and suction tubing and adhesive dressing (Ioban, 3M) are applied. After an occlusive seal is obtained, suction is applied (Figure 3). This causes the sponge to apply tension to the full thickness of the wound edges, including the abdominal fascia. After suction is applied, the sutures no longer have tension on them.

Vacuum-assisted fascial closure differs from these and other techniques in that it prevents both fascial retraction and visceral adherence, allowing for continuing attempts at abdominal closure several weeks after laparotomy. This is an extension of the standard vacuum pack technique and has two important components that allow for later closure. The first is the perforated polyethylene sheet placed over the bowel. This must be tucked under the fascial edges to prevent adherence. The second is the thick polyurethane sponge, as opposed to the surgical towel used in the original technique. This provides suction to the cross section of the abdominal wall, preventing fascial retraction by creating constant medial tension on the fascia without injuring it, as some similar techniques with suture might. These two features likely account for the higher closure rate seen with this technique and reduce the need for future hernia repair (Figures 4 and 5).

Adjuvants to Late Closure

Also important is the need to supplement the patient's nutrition to prevent a catabolic state from developing in an already stressed patient. Traditionally, patients with an open abdomen were fed via a parenteral route because physicians assumed decreased bowel

motility and absorption would be present with an open abdomen. Collier and associates were able to show that enteral feedings with an open abdomen were safe and could lead to decreased bowel wall edema and early closure of the abdomen.

Also paramount to the ability to close the patient is the overall fluid status of the patient. Although the appropriate means of resuscitation of a trauma patient are outside the bounds of this chapter, careful balancing of the patient's fluid status can greatly affect the success rate of closure. Early resuscitation efforts based on invasive hemodynamic monitoring have been shown to result in earlier correction of acidosis, coagulopathy, and hypothermia and in improved mortality. This could result in less interstitial edema and in higher success rates of abdominal closure.

Other authors have explored the concept that active diuresis can increase the success of closure. Diuresis has been said to be aided by the addition of albumin in the classic "push/pull" method. This combination has shown to be successful in removal of fluid in other populations (ARDS) but has not been validated in the open abdomen population.

The patient's physiology often dictates the rate of transfusions, but evidence shows that a more restrictive transfusion strategy can lead to increased success in early abdominal closure. Transfusion of blood and blood products and crystalloid resuscitation are known causative factors in the development of the abdominal compartment syndrome. Patients must be given the appropriate resuscitation to maintain perfusion, but care must be taken to tailor the amount given to address the patient's current needs.

Another means to attempt to preserve abdominal domain has been the practice of maintaining chemical paralysis in between subsequent trips to the operating room with open abdomens. This practice stems from the belief that persistent contraction of the abdominal musculature in the nonparalyzed patient can lead to retraction of the fascia and abdominal musculature. No good evidence has been shown to support the standard use of paralytics, and often in this complex patient population, the usage may subject these patients to additional risks of hypercoagulability, positioning, and long-term polyneuropathy.

In the end, the ability to close these patients falls on the shoulders of the surgeon. No amount of monitoring or strategy can substitute for an attentive surgeon who is constantly reassessing the patient and asking the question of whether the patient is ready for definitive closure. Although a variety of objective means can be applied, they only augment the physician in developing a plan for closure that both meets the patient's current needs and looks to avoid possible pitfalls that may develop in the patient's course, with adaptations when they do develop.

FAILURE TO ACHIEVE PRIMARY CLOSURE

There is no definitive maximal time for closure of a patient. The morbidity of a planned hernia should not be assumed lightly. A second operation at a remote date carries its own complications and disruption to patient recovery. Conversely, the serial "take backs" cannot continue indefinitely. The patient's progress often dictates the upper limit of when delayed primary closure will be attempted. When a patient's condition has progressed to the point that the sole reason for reintubation and continued critical care is the open abdomen, it is time to find an alternative means of closure. This allows patients to continue to progress in their recovery. Alternative closure may take many forms, such as native tissue, biosynthetic meshed implants, and absorbable mesh. Each of these closure methods has positive and negative aspects. Surgeons who frequently deal with this patient population should be experienced with multiple methods to allow tailoring of each patient's care.

TYPES OF DEFINITIVE ABDOMINAL CLOSURES

Modified Component Separation

Component separation (CS) uses a sliding myofascial flap to provide tension-free closure of large abdominal wounds without implantation of mesh. This allows for a vascularized tissue to be brought together with little or no tension. Care must be taken with this option because of the large scope of the operation.

Permanent Mesh (Polypropylene Mesh, Polytetrafluoroethylene)

Authors have argued that polypropylene mesh placement is an effective alternative for abdominal closure after emergency laparotomy, even when intraabdominal sepsis is present. Fistula rates as low as 7.1% have been reported. However, more commonly, authors have argued that polypropylene mesh use in this setting has resulted in an unacceptably high complication rate that includes fistula rates up to 50%. Some authors have used polytetrafluoroethylene (PTFE) mesh as a temporary patch to prevent evisceration and allow for the development of granulation tissue to serve as a bed for STSG. Its advantages are that it is relatively poorly incorporated, allowing for easier removal if the need arises. All permanent meshes can become infected and create a catabolic drain that can brew in an indolent manner for months. Although the short-term goal of abdominal closure is obtained, the long-term wound complications make the use of permanent mesh in this setting unacceptable when alternatives exist.

Polyglycolic Acid Mesh (Vicryl)/Split-Thickness Skin Graft

Most patients in the literature who cannot be primarily closed undergo abdominal closure with polyglycolic acid mesh with subsequent split-thickness skin grafting before leaving the hospital. Healthy granulation tissue occurs within about 7 to 10 days of insertion. However, the mesh itself usually is not incorporated tightly. Recent studies on abdominal closure in the open abdomen in trauma report an overall enterocutaneous fistula rate of 7% to 8%.

Biosynthetic Reconstruction

New biosynthetic meshes available on the market now have the advantage of the ability to be placed in the contaminated wound. Authors have shown success with only minor superficial wound infections in the early application of biosynthetic meshes to open abdomens when closure is not possible. Some questions have arisen about the long-term durability of this type of mesh. Some degree of bulge is accepted if the mesh is used to span a gap in the fascia. As long-term data continue to accumulate for the use of this biosynthetic mesh, its applications and its efficacy continue to be more accurately described. Cost also plays an important role. Some risk is assumed with placement of such an expensive option in a wound that may not be suitable for definitive closure.

A word of caution is warranted. Although a definitive closure is appealing, the patient's physiologic status must weigh heavily on the decision-making process. A catabolic patient with poor nutrition is not a good candidate for wound healing, regardless of the technique used. Patients must be ready to undergo the scope of operation and healing of the wound after surgery. If a patient is not metabolically ready for such a large scale intervention, a smaller less definitive solution may be the safer and more economic choice.

SPECIAL SITUATIONS IN DAMAGE CONTROL SURGERY

Fistulas in the Open Abdomen

Despite attention to detail and vigilant surveillance, situations arise in staged surgery, including fistula formation. The best plan for dealing with fistula formation is prevention of development. Techniques that can decrease the rate of formation include early closure, protection of the bowel, avoidance of permanent mesh, and burying of the anastomosis.

Early closure has been shown to decrease fistula formation. Measures to protect the bowel include use of bowel bag and decreased manipulation of the bowel on subsequent washouts. Also, the type of closure technique can have a dramatic impact on fistula rate. Studies have shown that use of absorbable mesh as discussed previously can reduce the fistula rate when compared with permanent mesh. The risk for fistulas occurs whenever a nondynamic mesh material is sewn to dynamic abdominal wall. This creates mechanical stress where sewn together, and if the bowel is stuck underneath (as it almost always is), then this increases risk for fistula.

The treatment of fistulas in the open abdomen follows the same tenants of surgery in other situations. The primary goal is to isolate the output and decrease the flow through the output. Isolation can be complicated by the fact that repeated washouts and dressing changes can disturb the body's attempt to wall off the collection. Also, the fact that these abdomens often progress to a "cocooned" appearance can make intervention problematic. Fortunately, the best plan is usually the simplest, meaning simple drainage. Attempts to resect or repair fistula in the hyperinflammatory setting usually lead to worsening of the problem, unless attempts are made very early in the process.

Ostomy in the Open Abdomen

In a variety of illnesses, surgeons are faced with dealing with both an open abdomen and an ostomy. Although ostomies can make dressing changes and care a challenge, they often are the safest option for the patient. The ostomy itself can sometimes be an obstruction to sequential closure. The ostomy can fix the underlying viscera to the abdominal wall, which restricts the medial slide of the abdominal wall necessary for delayed primary closure. When creating ostomies in patients with a planned hernia, surgeons should consider a more lateral placement of the ostomy. Although it increases the chances of a peristomal hernia, placement of the ostomy lateral to the rectus sheath preserves important planes, making component separation more efficacious.

CONCLUSION

The management of the open abdomen does not stop once the initial life-saving decompression occurs, but this marks the beginning of what often becomes the most complex portion of the patient's care. The postoperative decisions have a dramatic impact on the morbidity and mortality of the patient. Although algorithms and advice can help guide the surgeon in making decisions, nothing can replace a vigilant surgeon's reassessment of the patient and adaptation to changes in the patient's physiology and presentation. When an individually tailored approach is taken, this patient population can be safely navigated through the course with improved outcomes without long-term morbidity. Although this surgical approach is associated with a significant complication and readmission rate, its long-term survival and benefit are indisputable.

Blood Transfusion Therapy in Trauma

Terence O'Keeffe, MD, FACS, and Peter Rhee, MD, MPH, FACS, FCCM

INTRODUCTION

Many of the advancements in trauma surgery can be linked to periods of conflict, such as World War II and the Vietnam War. The past decade has seen similarly rapid changes that have taken hold in transfusion therapy—changes related, at least partly, to the treatment of casualties from Middle East conflicts. The concept of so-called 1:1:1 blood transfusion, where each unit of red cells is accompanied by a unit of plasma and a unit of platelets, has rapidly diffused from military practice into civilian hospitals. This concept has gone by many names, but it is now commonly referred to as "hemostatic" or "damage control" resuscitation, and includes the following tenets:

1. permissive hypotension,
2. early use of blood and blood products,
3. minimization of crystalloids,
4. use of hypertonic saline,
5. use of drugs such as tranexamic acid, factor 7 or 9, and
6. the use of whole blood if available.

Its application has been associated with improved mortality and morbidity rates, as well as with decreased resource utilization. Such benefits have been the subject of intense research activity, yielding some evidence on which to base these therapies; however, given the often retrospective nature of the data, the issue of survivor bias remains ever-present.

BLOOD COMPONENTS

Current civilian practice is to fractionate blood into its component parts. Doing so enables clinicians to target specific defects within an individual patient's hematologic profile, thus maximizing the potential benefit from a single donated unit of whole blood. However, for trauma patients, this practice is less than ideal.

In the recent Middle East conflicts, fresh whole blood has been used successfully by the U.S. Military because of the military's ability to access a "walking blood bank" (i.e., obtaining fresh donations from a previously screened group of individuals whose blood type is already known). Use of this fresh whole blood has been credited with helping reduce the incidence of mortality from the serious penetrating injuries that have been characteristic of these conflicts. Whole blood is rarely used in civilian settings, especially because refrigeration inactivates the platelets but also because data providing the effectiveness of refrigerated whole blood is currently lacking. Although a feasibility study of the use of whole blood in civilian trauma patients was recently completed, the results are not yet available.

Predominant practice in most blood banks involves fractionating a unit of blood into packed red blood cells (PRBCs); plasma, which is subsequently frozen and designated as fresh frozen plasma (FFP); platelets; and cryoprecipitate (Figure 1). Specific-component therapy can be highly useful. For example, most patients with anemia do not have a coagulopathy and therefore can be treated with PRBCs alone. Conversely, coagulopathic patients, such as those with a warfarin overdose, do not require PRBCs but rather need to be treated with FFP alone. Patients with hematopoietic disorders such as leukemia frequently have thrombocytopenia, and this can be treated with specific-component therapy with platelet transfusion alone.

Stored in a variety of citrated buffers, PRBCs have a shelf life of either 35 days if citrate-phosphate-dextrose-adenine solution is used or 42 days if additive solution is used. Transfusion of PRBCs is indicated for patients with ongoing, acute blood losses and for patients symptomatic from their anemia. The average unit of PRBCs has a hematocrit of about 80%, which will usually raise the hemoglobin level by 1 g/dL or the hematocrit by 3%. The decision for transfusion should NEVER be based on a number from a blood test alone.

Stored frozen at −18° C, FFP can be kept this way for up to a year. It contains varying amounts of fibrinogen, von Willebrand factor, and coagulation factors I, VII, VIII, IX, X, and XIII. FFP is indicated for the reversal of either acquired or congenital coagulation defects, as well as for the reversal of anticoagulant agents. For stable, nonbleeding patients, FFP should never be used to correct abnormal coagulation tests alone (e.g., per the international normalized ratio [INR]).

Stored at room temperature on a gentle shaker, platelets have a shelf life of only 5 days and are tested daily for bacterial contamination. They are a precious commodity and should be used extremely judiciously. They may be collected in two ways: (1) from random donors, yielding a volume of about 50 mL, that is, 5×10^{10} platelets; or (2) from a single donor by apheresis, yielding a volume of 200 to 250 mL, equivalent to 5 to 8 random units, that is, a minimum of 3×10^{11} platelets. Accepted transfusion triggers for platelet transfusion are shown in Table 1.

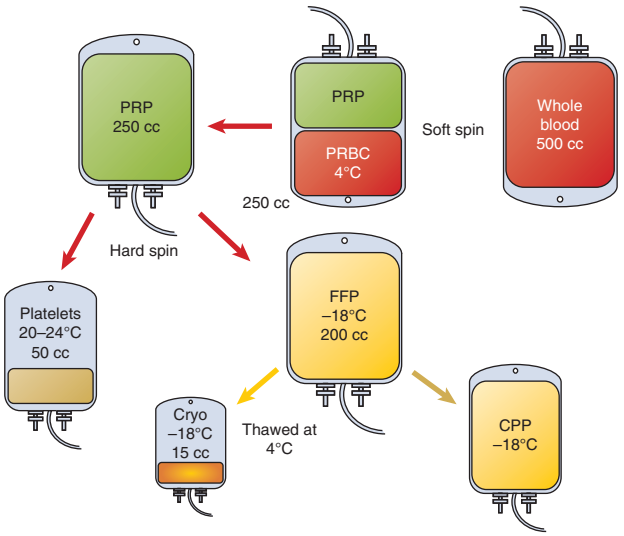

FIGURE 1 Fractionation of whole blood into its components for storage. *CPP,* Cryoprecipitate-poor plasma; *FFP,* fresh frozen plasma; *PRBC,* packed red blood cell; *PRP,* platelet-rich plasma. *(Courtesy of Dr. Ravi Sarode, Blood Bank Director, Department of Pathology, UT Southwestern Medical Center, Dallas, Tex..)*

Cryoprecipitate is so named because it is the cold-insoluble portion of FFP that precipitates out of solution when FFP is slowly thawed at 1° C to 6° C. It contains clotting factors from a single donor that are then suspended in 10 to 15 mL of plasma. Each unit contains a minimum of 80 IU of factor VIII and at least 150 mg of fibrinogen, in addition to significant amounts of von Willebrand factor, factor XIII, and fibronectin. It is stored frozen at −18° C until needed; it is then stored at room temperature after thawing. It has a short shelf life: it must be transfused within 6 hours of thawing and 4 hours of pooling, if pooling is performed.

Cryoprecipitate is available in prepooled concentrates of five units. Each unit from a separate donor is suspended in 15 mL plasma prior to pooling. Cryoprecipitate is indicated for bleeding or immediately prior to an invasive procedure in patients with significant hypofibrinogenemia (<100 mg/dL). It has been used in some massive transfusion protocols, but this is by no means universally accepted.

In most U.S. blood banks, although it remains controversial, leukoreduction has become the standard of care. It has been extensively studied but with contradictory results regarding its benefit to patients. Leukoreduction refers to an extra process that PRBCs go through to wash out and specifically remove any white blood cells. Doing so is thought to reduce the risk of complications to transfusion recipients by decreasing their exposure to the donors' humoral immune system.

Similarly, concerns have been raised about the use of older banked blood, especially considering the storage issues that occur with prolonged storage of PRBCs. Some storage problems, such as loss of 2,3-diphosphoglycerate (2,3-DPG) and loss of adenosine triphosphate (ATP), are rapidly corrected after transfusion back into a patient, whereas others, such as loss of membrane lipids, are irreversible and lead to decreased survival of the transfused PRBCs (Figure 2). These concerns have led to recommendations (not universally adopted) that patients with critical conditions, such as hypoxia, receive only "fresh" blood (i.e., <7 days old).

Trauma patients who need blood transfusions must be clearly separated into two groups: (1) those who are actively bleeding and (2) those who are no longer bleeding but remain critically ill in the intensive care unit (ICU). For patients who are actively bleeding, hemostatic resuscitation is critically important. We will cover the concept of massive transfusion, or hemostatic resuscitation, in more detail later in the chapter.

For ICU patients who are no longer bleeding, transfusing less blood appears to be better. That idea was first promulgated in 1999 with the Transfusion Requirements in Critical Care (TRICC) trial, which compared a restrictive transfusion strategy (maintaining

TABLE 1: Platelet transfusion triggers

Clinical condition	Platelet count per microliter
Stable heme/oncology	10,000
Complicated oncology	>20,000
Minor surgery	25-50,000
Major surgery	>50,000
Neurosurgery	100,000
Platelet dysfunction: congenital or acquired	As clinically indicated

hemoglobin levels between 7 and 9 g/dL) to a more liberal strategy (10 to 12 g/dL). According to that trial's results, the two strategies were equivalent in terms of survival rates, although better survival rates were found in younger patients (<55 years old) and in patients with lower Acute Physiology and Chronic Health Evaluation-II (APACHE II) scores (<20). The finding of similar survival rates with restrictive and liberal strategies has led to a lowering of the transfusion trigger in most institutions and to a general abandonment of the essentially arbitrary 10/30 rule (i.e., transfusing patients to 10 g/dL or to a hematocrit of 30%).

More recent studies looking at restrictive transfusion strategies in patients with cardiac risk factors who were anemic after hip surgery, or in patients with gastrointestinal bleeding, have confirmed the TRICC trial's findings. Healthcare organizations, in general, are moving toward controlling transfusions where clear evidence of benefit is lacking, thus helping alleviate blood supply concerns and decreasing the risk of complications.

AUTOLOGOUS BLOOD TRANSFUSIONS

Autologous blood transfusions once comprised as many as 6% of the units of blood transfused, but this practice has largely fallen out of favor. Reasons include the difficulties associated with storage and the need to ultimately discard many of these units. Moreover, autologous blood transfusions are of limited use in trauma patients, for whom the need for transfusions is usually unpredictable.

ACUTE COAGULOPATHY

Many studies have demonstrated that up to a third of trauma patients arrive at the hospital with an established coagulopathy, which significantly increases both the mortality rate (by up to 4 times) and the morbidity rate. Many patients were not receiving enough coagulation factors to be adequately treated for coagulopathy. Mathematic modeling has been used to ascertain the perfect "ratio" of FFP to PRBCs: the ideal ratio appears to be about 1 to 1.5 units of FFP to each unit of PRBCs. Multiple retrospective studies appear to corroborate that low ratios of FFP to PRBCs are detrimental, even though the exact ideal ratio remains controversial.

MASSIVE TRANSFUSION AND MASSIVE TRANSFUSION PROTOCOLS

In patients who are bleeding, delays in obtaining the results of coagulation testing can lead to undertreatment, so most massive transfusion protocols use fixed ratios of blood products and do not include coagulation testing. Massive transfusion has been variously defined, but the two most common and useful definitions are as follows: a transfusion requirement of 10 or more units of PRBCs in a 24-hour period *or* the replacement by transfusion of the patient's entire circulating blood volume within 24 hours. Both definitions have been criticized as arbitrary and retrospective. Other triggers have been proposed, such as a critical administration threshold of the transfusion of 3 units of PRBCs within 1 hour. Notwithstanding the way that massive transfusion is defined, this subgroup of severely injured patients clearly represents a separate clinical entity from the vast majority of trauma patients. The incidence of patients requiring a massive transfusion varies from 1% to 3% of the trauma patient population, depending on the institution and the frequency of penetrating trauma.

TABLE 2: Massive transfusion protocol example

MTP cooler	PRBCs (units)	FFP (units)	Platelets (units)
1	6	6	1
2	6	6	1
3	6	6	—
4	6	6	1
5	6	6	—
6	6	6	1

FFP, Fresh frozen plasma; *MTP,* massive transfusion protocol; *PRBCs,* packed red blood cells.
Note: Each platelet unit is an apheresis pack—equivalent to 5 to 6 random donor platelets.

Again, much of the impetus for the 1:1:1 ratio came from data from the military, which pioneered work on massive transfusions because of the massive injuries sustained by combatants in Afghanistan and Iraq. The preponderance of explosive injuries with multiple amputations and severe blood loss led to implementation of both the fresh whole blood and the massive transfusion protocol. With the return of many of the U.S. Army surgeons to civilian centers, the pendulum swung toward the use of massive transfusion protocols in the most severely injured civilian patients throughout the United States. It is fair to say that this is one of the most avidly researched areas in trauma currently, in both civilian and military arenas.

The essential components of a massive transfusion protocol are as follows: (1) its automaticity (i.e., blood products are prepared without being specifically requested); (2) its ability to be activated 24 hours a day, 7 days a week, and in locations as diverse as the emergency department, ICU, operating room, and angiography suite; (3) its lack of requirements for blood testing; (4) its delivery of blood products in predefined ratios; and (5) its automatic continuation until halted by a physician. The protocol's precise form, components, ratio, and timing depend on the individual institution, although the vast majority of level I and level II trauma centers now have some type of massive transfusion protocol. An example is given in Table 2. A further refinement is noted in Figure 3, where each blood component unit is sequentially numbered, so that the surgeon and/or anesthesiologist has a visual aid (not only showing the number of units transfused but also allowing quick calculation of the PRBCs-to-FFP ratio).

A thawed plasma protocol can be an adjunct to a massive transfusion protocol. Once FFP is thawed, it can be kept refrigerated for up to 5 days with minimal loss (roughly 20%) of functional activity. Keeping thawed plasma in stock can rapidly reduce the amount of time taken to get it to the bedside. With careful attention to the stock,

thawed plasma can also be used for nontrauma purposes, in essence recycling it and preventing waste—a useful and cost-effective practice at many institutions.

Not all civilian authorities are convinced of the efficacy of the 1:1:1 fresh whole blood protocol. In fact, some have suggested that the increased dosage of FFP can lead to the development of transfusion-related acute lung injury (TRALI) and to multiple-organ dysfunction syndrome (MODS). Some studies have demonstrated that early transfusion of plasma is associated with MODS, with the greatest effect in patients who received less than 6 units of PRBCs. These troubling associations make the necessity of prospective randomized trials even greater. The best prospective data that we have currently come from the U.S. Department of Defense's PRospective Observational Multicenter Major Trauma Transfusion (PROMMTT) study. This study enrolled patients who received early initial transfusions and required at least 3 units of PRBCs in the first 24 hours. The trial showed that higher plasma-to-platelet ratios were associated with decreased mortality rates, without causing an increase in late deaths.

We hope that the ongoing randomized clinical trial now being conducted at 12 clinical sites across the United States and Canada—the Pragmatic, Randomized Optimal Platelet and Plasma Ratios (PROPPR) trial—will definitively answer this question, but results are unlikely to be available until 2014.

COAGULATION TESTING IN THE TRAUMA PATIENT

Trauma patients hemorrhage whole blood and therefore lose not only red blood cells (RBCs) but also platelets and coagulation factors. It is becoming increasingly clear that the results of current coagulation tests, such as prothrombin time (PT), INR, and partial thromboplastin time (PTT), are poor reflections of the rapidly changing blood profile in trauma patients, particularly those who are receiving multiple transfusions. Furthermore, most laboratory tests have a lag time of 40 to 60 minutes before results are available to clinicians, making interpretation even more difficult.

The thromboelastogram (TEG), although not as easy to interpret as a simple number such as the INR, is proving its utility both in research studies and in the clinical arena. Figure 4 shows an example of a TEG tracing. The TEG helps assess multiple different arms of the clotting cascade, including platelet function, and therefore may represent the true in vivo clotting profile more completely than, say, the INR. Its downsides include the necessity for dedicated equipment, which is fairly sensitive, and the requirement of frequent and careful calibration. Rapid TEG testing can be incorporated, rather simply, into clinical practice, but full thromboelastography suffers from the same drawback as coagulation profiles, namely, a significant time delay from testing to results.

Newer technology (e.g., VerifyNow; Accumeterics, San Diego, Calif) has been developed that looks more narrowly at just platelet function, but these machines have not been widely introduced into clinical practice. They may have more of a role in assessing the impact of antiplatelet therapy instead of the coagulopathy of trauma. But with the aging of the trauma population, clinicians are seeing larger and larger numbers of geriatric trauma patients who are on anticoagulants of various types.

HEMOSTATIC ADJUNCTS

Factor VIIa generated much interest as an adjunct for bleeding trauma patients in the early 2000s, but clinical trials did not reveal a significant benefit, certainly not enough of a benefit to justify its considerable expense. Whereas this drug has fallen out of favor, there have been others that have come to the forefront, such as prothrombin complex concentrates (PCCs) and, more recently, tranexamic acid (TXA).

A heterogenous class of plasma-derived compounds, PCCs were initially developed to treat hemophilia B. They have been used with some success to treat congenital or acquired deficiency of vitamin K–dependent clotting factors, especially in trauma patients. Containing varying amounts of primarily factor VIII or IX, they have been used, mostly, to reverse excessive coagulopathy related to warfarin

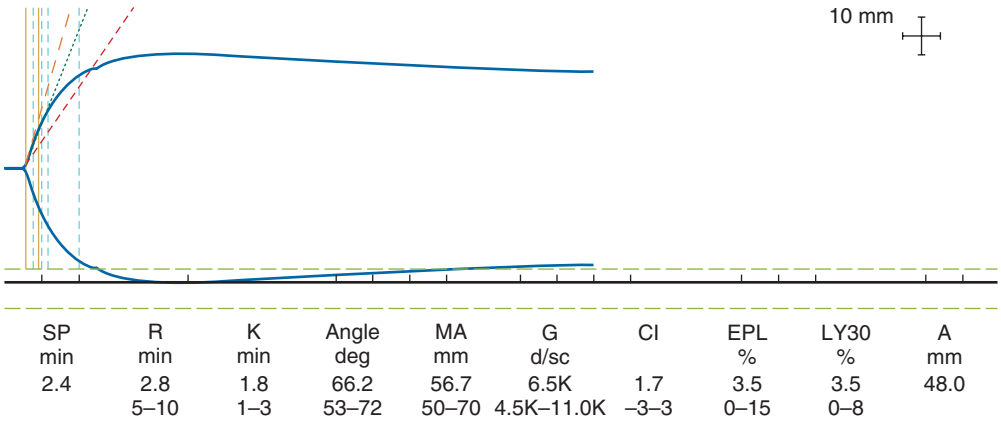

FIGURE 4 Sample thromboelastography tracing.

and, increasingly, to treat coagulopathy in trauma patients. But the reports on PCCs are largely uncontrolled case series, so until the availability of better data, it is difficult to separate out their effect from that of concurrently used therapies.

In contrast, level I evidence exists for the use of TXA in trauma patients, namely, the Clinical Randomisation of an Antifibrinolytic in Significant Haemorrhage (CRASH-2) trial results. That trial randomized 17,000 patients in 40 countries to receive either TXA or placebo. TXA resulted in a significant drop in the mortality rate from 16% to 14.5%. Interestingly, a prespecified subgroup analysis showed a *worse* mortality rate in patients given TXA 3 or more hours after injury. In addition, some emerging military data are concordant with the CRASH-2 trial results, and a civilian U.S. clinical trial is planned for the near future. Many U.S. trauma centers have already created guidelines on the use of TXA in trauma patients, with most centers restricting it to the first 3 hours after injury.
